In its broadest application dimorphism includes the alternation of forms such as the polyp and medusa of the coelenterates. It is commonly used to indicate less fundamental differences due to the conditions attending the development of essentially similar individuals. Thus some of our butterflies differ noticeably in the generation developed during the summer and that which emerges in the spring after passing the winter in an immature stage. This condition is seasonal dimorphism, as also is the occurrence of wet- and dry-season forms in some tropical species. Conspicuous difference between the sexes other than reproductive adaptions is sexual dimorphism. This term is also sometimes applied to the occurrence of two forms in a single sex, like the black and yellow females of the common yellow swallowtail butterfly.

The term is used by mineralogists to describe the phenomenon of certain natural compounds crystallizing in two different forms.

DINGO. See **Canines**.

DINES ANEMOMETER. A type of pressure-tube anemometer, named after the inventor, in which the pressure head is located on the windward end of the wind vane so that it is kept facing into the wind. The suction head is mounted concentrically with the shaft, near the bearing that supports the vane, and develops a suction that is independent of wind direction. The pressure difference between the suction head and the pressure head is proportional to the square root of the wind speed and is measured by a specially designed float manometer with a linear wind scale. The Dines anemometer was first described by William Henry Dines in 1892 and had all the essentials of the final form of the pressure-tube anemometer. With various modifications, the Dines anemometer remained a useful wind measuring device into the 1960s.

DINES RADIOMETER. An instrument for measuring radiant energy. The Dines radiometer consists of an ether differential thermometer with blackened bulbs. One of the bulbs is exposed to the unknown radiation and the other to a blackbody source with a temperature that can be varied. Equality of radiation is indicated by the balance of the differential thermometer.

DINOFLAGELLATA. An order of one-celled animals. Chiefly marine species, whose body is surrounded by an envelope of cellulose, often beautifully figured. *Mastigophora*.

Triggered by the right combination of meteorological and oceanographic conditions, these one-celled organisms can multiply at what has been termed explosive rates to cause the so-called "poisonous tides" or "red tides." Areas of the ocean up to many square miles may be colored yellow, red or olive-green by the presence of these microorganisms. Dinoflagellate toxins resemble the deadly botulinum, blocking nerve impulses that prevent the production of acetylcholine, the substance that acts on the end plate of muscle fiber to make it contract. It has been postulated that in an explosive growth or "bloom" of the dinoflagellate population a biological chain-type reaction may occur — poison from the microorganisms kills fish; the decaying fish increase the supply of nutrients in the seawater; the increased nutrients yield more dinoflagellates, which generate more poison, and so on — until a natural reversal of the conditions which favor the dinoflagellate bloom occurs.

Outbreaks of poisonous tides have occurred along practically all coasts of the United States, but notably Florida, parts of the Gulf Coast, the waters along southern California, and the Gulf of California. Such tides have occurred on the west coast of South America, the west coast of Africa, and the coasts surrounding the tip of India. Less frequently, such tides occur in the English Channel, the Red Sea, and the Gulf of Aden. The southern waters of Japan, the Philippines, Malaysia, northwestern and southeastern Australia, and the north island of New Zealand also have been affected. Shellfish contaminated by such tides have caused numerous deaths, possibly running into the tens of thousands (recurrent epidemics of fish poisoning) although statistics available are not complete or reliable.

There was a particularly bad outbreak in Florida in 1946 at which time some of the coastal water became thick and viscous, killing barnacles, oysters, shrimps, crabs, and turtles. Decaying fish piled along at least 60 miles (96 kilometers) of the beaches. Because the spray from the surf was so irritating, schools and resorts near the shore were closed. There are many outbreaks over the world each year of the red tide, but on the average the condition persists for only a few days at any one location. It is postulated that the outbreaks result from increased concentrations of nutrients that may result from tidal turbulence or by runoff from heavy rains on land. Vitamin B-12 is essential to dinoflagellate metabolism and, in the laboratory, the microorganisms thrive in diluted seawater that has been enriched with vitamin B-12. This vitamin is produced in large quantities by bacteria and blue-green algae in the soil and salt marshes, from which rains can transport it to the ocean.

Dinoflagellate blooms are frequently followed by blooms of creatures that prey upon the dinoflagellates. Notably, the luminous and predatory dinoflagellate *Noctiluca* appears.

Poisonous tides have been recorded for centuries and it is believed by some that reference in Exodus (7:21) relates to this phenomenon, "And the fish that was in the river died; and the river stank, and the Egyptians could not drink of the water of the river."

Dinoflagellates, among numerous other marine species, exhibit pronounced bioluminescence under favorable conditions. They are considered a major source of surface luminescence in the ocean. They emanate a blue light, characterized by flashes that range from 40 to 150 microseconds, in response to certain physical stimuli. There is whole-cell luminescence and scintillation from subcellular organelles. A luciferin binding protein releases luciferin in response to pH change. See also **Bioluminescence**.

Dinoflagellates and other microscopic forms of phytoplankton comprise the basis of the marine food web and play a pivotal role in the global carbon cycle.

DINOSAURS (DINOSAURIA). Dinosaurs are a group of extinct vertebrates that lived from 230 to 65 million years ago. Traditionally, dinosaurs were considered as reptiles because of the type of openings in their skulls and the structure of their pelvis. More recently, dinosaurs are considered to occupy a grey area between traditional reptiles (specifically crocodiles) and traditional birds. This new interpretation is based in part upon the discovery of featherson small carnivorous dinosaurs (theropods). Feathers have traditionally been considered an avian character; thus their discovery has added to the growing body of evidence that some dinosaurs were more closely related to birds than they were to other reptiles. See also **Birds (Aves)**; and **Reptilia**.

Basic Design

There is a common misperception that anything large and extinct is a dinosaur, especially if it is a skeleton. But dinosaurs are a specific group of animals defined by a set of criteria, some of which are esoteric, including the absence of a postfrontal bone in the skull, an elongate crest on the humerus for muscles, three or fewer bones in the fourth finger of the hand and one in the fifth finger (if it is present at all), three or more vertebrae in the sacrum, an open hip-socket, ball-like head on the femur, a prominentforward projecting crest on the tibia, and a well-developed sheet of bone joining the astragalus (an ankle bone) to the tibia. Although some of these features may occur in other closely related reptiles (e.g. pterosaurs, *Marasuchus*), only in the dinosaurs do all of these features occur. See also **Pterosaurs (Pterosauria)**.

Dinosaurs have also been divided into two major groups, or orders, the Saurischia and Ornithischia. Originally, this division was based on differences in the pelvis, but more recent studies have added other characters as well. In saurischians, the three bones of the pelvis (ilium, pubis and ischium) form a triangle (Fig. **1a**), whereas in ornithischians, they form a rectangle (Fig. **1b**). Saurischians also have a small opening below the nasal opening in the skull, and have long neck (cervical) ribs that lie parallel with the neck vertebrae. Ornithischians, on the other hand, have an accessory boneat the tip of the lower jaws called a *predentary*, triangular cheek teeth that are largest in the center of the tooth row, and a coronoid process behind the tooth row on the lower jaws.

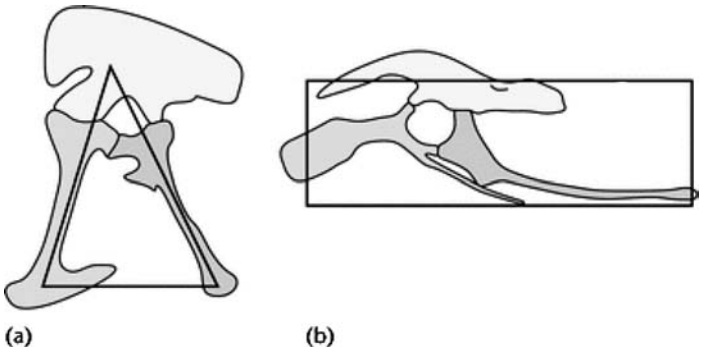

Fig. 1. Dinosaurs have traditionally been divided into two groups based primarily on the pelvis. Three bones form the pelvis, the horizontal ilium (yellow), the forward projecting pubis (green), and the rearward projecting ischium (purple). In saurischians, the three bones typically form a triangle **(a)**, whereas in ornithischians, they typically form a rectangle **(b)**. See on line for color.

Diversity

Saurischians include the carnivorous, bipedal theropods, and herbivorous, quadrupedal sauropods ("brontosaurs"). Ornithischians were all herbivorous, and include bipedalornithopods, and quadrupedal horned ceratopsians, armor-plated stegosaurs and ankylosaurs (Fig. 2).

Theropods were horizontally built dinosaurs with a moderately long tail having interlocking processes to keep it rigid as a counterbalance to the body over the hind legs. Their heads were large, relative to body size, and perched on moderately long to very short necks. Theropods range from about half a meter (1.5 feet) (*Compsognathus*) to 15 meters (49 feet) in length (*Tyrannosaurus*), and weighed 10 to 5,000 kilograms (22 to 11,023 pounds). Most theropods have blade-like teeth with serrated edges. These serrations made it possible for the teeth to cut through hide and across muscle fibers. The hands and feet have curved, pointed claws to grasp prey. In deinonychid theropods, suchas *Deinonychus* and *Velociraptor*, the claw of the second digit on the foot is a long, thin blade that was used to kill the prey.

Sauropods include some of the largest land animals that ever existed, with lengths of 30 to 45 meters (98 to 148 feet) and weights of 45,000 to 140,000 kilograms (99,208 to 308,647 pounds) (*Amphicoelias*), although one of the smallest adults is 7 meters (23 feet) (*Saltasaurus*). Sauropods typically have a proportionally small head compared to the body size, and this head is perched on a very long neck. The tail is long to very long, but it did not serve as a counterbalance because these dinosaurs were quadrupedal. Spoon-shaped to pencil-shaped teeth were usually clustered to the front of the mouthwhere they could crop vegetation.

One of the chief prey of theropods was the bipedal ornithopods. These dinosaurs were also built horizontally, with a long tail counterbalancing the body over the hind legs. However, unlike theropods, some ornithopods (hadrosaurs and large iguanodonts) retained long forelimbs that allowed them to assume a quadrupedal posture occasionally. The back and tail were stiffened by long bony rods in the muscle, much like the long rods in thedrumstick of a turkey. Ornithopods range in size from a little over a meter (3.5 feet) and a weight of 15 kilograms (33 pounds) (*Lesothosaurus*) to over 15 meters (49 feet) and 11,000 kilograms (24,252 pounds) (*Shantungosaurus*). Primitively, ornithopods had teeth in the front of the upper jaw, but these were replaced in more advanced forms with a more bird-like beak. The cheek teeth of ornithopods show a considerable amount of variation, from simple triangles with denticulate margins suitable for slice vegetation, to densely packed, flat-surfaced crowns designed for grinding plant material. The cheek teeth are inset from the sides of the jaws to accommodate a fleshy cheek that kept food from spilling out as it was processed by the teeth.

One other bipedal ornithischian group, the pachycephalosaurs, used to be consideredan ornithopod because it was bipedal. However, the development of a thickened collar of bone along the back of the skull has been used to link the group with the ceratopsians as the marginocephalians. The top of the skull is a thickened mass of bone that may have been used in flank-butting for territory or mates. The rib cage is unusually wide for a dinosaur, possibly to protect the vital organs from damage by flank-butting.

Ceratopsians, or the horned dinosaurs, are typified by skulls adorned with horns and a frill or collar of bone (except in the most primitive forms, such as *Psittacosaurus*). The horns could have been used in defense against predators, but they probably were used more in conjunction with

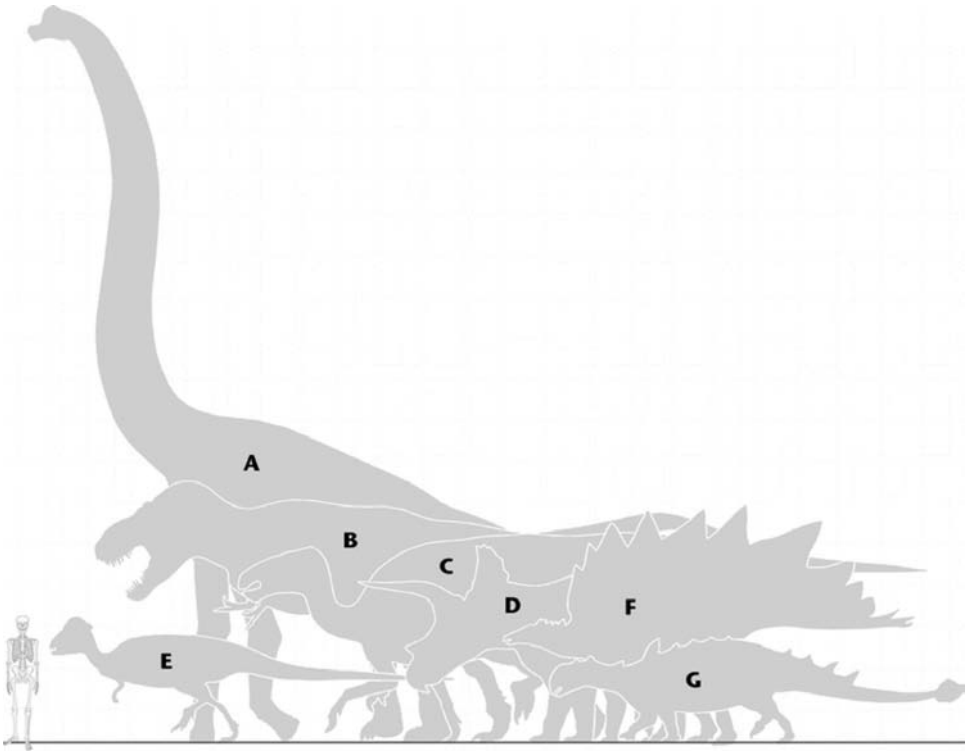

Fig. 2. The major dinosaur groups include the sauropodomorphs (A), represented by the sauropod *Brachiosaurus*; Theropoda (B) by *Tyrannosaurus*; Ornithopoda (C) denoted by the hadrosaur *Edmontosaurus*; the Ceratopsia (D) depicted by *Triceratops*; the Pachycephalosauria (E) by *Pachycephalosaurus*; Stegosauria (F) by *Stegosaurus* and the Ankylosauria (G) by *Euoplocephalus*. All to scale.

the frill to make the individuals look larger and more threatening. Healed puncture in the skulls of several ceratopsian specimens indicates that the horns were used offensively against others of their kind. The ceratopsian head is enormous compared to the body size (up to 2 meters (6.5 feet) in *Torosaurus*), and the tail relatively short. At the front of the upper beak is a counterpart to the predentary, called a *rostal bone*. The beak of ceratopsians is short and deep, resembling that of a parrot. The cheek teeth are relatively large and reinforced on the outer sides by a prominent keel or ridge. These teeth are adapted for slicing tough, woody plant material. Ceratopsians also have inset cheek teeth, suggesting the presence of a fleshy cheek to contain the food. Ceratopsians range from the meter (3.3 feet) long, 22 kilograms (48.5 pounds) *Psittacosaurus*, to the 9 meters (29.5 feet), 6,000 kilograms (13,228 pounds)*Triceratops*.

Stegosaurs and ankylosaurs have bone plates that formed within the skin of the neck, back and tail. In *Stegosaurus*, the plates are triangular and stand vertically in alternating, staggered rows along the back; the end of the tail terminates in two pairs of spikes that project outwards. The plates served to make the animal look bigger and more intimidating, while the spikes served for defense. In ankylosaurs, the plates cover the body in a loose pavement, with smaller discs of bone interspersed in the gaps between the much larger plates. The teeth of both stegosaurs and ankylosaurs are small and triangular, suggesting a diet of relatively soft vegetation. As with other ornithischians, theteeth are inset, suggesting fleshy cheeks, which in some ankylosaurs, had a dermal plateembedded in them. Stegosaurs ranged from the 4 meters (13 feet) long, 750 kilograms (1,653 pounds) *Chunkingosaurus*, to the giant 6 meters (20 feet), 2,000 kilograms (4,409 pounds) *Stegosaurus*. Among ankylosaurs, the 3 meters (9.8 feet), 500 kilograms (1,102 pounds) *Struthiosaurus* was one of the smallest, whereas the 9 meters (29.5 feet), 4,000 kilograms (8,818 pounds) *Ankylosaurus* was the largest. Ankylosaurs have been divided into two families, the Nodosauridae, characterized by spikes projecting from the neck and shoulders, and Ankylosauridae, characterized by a bone club on the end of the tail.

Habitats and Abundance

Dinosaurs are found in a variety of rocks deposited in a variety of environments, but, as a general rule, plant fossils are rarely found where dinosaur bones occur, making it difficult to reconstruct ancient environments accurately. Plants fossilize best in acidic environments, such as swamps or other water-logged soils, where bone is destroyed. In rare instances, plants and dinosaur bones do occur in the same formation.

The most common rock types for dinosaur bone are sandstones of ancient river channels. In such settings, isolated bones transported from distant areas may be mixed with partial or nearly complete skeletons. When several individuals co-occur, a bone bed may result, such as at Dinosaur National Monument (northwestern Colorado and northeastern Utah, USA). Such sites can give a glimpse into the structure of the dinosaur community if different species are present, or show the structure of herds if only a single species is present. Mixed bone beds tend to form by gradual accumulation of individuals dying of biological causes (old age, disease, predation etc.), whereas single-species bone beds tend to form from external physical processes (drowning in floods, droughts, etc.). Dinosaur bones also occur in mudstones that represent the adjacent flood plain to river channels. Bone beds in such rocks are rare; instead single skeletons or individual bones tend to occur. Death of such individuals can have biological or physical causes.

Other dinosaur bones occur in lithified sand dunes (found mostly in Mongolia), where intact skeletons are individuals buried by ancient sand storms. Some of the most spectacular of these are skeletons of the small theropod *Oviraptor* found associated with clutches of eggs that they were guarding. Perhaps the most peculiar occurrences of dinosaur bones are those found in marine rocks. These probably originated from drifting carcasses washed to sea from rivers. Bones would slowly rain down to the sea floor as they were liberated from the encasing tissue by scavengers and decay. See also **Fossils and Paleontology**.

Habits and Lifestyles

The variety of shapes and sizes implies a diversity of behavior and biology. The small teeth of the early theropod *Coelophysis* imply a diet of small vertebrates, andthe stomach contents of a few individuals show that this diet may include young of their own kind. Other theropods, such as *Tyrannosaurus*, have much larger teeth, implying larger prey. Tooth marks on dinosaur bones can be matched to some of these teeth and show conclusively that theropods were carnivores. But were they scavenging from carcasses or actively hunting? In some instances of partial skeletons bearing tooth marks, the answer is most assuredly scavenger. But in two instances, the answer is unequivocally predator. In one example, a skeleton of the small theropod *Velociraptor* was found with a small ceratopsian, the *Protoceratops*. One forearm of the *Velociraptor* is clenched in the beak of the *Protoceratops*, and the sickle claw of one foot is extended in the throat region of the *Protoceratops*. They were found in an ancient sand dune, but it is not known if they died during or shortly before the sand storm buried them. In the other example, several tail vertebrae of a nearly complete skeleton of the hadrosaur *Edmontosaurus* are mangled and show damage by large teeth. Regrowth of some bone shows that the animal survived the attack. Nevertheless, the pattern of the tooth damage matches the size of an adult *Tyrannosaurus*.

Sauropods were once thought to have lived in large lakes, where the water would buoy the large body. But reanalysis of skeletons demonstrated that sauropods were well adapted for terrestrial life. This interpretation is supported by the absence of sauropods from lake deposits, but their presence in river channels and flood plain sediments, where they co-occur with stegosaurs, theropods and ornithopods. The purpose of the long neck is a puzzle, but may have allowed some sauropods to feed over large areas as they slowly walked, and others to feed from trees. This difference in feeding strategies explains the different tooth patterns seen among various sauropod types. Some species of sauropods are thought to have formed herds because several individuals, sometimes of different sizes, may be found together, or because of numerous overlapping trackways trending in the same direction.

Ornithopods also occur as multiple individuals in bone beds, which, in some instances, may have numbered in the thousands. These mass accumulations dominated by a single species suggest that ornithopods congregated into large herds. This interpretation is supported by fossil trackways that also show numerous individuals of the same track maker traveling in the same direction. The occurrence of the hadrosaur *Edmontosaurus* in the North Slope of Alaska and in Montana suggests seasonal migration. At least one ceratopsian may have also made the same journey. A skull of *Pachyrhinosaurus* from Alaska is similar to those found in a *Pachyrhinosaurus* bone bed found in Alberta, Canada. Might these individuals of *Pachyrhinosaurus* in the bone bed have perished together while migrating? Bone beds of other ceratopsian species are known from southern Canada and northern Montana. Surprisingly, no bone beds of *Triceratops* are known, suggesting that they roamed the landscape singly. Stegosaurs generally do not occur in single-species bone beds, with the exception of *Kentrosaurus* from Tanzania. Most other stegosaurs co-occur with other dinosaurs in bone beds. In one instance, about a dozen *Stegosaurus* have been found with about an equal number of the ornithopod *Camptosaurus*, suggesting that the two species congregated in a mixed herd. The ankylosaur *Pinacosaurus* occur as solitary individuals as adults, but in small herds or creches when very young (about a meter long). Other species of adult ankylosaurs occur in bone beds (e.g. *Talarurus* from Mongolia), but most others are solitary individuals (e.g. *Euoplocephalus*, *Edmontonia* and *Ankylosaurus* in North America).

Oddities Within the Group

Dinosaurs are full of oddities: gigantism, horns, frills, plates, spikes, knobs, domes, etc. The largest land animals that have ever walked the earth are the sauropods, including one with vertebrae that were eight feet tall! This giant, *Amphicoelias*, is only known from fragmentary remains that are now lost. From the description, a 24 meter (79 foot) long *Diplodocus* could have just walked beneath *Amphicoelias*. *Brachiosaurus*, or the giraffe sauropod, truly did have its head in the clouds. The head towered 16 meters (52.5 feet) above the ground. A lizard-like frill is known to have been present along the back of the tail in *Diplodocus* and it presumably extended onto the back and possibly the neck as well. The fossilized remains show that the frill consisted of a single row of triangular flaps of skin. The purpose of such a frill is not known nor whether similar skin flaps were widespread among other sauropods.

Many of the odd structures are located on or around the head of dinosaurs, and comparison with modern ungulates implies that they were used mostly for display. For example, among theropods, *Dilophosaurus* had two very thin, very delicate crests of bone along the top of the skull.

Perhaps these crests were covered by colorful skin during the breeding season. Similar structures in other theropods include the single crest or "horn" on the snout of *Ceratosaurus*, and the outwardly projecting "brow" horns of *Carnotaurus*. Tall processes on the back vertebrae of *Spinosaurus*, *Baryonyx* and *Suchomimus* make the individuals look bigger and more intimidating. It is always better to avoid a fight by bluff, which is probably what happened frequently during the mating season. Gigantism also occurs in theropods, although not to the extent seen insauropods. Nevertheless, 14 meter (46 foot) *Tyrannosaurus* and *Gigantosaurus* are the largest ever terrestrial carnivores.

Display structures on the skull are best developed in certain ornithopods, especially the hadrosaurs. These structures include tall, hollow, narrow crests in *Corythosaurus*, a backward projecting spike in *Sauropolophus*, a U-shaped backward projecting crest in *Parasaurolophus*, and a hatchet-shaped crest in *Lambeosaurus* (these structures in hadrosaurs have also been suggested as improving smell and vocalization, but the variety of crests is more analogous to the variety of horns seen in antelopes). The iguanodontid *Ouranosaurus* from Africa had very tall processes on its back vertebrae, giving the appearance of having a "sail." In profile, *Ouranosaurus* could look more intimidating to rivals or more attractive to a potential mate (bigger sail). Other iguanodontids, such as *Iguanodon* itself, have a modified thumb that is a spike, possibly used in defense. Real odd-balls are the pachycephalosaurs, which had greatly thickened bones on the skull roof. These domes were once thought to act like helmets in head-to-head butting, but now it is thought that these "domes" maximized the mass in butting the flanks of the opponent. Some, such as *Stygimoloch*, had clusters of spikes at the rear corners of the skull that were probably used to maximize the pain in this flank-butting.

The largest head of any dinosaur belongs to the ceratopsian *Torosaurus* with amassive 2 meter (6.5 foot) long skull. Although most ceratopsians have horns on their face, *Pachyrhinosaurus* had a very rough boss atop the nose. Whether or not this boss was the base of a keratinous horn is not known, but it seems probable. *Einiosaurus* had a large bony horn on its nose, but it is drooped forward, resembling a giant can opener. With the tip facing downwards, this horn could not have been effective as a stabbing weapon. Ceratopsians also have some of the largest nasal cavities among any dinosaurs, the purpose of which may have been to cool the blood to the brain. At one time it was thought that the plates of *Stegosaurus* may have had a similar cooling effect, but it seems more likely that the plates made the animals look larger and more intimidating. By increasing blood flow to the plates, the plates may have blushed, causing them to stand out against the forest greens. Some stegosaurs, such as *Huayangosaurus* and *Kentrosaurus*, had rearward projecting spikes on their shoulders. What these odd structures were for is not known because they certainly could not be used offensively. Among ankylosaurs, the ankylosaurids have modified the last half of their tail vertebrae into a rigid structure. This structure acts as the "handle" to the club-like enlargement of armor plates at the end of the tail. The nodosaurid *Edmontonia* has a large, forward projecting spike on each shoulder. This spike has a short tine, much like that seen on a deer antler, which may have been used to lock the spike of an opponent in shoving contests.

Fossil History

Dinosaurs were a very successful group, lasting 165 million years. There is more time separating the first and last dinosaurs than separates us in the twenty-first centuryfrom *Tyrannosaurus rex*. During that time dinosaurs underwent a great deal of evolution. Unfortunately, we will probably never know all the species that ever lived. For example, we know nothing about the dinosaurs that inhabited the Appalachian Mountains, which we know were in existence during most of the Mesozoic. Mountains are sites of erosion, not deposition, therefore any individual dying in those mountains would not have been buried and fossilized. Conversely, the best fossil record of dinosaurs comes from the lowlands that bordered inland seas or oceans. Here, sediments from the highlands are deposited, especially during annual floods (anyone who has experienced the terrible floods alongthe Mississippi River can attest to the great volumes of mud that can be deposited on the flood plain). Not surprisingly, then, most of the named dinosaur species come from river channel and flood plain deposits, such as the Late Triassic Chinle Formation of Arizona, the Late Jurassic Morrison Formation of Colorado, Utah and Wyoming, the Early Cretaceous Wealden Formation of southern England, and the Late Cretaceous Hell Creek Formation of Montana and South Dakota. But some dinosaurs have been found far from the coastal lowlands, specifically in the Late Cretaceous sand dune deposits along the Mongolian-Chinese border.

Although dinosaurs have been collected for more than 150 years, a dozen or more newspecies have been discovered every year during the past decade. Part of this burst of new species is due to there being more dinosaur paleontologists alive today than there werein total between 1824 (when the first dinosaur, *Megalosaurus*, was named) and 1990. At present, there are over 840 valid species and this number will continue to rise. See also **Fossils and Paleontology**; and **Paleontology (The History)**.

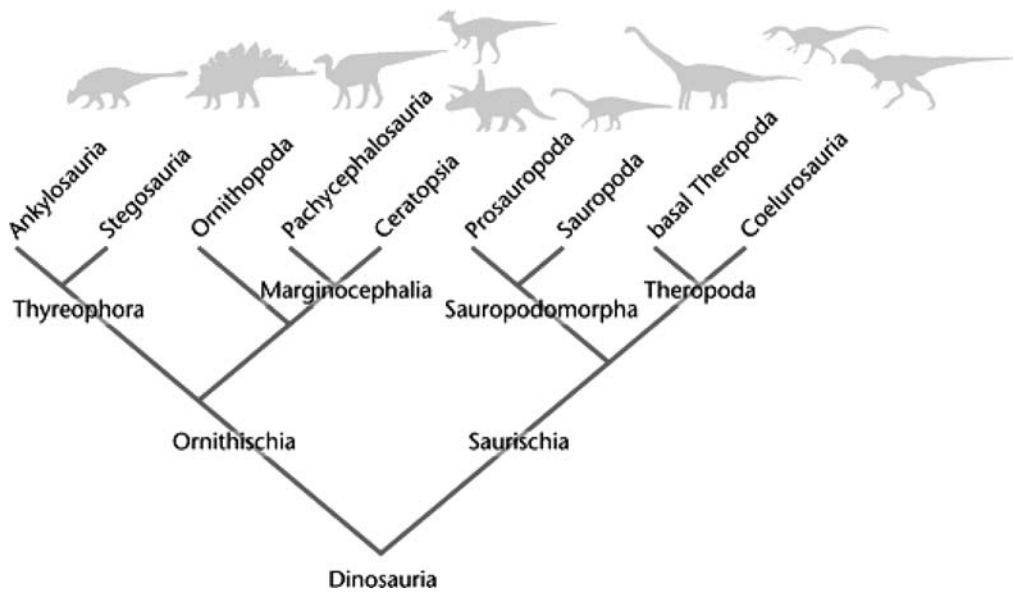

Fig. 3. Cladogram showing the most current thinking about the relationship of the dinosaurs (after Sereno, 1999). Unlike the traditional evolutionary trees that were based on superficial resemblances of species and the geological age of the fossils, cladograms rely upon shared advanced or derived characters to unite dinosaur species regardless of geological age. The reason for the change in analysis is to concede that the fossil record is very incomplete and that the fossil record may not preserve the firstoccurrence of an advanced character. For example, the closest dinosaur relative to the Late Jurassic bird *Archaeopteryx* (~152 Ma), are the troodontids, typified by *Troodon* and *Saurornitholestes* from the Late Cretaceous (~75 Ma).

The first dinosaur bones were not recognized as such, but were thought to be the fossilized remains of giants that perished in the Biblical Flood. The first scientific description was of the "giant reptile" *Megalosaurus* by William Buckland in 1824. A year later, Gideon Mantell named *Iguanodon*. These and other early discoveries of dinosaurs were made in quarries, usually by quarrymen, who supplemented their meagre wagesby selling fossils. One of the most important of these early discoveries was the first significant portions of a dinosaur skeleton discovered, the Maidstone *Iguanodon* purchased by Mantell in 1834. Although this specimen had portions of both the fore- and hindlimbs, the importance of this specimen was never appreciated. This oversight allowed Joseph Leidy to point out in 1858 that the great difference in size between the fore- and hind limbs of *Hadrosaurus* meant that it was a biped. Prior to that statement, dinosaurs were thought to be giant bear-like or lizard-like quadrupeds.

Deliberate prospecting for fossils did not develop until the late 1800s when O. C. Marsh of Yale University and E. D. Cope of the Academy of Natural Sciences hired men to dig up dinosaurs (and other vertebrates) for them in the western United States. This approach produced the first "Golden Age" of dinosaur discovery. Between 1877 and 1899, Marsh and Cope dominated dinosaur paleontology, naming 75 and 55 genera and species, respectively. Although not all of their dinosaur species are valid any more (some are different names for the same dinosaur), a few of their more important species include *Allosaurus*, *Apatosaurus*, *Camarasaurus* and *Triceratops*. Some of the men they hired went on to work for other museums at the turn of the twentieth century, such as Henry Osborn (American Museum of Natural History) and John Hatcher (Carnegie Museum of Natural History). These men were active in the "Age of Global Dinosaur Paleontology" (1900–1940) when many major museums in the United States and Europe were trying to obtain display specimens for their galleries. During this time, numerous discoveries were madein southwestern Canada, western United States, East Africa, India, Argentina and Mongolia, among others. Some of the most significant dinosaur specimens found during this time includes *Tyrannosaurus*, *Diplodocus*, *Brachiosaurus*, *Plateosaurus*, and *Protoceratops*. Andrew Carnegie was so proud at having a species of *Diplodocus* named after him that he paid to have casts of the skeleton shipped to many of the larger museums, such as in Paris, St Petersburg and Madrid. See also **Cope, Edward Drinker (1840–1897)**; **Marsh, Othniel Charles (1831–1899)**; and **Osborn, Henry Fairfield (1857–1935)**.

World War II interrupted this boom in dinosaur paleontology and it was slow to recover afterwards. A series of expeditions were made by the Soviets in the late 1940s, leading to the discovery of numerous skeletons of *Tyrannosaurus* and the hadrosaur *Saurolophus*. The modern "Renaissance Period" began in the late 1960s and early 1970s, when Polish paleontologists mounted their own expeditions into Mongolia. At about the same time, John Ostrom from Yale University began collecting in the Lower Cretaceous Cloverly Formation of Montana and Wyoming. Among his important discoveries was the small theropod dinosaur *Deinonychus*. This discovery led Ostrom to examine the possibility that dinosaurs were not the slow, sluggish ectotherms that they had been portrayed as at times, but were very active, possibly even endothermic. Ostrom also noted similarities between *Deinonychus* and the early bird *Archaeopteryx*, thus reviving the debate that birds had a dinosaur origin. The recent discoveries of feathered dinosaurs in China have greatly strengthened this hypothesis. At about the time of Ostrom's early work, many of the "baby boomers" were coming of age and they have led the current resurgence of dinosaur paleontology. Important discoveries of dinosaur specimens have been made on all continents, including Antarctica. Over half of the known dinosaur species have been discovered in just the past two decades.

Phylogeny

Despite the great differences between advanced ornithischians and saurischians, the primitive members share features demonstrating a common ancestry. This ancestor was probably related to the small, slender-limbed, bipedal dinosauromorphs *Marasuchus* and *Lagerpeton* from the Middle Triassic (~240 Ma) of Argentina. Within 10–15 million years, both ornithischian (*Pisanosaurus*) and saurischian (*Eoraptor* and *Herrerasaurus*) dinosaurs appear. The later diversification of the dinosaurs taxonomically and in size, during the Late Triassic and Early Jurassic, is believed to have beena fortuitous opening of ecological niches.

The initial geographical radiation of the dinosaurs was made possible by the continents having previously coalesced into the supercontinent Pangaea. Thus, as new adaptive designs appeared (recognized as suborders, such as Stegosauria), they spread globally very rapidly. Most of the major suborders had evolved by the end of the Early Jurassic (~178 Ma), with the exception of the ceratopsians and pachycephalosaurs. These two groups make their earliest appearance by the end of the Lower Cretaceous (~98 Ma), about the time that Pangaea had broken into two continents, the northern hemisphere Laurasia andthe southern hemisphere Gondwana.

The general trend among most dinosaur groups is to increase the body size. Some of the better examples include ceratopsians, where the most primitive ceratopsians are about 1.5 meters (5 feet) long and *Triceratops* is 9 meters (29.5 feet) long, or among theropods, the 1 meter (3.3 feet) long *Eoraptor* and the 14 meters (46 feet) long *Giganotosaurus*. Another evolutionary trend is the loss of digits, as exemplified by theropods. The Late Triassic *Herrarasaurus* has a four-digit hand, the Late Jurassic*Allosaurus* a three-digit hand, *Tyrannosaurus* from the Late Cretaceous a two-digit hand, and *Mononykus*, also from the Late Cretaceous, a one-digit hand. Other theropods show varying degrees of "bird-ness" and provide clues to the origin of birds. For example, the skeleton of *Velociraptor* looks like a much larger version of *Archaeopteryx*, including the elongated arms and rearward directed pubis. *Oviraptor* has a greatly shortened tail ending in a pygostyle formed by the fusion of the last fewvertebrae, a feature also seen in the early bird *Sinornis*. The ornithomimid *Caudipteryx* has feathers, including a fan-like group on the end of the short tail.

Much of the recent work on the phylogenetic relationships of dinosaurs uses cladistics, whereby novel characters not seen in more primitive species are used to determine relationships. Figure 3 shows the result of the most recent analysis.

Synopsis

Dinosaurs were a very successful group that survived over 165 million years. They underwent rapid evolution, producing novel adaptive characters. These characters allow us to divide dinosaurs into seven suborders: Theropoda, Sauropodomorpha, Ornithopoda, Stegosauria, Pachycephalosauria, Ankylosauria, and Ceratopsia. Six of these suborders had appeared within the first 50 million years, and the seventh by the last 35 million. The success of these adaptive characters is seen in that none of the suborders went extinct until the end of the Cretaceous. At that time, whether through the catastrophic impact of an asteroid or the gradual collapse of the ecosystems, all dinosaurs went extinct. Only the birds remain of the suborder Theropoda.

DIODE. A two-electrode device, having an anode and a cathode, which has marked unidirectional characteristics. Many types of diodes are known.

A *semiconductor diode* is a two-electrode semiconductor device having an asymmetrical voltage-current characteristic. A *double-base diode* is a semiconductor diode in which a potential gradient is produced across the base region by the application of a voltage between two electrodes at either end of the base. The correct polarity and magnitude of this voltage causes the diode to exhibit a controllable, negative resistance between one of the base electrodes and the anode.

A *junction diode* is a semiconductor diode whose nonsymmetrical volt-ampere characteristics are manifested as the result of the junction found between n-type and p-type semiconductor materials. This junction may be diffused, grown or alloyed.

A *crystal diode* is a diode consisting of a semiconducting material such as germanium or silicon, as one electrode, and a fine wire "whisker" resting on the semiconductor as the other electrode. Because of its low capacitance, the device has found application as a rectifier or detector of microwave frequencies.

A *vacuum tube diode* is the simplest form of vacuum tube. The ENIAC (Electronic Numerical Integrator and Computer), developed by the University of Pennsylvania in the early 1940s, contained more than 18,000 such vacuum tube diodes, weighed over 30 tons, and occupied a room some 30×50 feet (9×15 meters).

DIODE LOGIC. A form of logic circuit using diodes and resistors. The abbreviation DL is sometimes used to refer to this class of circuits. Circuits for performing the functions OR and AND are shown in the figure. Considering a positive signal to represent 1, one notes that a positive voltage connected to any one of the inputs *A*, *B*, or *C* in part (a) of Fig. 1 will result in a positive signal at the output. Thus, the circuit performs the logic OR operation. In (b), the AND operation is accomplished; to obtain a positive (1) output *A*, *B*, and *C* must all be positive (1).

See also **AND (Circuit)**; and **OR (Circuit)**.

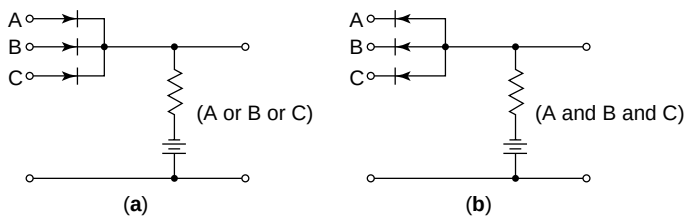

Fig. 1. Diode logic circuits: (**a**) OR circuit; (**b**) AND circuit.

DIODE TRANSISTOR LOGIC. A form of logic circuit using diodes, transistors, and resistors. The abbreviation DTL is sometimes used to refer to this class of circuits. Circuits for performing the logical operations NOT OR (NOR) and NOT AND (NAND) are shown in Fig. 1. The arrangement

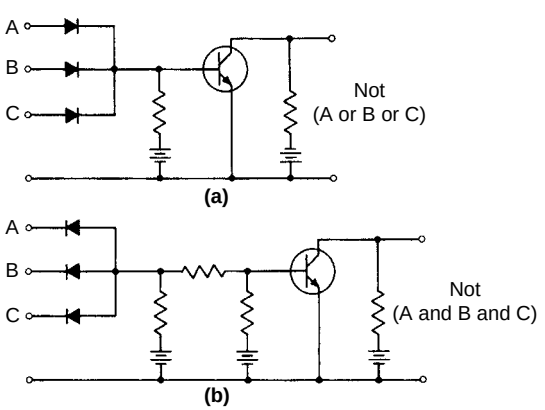

Fig. 1. Diode transistor logic circuits.

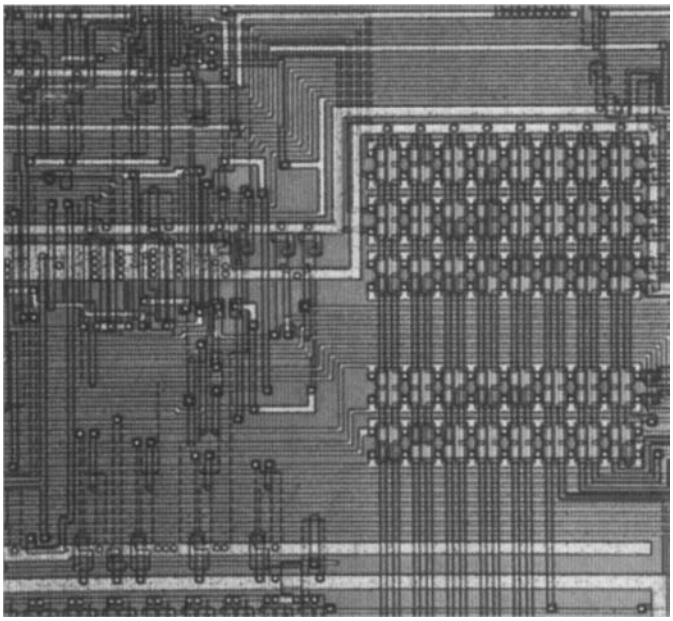

Fig. 2. Photomicrograph of an integrated circuit (IC) that uses large numbers of semiconductor diodes.

is an extension of diode logic wherein the logic operation is effected by diodes and the transistor furnishes an inversion of sign and amplification. A positive signal represents the 1 logic state for the circuits in the figure. In (a) the transistor will be brought into conduction with the collector voltage close to ground potential (0 output, corresponding to NOT 1) when either *A* or *B* or *C* is positive (1 condition). In (b), the transistor will be brought into conduction only when all inputs *A*, *B*, and *C* are in the 1 condition (positive signal). The state will result in a transistor output corresponding to 0 (NOT 1). In both circuits the output of the transistor is positive corresponding to 1, whenever it is cut off. Actual fabrication techniques may combine the function of several of the components shown into a single device. See Fig. 2.

DIOECIOUS ORGANISMS. See **Organisms (Dioecious)**.

DIOPHANTINE EQUATION. An equation containing two or more variables and, in general, satisfied by an infinite number of values for each of the unknowns is called indeterminate or Diophantine, after Diophantus of Alexandria (about 320 A.D.). More generally, Diophantine analysis is the study of single equations or systems of them in two or more unknowns, the solutions being required in integers or rational numbers.

See also **Number Theory**.

DIOPSIDE. The mineral diopside is a monoclinic pyroxene corresponding to the chemical formula $CaMgSi_2O_6$, calcium magnesium silicate. Its crystals, like those of other pyroxenes, tend to be short stout prisms of square or octagonal cross-section. Compact, granular, lamellar and fibrous varieties are often found. The prismatic cleavage is characteristic, cleavage planes intersecting at angles of 87° and 93°. A basal parting is often noted, but should not be confused with the cleavage. The hardness of diopside is 5–6; specific gravity, 3.2–3.3; uneven fracture tending toward conchoidal; luster, vitreous to dull; sometimes pearly on the base; color, light or dark greens, but may be colorless, gray, yellow or blue, although the latter color is rare.

Diopside is a primary mineral in rocks like diorites, gabbros and the like, but is also found in schists, and, as the result of contact metamorphism, in such rocks as crystalline limestones and dolomites. Diopside is found in association with vesuvianite, garnet, spinel, scapolite, tremolite, tourmaline and similar minerals. It is a rather widespread mineral, important localities being found in the following European countries: Finland, Sweden, Switzerland, Italy; it is found in eastern Siberia near Lake Baikal. In

Canada diopside localities are in Lanark and Hastings Counties, Province of Ontario, and in the United States in Lewis and St. Lawrence Counties, New York, and in Maine.

ELMER B. ROWLEY, Union College, Schenectady, NY

DIOPTASE. The mineral dioptase is a rather rare copper silicate corresponding to the formula $CuSiO_2(OH)_2$, occurring in prismatic crystals of the hexagonal system, tri-rhombohedral in form. It may be found in crystalline aggregates or simply massive. Dioptase displays a conchoidal to uneven fracture; hardness, 5; specific gravity, 3.28–3.35; luster, vitreous; color, a beautiful emerald green. It has been found in the former U.S.S.R., Congo, Central African Republic, South West Africa, Chile, and in the United States in Arizona. The name is derived from the Greek words meaning through and to see, because cleavage was observed by looking through the crystals.

DIOPTRIC SYSTEM. If an optical system is convergent, it is called dioptric if both focal lengths are positive. If an optical system is divergent, it is called dioptric if both focal lengths are negative. See also **Mirrors and Lenses**.

DIORITE. Diorite is a deep-seated igneous rock composed dominantly of sodiaplagioclase feldspar with hornblende, biotite, and (or) augite. Orthoclase may be present in small amounts, also quartz. Any considerable proportion of the latter mineral produces a quartz-diorite. With increasing amount of orthoclase, we have granodiorite, which is generally understood to be a rock intermediate in character between quartz-diorite and granite. If quartz is absent and there are essentially equal amounts of orthoclase and plagioclase the rock is then known as a monzonite from the type locality, Monzoni, in the Tyrol. There are quartz monzonites and, where the deficiency of silica is great enough, nephelite monzonites. Rocks of the latter sort have been reported from Madagascar. A variety of quartz, diorite, containing both hornblende and biotite, is called tonalite from the Tonale Alps, although the rock found there is more nearly a granodiorite.

DIOXIN. Although 75 variations of dioxins are known, the compound considered to possess the greatest toxicity and the subject of a continuing debate among industrial and environmental scientists specifically is 2,3,7,8-tetracholor dibenzo-*p*-dioxin and generally referred to as TCDD or, in much of the literature, simply as *dioxin*.

Attention to dioxin was propelled into scientific and public scrutiny as the result of the use of the herbicide 2,3,5-T (Agent Orange) during the Vietnam conflict. Also, a major localized contamination resulted from an accident in a chemical plant in Seveso, Italy, in 1976.

Minute amounts of dioxin are created in certain combustion processes and by a few chemical manufacturing processes, including the use of chlorine in paper bleaching.

In late 1991, a group of investigators, Sutter, et al. (Chemical Industry Institute of Toxicology, Research Triangle Park, North Carolina), reported of their studies on the effects of dioxin at the genetic and molecular level. It appears that dioxin may elicit its effects by altering gene expression in susceptible cells. In brief detail, the introduction of the Sutter, et al. paper (reference listed) summarizes: "Five TCDD-responsive complementary DNA clones were isolated from a human keratinocyte cell line. One of these clones encodes plasminogen activator inhibitor-2, a factor that influences growth and differentiation by regulating proteolysis of the extracellular matrix. Another encodes the cytokine interleukin-1β. Thus, TCDD alters the expression of growth regulatory genes and has effects similar to those of other tumor-promoting agents that affect both inflammation and differentiation."

As of early to mid 1990s, studies of dioxin continued. Epidemiological studies have shown an increase in the occurrence of soft-tissue sarcoma and non-Hodgkin's lymphoma, but these findings have been challenged by other studies. Some research has indicated that a given dosage of TCCD may kill a guinea pig and leave a hamster unaffected, or that female rats will develop liver cancer, while male rats will not from the same dosage. One effect that has pretty well risen above debate is that TCCD can cause chloracne (a disfiguring skin condition) among some humans who have been exposed to dioxin.

DIPHTHERIA. An acute infection caused by *Corynebacterium diphtheriae* (thin gram-positive rods), first isolated by Loeffler in 1884. The disease is characterized in its early stage by an inflammatory lesion, usually a membranous pharyngitis. Pharyngeal diphtheria is the most frequently occurring form. In addition, the larynx, trachea, nares and middle ear may be involved. A potent exotoxin elaborated by the bacterium produces serious neurologic (myelin degeneration; motor nerve damage), cardiac (myocarditis), and renal (tubulary necrosis) effects. The toxin inhibits protein synthesis. It is the toxin that participates in the formation of the diphtheritic membrane, unique to the disease and a hallmark for diagnosis. The membrane is a gray-to-black, leathery, adherent formation made up of necrotic cellular debris, leukocytes, and bacteria and can cause blockage of the upper airway when it extends into the larynx. Diphtheria infection also takes a cutaneous form, with involvement of the skin as well as of the conjuctiva.

Prior to widespread immunization, particularly of young school children, diphtheria was a major disease and important cause of death. Traditionally, the highest incidence occurred in children under 10 years of age. In more recent years, the disease has been seen in more persons of age 15 or older. The infection is easily spread by way of the respiratory route, can be carried by persons without the disease, and has been a mandatory notifiable disease in the United States and a number of other countries for many years. Among children, the cutaneous form is considered by some authorities to be even more contagious than the respiratory form. In 1920, prior to immunization programs, about 200 cases/100,000 population, with 15 deaths/100,000, were reported. The incidence has decreased steadily since then, with about 0.3 cases/100,000 (0.0015 death/100,000) as of the early-1980s. Reported cases in the United States in recent years number less than 100/year, but the total, including unreported cases, may range between 200 and 400. The disease in present times tends to occur in outbreaks, particularly in crowded urban areas, among inadequately immunized children, and unimmunized transient farm workers.

In an excellent review article, L.C. Kleinman (UCLA School of Medicine) traces the early beginnings of diphtheria and the manner in which both the medical and sociological aspects of diphtheria were approached in the United States and Britain when the disease occurred in epidemic proportions. Kleinman draws an interesting comparison with the current status of AIDS approaches and suggests that considerable perspective can be gained from the experiences gained nearly three-quarters of a century ago. In particular, Kleinman observes: "The history of diphtheria suggests that mandatory testing and case identification, isolation techniques, and public education can all be part of a compassionate and effective response to an epidemic. Even today, these traditional public health tools can play a critical part if they are used judiciously, with respect for due process, and in conjunction with the provision of needed health care and social services. The history of diphtheria suggests, for example, that any plan for human immunodeficiency virus (HIV) testing today should be coupled with a multicultural, multimedia effort to remove the stigma from AIDS and to protect the rights and liberties of infected persons. Perhaps most important, the history of diphtheria suggests how vital it is to provide access to the full range of diagnostic and therapeutic services to those who are at risk. Angell [*N. Eng. J. Med.*, 1498 (May 23, 1991)] suggested we begin by testing health care workers, hospitalized patients, sexual partners of HIV-infected persons, and pregnant women, and that the federal government pay for the medical care of patients with AIDS in a program analogous to that for end-stage renal disease." The

Kleinman article [*N. Eng. J. Med.*, 773 (March 12, 1992)] is suggested reading.

Diphtheria Preventive Measures. The Shick test is a skin test for determining susceptibility to diphtheria. In one arm, there is an intradermal injection of diphtheria toxin and of purified diphtheria fluid toxoid in the other arm. This test is of value in assessing the level of immunity in contacts of a patient, or in a community where an outbreak has developed. It has been estimated that a minimum of 70–80% of school and preschool children in urban areas must be immunized in order to prevent community-wide outbreaks of diphtheria. For several years, the common practice has been early immunization of young children, and the administration of diphtheria-tetanus toxoid as a booster every 10 years in older children and adults.

The signs and symptoms of diphtheria appear after an incubation period of 2 to 4 days on the average, but symptoms can occur in 1 day and up to 7 days. Sore throat (in the pharyngeal form) and mild fever (100–100.9 °F; 37.8–38.3 °C) commonly usher in the disease. The previously mentioned membrane may appear early and spread rapidly and may be accomplished by swelling of the neck, resulting in the so-called "bull neck" in appearance. In the laryngeal form, cough and noisy, difficult respiration occur. The severity of systemic symptoms may be delayed and depend upon the amount of toxin absorbed. In severe pharyngeal cases, prostration will be marked. Nasal diphtheria is localized to the anterior nodes and usually follows a benign course. Cutaneous diphtheria may occur as a secondary infection of a pre-existing wound; or as a superinfection of pre-existing skin lesions (impetigo, infected insect bites, ecthyma, and eczema); or as a primary cutaneous infection, usually commencing as a tender pustule on a lower extremity. The latter condition (sometimes called "jungle sore") occurs mostly in the tropics.

The exotoxin produces myocarditis in 10–15% of cases and is the usual cause of death in fatal cases. In about 10% of cases, peripheral neuritis occurs within 2 to 6 weeks after onset of the disease. The most dangerous aspect is involvement of the motor nerves associated with respiration.

Therapy may involve administration of equine antiserum. Where there is sensitivity to this serum, desensitization procedures should be attempted.

Diphtheroids. A number of saprophytic organisms (organisms that live on dead organic matter) in the genus *Corynebacterium* and known as diphtheroids frequently occur on the skin, on mucous membranes, and in various environments and, for many years, were not regarded seriously. It has been found that such organisms can cause serious infection, including life-threatening situations, as may be the case in connection with bacterial endocarditis (after cardiac surgery) and in other situations involving surgery, trauma, and immunosuppression, such as reconstructive hip surgery. These conditions usually respond to antibiotic therapy.

DIPLOBLASTIC. Derived from two embryonic germ layers. The first step in the formation of tissues in the developing multicellular animal is the formation of two layers, one covering the outside of the body and the other lining a cavity within it. These are the ectoderm and endoderm, respectively. The bodies of sponges, coelenterates, and possibly ctenophores develop by the further differentiation of these two layers alone.

DIPLOID. The double number of genes or chromosomes ($2N$). In the metazoan animals the somatic or body cells all contain the diploid number of genes and chromosomes — there are two of each kind. For each chromosome of a particular length and shape there is a mate of the same length and shape. The genes on these like chromosomes are also alike in the trait that they influence, but they may differ slightly in the way they effect this trait. The human, for instance has a diploid chromosome number of 46 and the diploid gene number is estimated at about 40,000. The reproductive cells receive only the haploid gene and chromosome number as a result of meiosis. The haploid number is one-half of the diploid ($2N$).

In higher plants most of the tissue again is diploid, but there is a small haploid gametophyte. In some of the lower plants the diploid tissue is very small. See also **Alternation of Generations**; and **Cell (Biology)**.

DIPLOPODA. The millipedes. A class of the phylum *Arthropoda*. Millipedes are worm-like animals with a head and segmented body. Each segment bears two pairs of legs, excepting the first and last few. The head bears a pair of antennae and in some species a pair of eyes. Most millipedes have a cylindrical body. See Fig. 1.

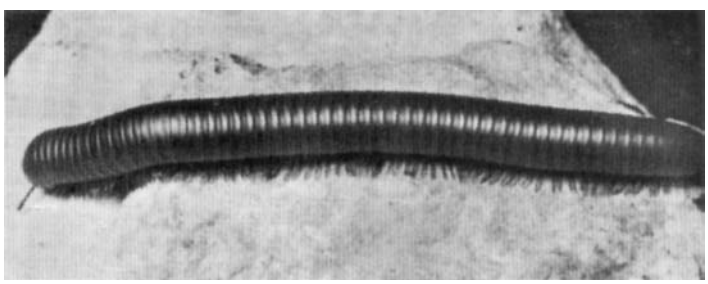

Fig. 1. Millipede (*Diplopoda*). (*A.M. Winchester*.)

These animals live in moist places, usually among rubbish on the surface of the ground, and eat decaying organic matter or plant tissues. Some attack roots and are therefore of economic importance.

The class is divided into two orders, *Pselaphognatha* and *Chilognatha*. All common species belong to the latter.

DIP NEEDLE. An instrument consisting essentially of a magnetic needle poised to swing on a horizontal pivot and thus indicate the "dip" or inclination of the earth's magnetic field. Also termed magnetic inclinometer. The zero diameter of the vertical graduated circle must be carefully leveled and adjusted to the magnetic meridian. In order to correct for errors of level, balance, magnetization, and eccentricity, the circle should be reversed north to south, the needle axis should be reversed in its bearings, the magnetization should be reversed, and for each of these positions, both ends of the needle should be read on the circle. A complete observation is thus the mean of sixteen circle readings.

DIPOLE. Two equal electric charges of opposite sign, separated by a small distance, form an *electric dipole*. A circulating current loop, of dimensions small compared to the distance at which it is being observed, can be considered as a *magnetic dipole*. More generally, any given distribution of electric or magnetic charges about a point can be described by means of a series of multipole terms (see also **Quadrupole**). The electrostatic potential of the dipole term at a distance r from the point is proportional to $1/r^2$.

DIPOLE ANTENNA. A straight radiator, usually fed in the center, and producing a maximum of radiation in the plane normal to its axis. The length specified is the overall length. Common usage in microwave antennas considers a dipole to be a metal radiating structure that supports a line current distribution similar to that of a thin straight wire, a half wavelength long, so energized that the current has two nodes, one at each of the far ends. See also **Antenna (Communications)**.

DIPOLE MOMENT. In the simplest case, let two electric charges $+q$ and $-q$ be separated by the distance **d**. Then the permanent electric dipole moment is the vector $\mathbf{p} = q\mathbf{d}$. More generally, if discrete charges q_i are located at points x_i, y_i, z_i the magnitude of dipole moment is given by $p_\alpha = \sum q_i \alpha_i,\ \alpha = x, y, z$. If the charge distribution is continuous, the summations are replaced by integrals. An induced dipole moment can be produced by an electric or magnetic field (see also **Magnetism**). Atomic or molecular dipole moments, permanent or induced, are of considerable value in the study of atomic or molecular structure. The magnitude of such moments is usually reported in Debye units. The magnetic dipole moment produced by a current i flowing in a loop area A has magnitude $m = iA$. It is a vector with directional normal to the plane of the loop and sense taken as the direction of progression of a right-handed screw rotating with the current.

DIPOLE RADIATION. A term applied to radiation that occurs as a result of the variation with time of a dipole moment. Dipole radiation may be either electric or magnetic, according to the nature of the dipoles causing it.

DIPROTON. The name given to a combination of two protons in a singular nuclear system.

DIPTERA. Flies, mosquitoes, midges, gnats and other insects. An order characterized by sucking and sometimes piercing mouths and the presence of a single pair of wings. The hind wings are represented by the halteres, slender clubbed appendages, often inconspicuous. A few species lack wings. The metamorphosis is complete and the larvae of many species are known as maggots.

This is one of the largest orders of insects, with about 50,000 described species, and in variety of adaptations it is exceeded by no other. Some species suck the juices of plants, some eat the tissues during larval life, some visit flowers for nectar, some suck blood, some are parasitic inside or outside the bodies of warm-blooded animals, and many are parasitic on other insects or are predacious. Many are scavengers, living on decaying organic matter or on the wastes of animals.

Species of economic importance include some of the plant-feeders, such as the Hessian fly, the blood-sucking horseflies and mosquitoes, and the parasitic bot flies.

Two major suborders of *Diptera* include *Orthorrhapha* (straight-seamed flies); and *Cyclorrhapha* (circular-seamed flies).

The main families of *Diptera* include:

Anthomyiidae	Root maggots
Asilidae	Robber flies
Blepharoceridae	New-winged midges
Bombyliidae	Bee flies
Braulidae	Bee lice
Cecidomyiidae (also called *Itonididae*)	Gall gnats
Chironomidae	Midges, gnats, and punkies
Chloropidae (also called *Oscinidae*)	Fruit flies, grass stem maggots, eye gnats
Culicidae	Mosquitoes
Dolichopodidae	Long-legged flies
Drosophilidae	Pomace or fruit flies
Ephydridae	Shore flies
Hippoboscidae	Louselike flies
Muscidae (includes *Calliphorinae*)	House flies
Mycetophilidae	Fungus gnats
Oestridae (includes *Gastrophilidae* and *Cuterebridae*)	Bot flies
Ortalidae	Ortalid flies
Phoridae	Humpbacked flies
Psychodidae	Moth flies and sand flies
Rhagionidae (also called *Leptidae*)	Snipe flies
Sarcophagidae	Flesh flies
Simuliidae	Black flies, Buffalo gnats
Stratiomyiidae	Soldier flies
Syrphidae	Flower flies, hover flies, syrphids
Tabanidae	Horseflies, deerflies
Tachinidae	Tachinid flies
Tipulidae	Crane flies (daddy-longlegs)
Trypetidae	Fruit flies

DIRAC DELTA FUNCTION. The improper function $\delta(x - x_0)$, so defined that

$$\int f(x)\delta(x - x_0)dx = f(x_0)$$

for any x. It may be approximated by

$$\delta x = \lim_{h\to\infty} \begin{cases} 0; & -h/2 > x \\ 1/h; & -h/2 > x < h/2 \end{cases}$$

The function

$$u(x) = \int_{-\infty}^{\infty} \delta(x) = dx = \begin{cases} 0; & x < 0 \\ 1; & x > 0 \end{cases}$$

is known as the unit step function. The Dirac delta function is also known simply as the delta function.

DIRAC PARTICLE. See **Field Theory**.

DIRAC, PAUL ADRIEN MAURICE (1902–1984). Dirac was an English physicist. He enrolled at Bristol University in electrical engineering. When he received his degree the country was in a depression, so he continued school pursuing mathematics. He was especially interested in projective geometry. He also became highly interested in physics and in relativity theory.

In 1923, Dirac went to Cambridge University and had the opportunity to study with Ralph Fowler who was working in quantum theory. Today, Dirac's name is equated with significant contributions to quantum mechanics and marks him as one of the founders of modern quantum electrodynamics. He is especially known for his formulation of a mathematical description of elementary particles that accords with both quantum mechanics and also the theory of relativity. Dirac predicted the existence of the positrons and electron spin. He was awarded the 1933 Nobel Prize for Physics jointly with Erwin Schrodinger for his modification of Schrodinger's wave equation.

See also **Dirac Delta Function**; **Field Theory**; and **Schrödinger Equation**.

J. M. I.

DIRECT-COUPLED AMPLIFIER. As used in digital data acquisition and instrumentation systems, the term *DC amplifier* has two connotations: (1) a *direct-coupled* amplifier, that is, a low-resistance DC connection is used between each stage and the succeeding stage in the amplifier, and (2) an amplifier with a frequency response that extends to zero frequency (D.C.). It should be pointed out that although all DC amplifiers (direct-coupled) have a frequency response that extends to D.C., not all amplifiers with this type of frequency response are direct-coupled. A carrier amplifier, for example, has a response extending to D.C., but it is not direct-coupled.

One type of direct-coupled differential amplifier is shown in Fig. 1. Only the first stage of the amplifier is shown in detail because the most important characteristics of an amplifier usually are determined by the first stage of the amplifier. The two or three remaining stages are shown as a single symbol. These stages provide high gain, typically greater than 1,000, and also the output-drive capability of the amplifier. Usually, the conversion from differential input to single-ended output is also effected in these stages.

As shown, the input stage is comprised of a pair of transistors, the bases of which are biased by current sources. A current source also determines the emitter current of the transistor pair. Feedback resistor R_{f1} and emitter resistor R_{e1} determine the gain of the stage. There is a direct coupling of the differential-output signal generated at the collectors of the first-stage transistors and the bases of the transistors in the second stage.

Usually, the gain of the first stage is on the order of 100. Thus, the first stage essentially determines the drift and noise characteristics of the overall amplifier. Because of the manner in which the first-stage is configured, the drift characteristics are determined by the difference in the drifts of the two input transistors. The base-emitter voltage drop is

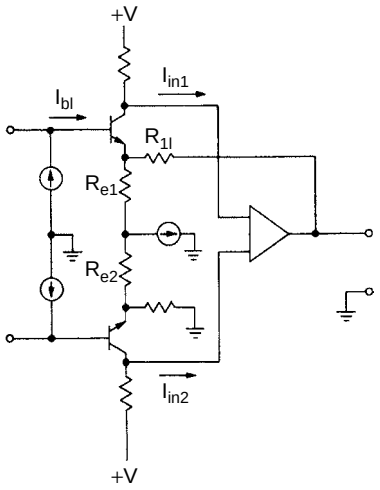

Fig. 1. Direct-coupled differential amplifier.

the major contributor to zero-offset temperature coefficient. The overall amplifier drift can be minimized (a few microvolts/°C) by using matched transistors in the differential configuration. Where additional temperature compensation is used in the first stage, a drift of less than 1μ V/°C can be achieved. Noise characteristics are mainly related to the intrinsic noise of the input transistors. Some control over this can be effected by selection of the biasing point. The usual procedure is to select low-noise transistors.

The design of the first stage also affects the common-mode characteristics. Where possible, the configuration should be made symmetrical with respect to ground—thus, the inclusion of the dummy feedback resistor R_{f2}. Also, the input base-bias sources must be balanced. The balance between the RC constants of the base-to-collector capacitance and the collector resistance determine high-frequency common-mode characteristics. Where a design may be critical, an adjustment of one of these parameters may be required. The common-mode performance of the amplifier also may be improved by common-mode feedback between the first-stage emitter and a common-mode point in a subsequent stage. Feedback is frequently applied to the ground side of the emitter-bias source.

The type of amplifier just described schematically is used extensively in digital-data acquisition and instrumentation systems. Direct-coupled design permits wide bandwidth, typically 0 Hz to frequencies in excess of 50 kHz and at relatively high gains. As compared with some other designs of differential amplifiers, the d.c. amplifier is relatively inexpensive. For some applications, a disadvantage is the relatively low common-mode voltage capability. The common-mode voltage essentially is limited to 10 to 20 V because of the breakdown characteristics of the input transistors.

THOMAS J. HARRISON,
IBM Corporation, Boca Raton, FL

DIRECT-CURRENT CIRCUITS. Unidirectional current is produced from batteries, from dynamo machinery equipped with commutators, or by means of rectifiers. Direct-current generators are built with their D.C. magnetic poles on the stator. Armature conductors on the rotor have A.C. voltages induced in them as they are rotated; the same principle of flux cutting as holds for A.C. generators. An automatic mechanical switching device, called a commutator, is placed on the shaft. It carries fixed brushes, and with its many insulated copper bars connected to the armature coils, it inverts every other alternation of the voltage to give unidirectional, or D.C., voltage at the two armature terminals. It is the commutator that requires the rotor to be the armature so that coils and their switching arrangement always move exactly together. Direct-current generators are generally limited to several thousand kilowatts and their application lies mainly in industrial plants. The disadvantage of D.C. over the years has been the difficulty of transforming it from low voltage to the high voltage desired for long-distance transmission of electrical power. Difficulties of commutation have prevented generation at high voltages. Silicon-controlled rectifiers and other solid-state devices have been used. In the mid-1950s, development of the high-voltage mercury-arc valve improved the competitive position for D.C. transmission. Converters based on mechanical switches were tested in England and Sweden in the 1920s and 1930s. As early as 1889, the Swiss engineer Thury developed a system consisting of D.C. generators and motors connected in series on the D.C. side. There were installations of this system in Europe over the period of 1890 to 1937, at which time a conversion to mercury-arc valves was made. The fact that D.C. lines and cables are less expensive than those of 3-phase A.C. transmission offers a major incentive for continuing to find effective ways for solving D.C. transmission problems.

Characteristics of recent high-voltage D.C. systems are described in the entry on **Electric Power Production and Transmission**.

In a general network composed of resistors and unidirectional electromotive forces, the determination of the currents that flow can be effected by the straightforward application of Kirchhoff's Laws of Networks. Many problems arising in practice either reduce to, or may be simplified materially by reducing portions of a more general network to, combinations of resistors in series or resistors in parallel. As an illustration of the application of this principle, consider the two circuits shown in Fig. 1. Application of the Kirchhoff law concerning voltage rises and voltage drops to the circuit at the top yields the result

$$E = R_1 I + R_2 I + R_3 I + R_4 I$$

This expression can be written

$$E = (R_1 + R_2 + R_3 + R_4) I$$

or

$$E = RI$$

The latter expression is Ohm's Law, which relates the change in potential across the resistance to the current flowing through it. From the expression above, it is concluded that the resistance of a series combination of resistors is equal to the sum of the individual resistances. In a similar manner, by the application of the Kirchoff current law to the circuit at the bottom of the figure, one obtains

$$I = E\left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4}\right)$$

and

$$I = \frac{E}{R}$$

where

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4}$$

The reciprocal of resistance is called conductance. By examination of the results just obtained for the parallel connected resistors, one concludes that the reciprocal of the equivalent resistance of a number of resistors connected in parallel is equal to the sum of the reciprocals of the individual resistance values. In terms of the conductance concept, the equivalent conductance of a group of parallel, connected resistors is the sum of the individual conductances. The common symbol for conductance is G. Complex D.C. networks consisting of an interconnection of simple resistances and power source elements are normally analyzed by either the mesh or node method. The point at which two or more elements have

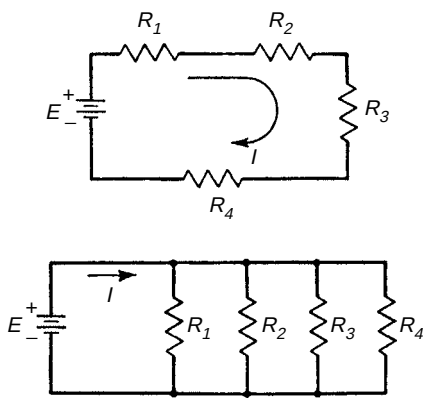

Fig. 1. Simple direct-current circuits.

a common connection is called a *node* and the element itself is called a *branch*. Networks that may be drawn on paper so that no lead must pass over another are referred to as *planar*. A closed path in a network is a *loop*. Loops that do not contain other loops are called meshes.

On the *mesh method of analysis*, the circuit is divided up into independent meshes and Kirchhoff's voltage law applied to each mesh. For a three mesh network, the three mesh equation may be written in its following form:

$$R_{11}I_1 - R_{12}I_2 - R_{13}I_3 = E_1$$

$$-R_{21}I_1 + R_{22}I_2 - R_{23}I_3 = E_2$$

$$-R_{31}I_1 - R_{32}I_2 + R_{33}I_3 = E_3$$

where R_{11}, R_{22} and R_{33} are the total resistances in meshes 1, 2, and 3, respectively. $R_{12} = R_{21}$ = total mutual resistance between mesh 1 and 2. $R_{13} = R_{31}$ = total mutual resistance between mesh 1 and 3. $R_{23} = R_{32}$ = total mutual resistance between mesh 2 and 3. E_1, E_2 and E_3 are the three source voltages acting in the three meshes. The equations are solved for I_1, I_2 and I_3, the three mesh currents.

In the *nodal method of analysis* the circuit is divided up into independent nodal pairs and Kirchhoff's current law is applied to all nodes but the reference node. For a three nodal-pair network, one gets

$$G_{11}E_1 - G_{12}E_2 - G_{13}E_3 = I_1$$

$$-G_{21}E_1 + G_{22}E_2 - G_{23}E_3 = I_2$$

$$-G_{31}E_1 - G_{32}E_2 + G_{33}E_3 = I_3$$

where G_{11}, G_{22} and G_{33} are the total conductances connected to nodes 1, 2, and 3, respectively. $G_{12} = G_{21}$ is the total conductance between node 1 and 2. $G_{13} = G_{31}$ is the total conductance between node 1 and 3. $G_{23} = G_{32}$ is the total conductance between node 2 and 3. I_1, I_2 and I_3 are the source currents at node 1, 2, and 3, respectively. Solve for E_1, E_2 and E_3, the three pair voltages between node 1, 2 and 3 and reference node, respectively. The electrical power flowing in a D.C. circuit is found by multiplying the voltage by the current, the unit of power being watts. Heat that is generated by electrical current flowing through a resistance of R ohms for T seconds is:

$$\text{Heat} = I^2RT \text{ watt-seconds}$$

The watt-second is a unit of electrical energy so small that 1,055 watt-seconds are required to equal one Btu. See also **Electric Circuits**; and **Kirchhoff Laws of Networks**.

DIRECTIONAL ANTENNA. See **Antenna (Communications)**.

DIRECTION COSINE. Let a set of rectangular coordinate axes in space be chosen and let L be any line in space. Through the origin of the coordinate system draw another line L', parallel to the given line L. Let α, β, γ be the angles which L' makes with the X-, Y-, Z-axes, respectively. These angles are the direction angles of the given line and their cosines $\lambda = \cos\alpha$, $\mu = \cos\beta$, $\nu = \cos\gamma$ are the direction cosines of the line. When two angles are given, the third can be found, except for sign, by the Pythagorean theorem, for

$$\lambda^2 + \mu^2 + \nu^2 = 1$$

If two rectangular coordinate systems with a common origin are given there will be nine direction cosines, one for each angle between the various pairs of coordinate axes. These cosines, not all of which are independent, can be written as the elements of an orthogonal matrix R and relations between them are conveniently found by matrix or vector methods. If $\mathbf{x}'$ is a vector in one of the coordinate systems and $\mathbf{x}$ is the same vector in the other system, the two vectors are related by the matrix equation $\mathbf{x}' = R\mathbf{x}$.

DIRECTION (Mathematics). The position of one point in space relative to another without reference to the distance between them. Direction may be either three-dimensional or two-dimensional. Direction is not an angle but is often indicated in terms of its angular difference from a reference direction. The *direction angles* of a line are the 3 angles it makes with the positive directions of the coordinate axes. Its direction cosines are the cosines of these angles. Any set of 3 numbers proportional to its direction cosines are called *direction numbers* for the line. A direction at a point on a surface in which the curvature of a normal section is a maximum or a minimum is called a *principal direction*.

DIRECT TIDE. A gravitational solar tide or lunar tide in the ocean or atmosphere that is in phase with the apparent motions of the attracting body, and consequently has its local maxima directly under the tide-producing body and on the opposite side of the earth.

A gravitational tide that is in opposite phase to the apparent motions of the sun or moon is called a reversed tide.

DIRICHLET, PETER (1805–1859). Dirichlet was a German mathematician who was fortunate to have been taught by Ohm early in life. He is said to have carried Gauss's book, ***Disquisitiones Arithmeticae***, everywhere. In college, Dirichlet was taught by such notables as Biot; Fourier.Laplace, Legendre, and Poisson.

Dirichlet had almost instant mathematical fame with his first paper concerning the famous Fermat's Last Theorem. He also gave the first set of conditions, sufficient to guarantee the convergence of a Fourier series, now Dirichlet Conditions. His name is also given to Dirichlet Boundary Conditions and produced Dirichlet's Theorem on Primes. Many feel, analytic number theory began with Dirichlet's work on the existence of primes in a given arithmetic progression.

See also **Number Theory**.

J. M. I.

DIRIGIBLES AND AIRSHIPS. Dirigibles, as do other airships, derive their lifting power from aerostatic forces rather than the aerodynamic forces such as those that support the airplane. See also **Aerodynamics and Aerostatics**; and **Supersonic Aerodynamics**. The lift of an airship is one of buoyancy, and this is derived from the difference between the density of the atmosphere and that of the lifting gas contained by the airship. Hydrogen and helium have been used as lifting gases.

The size of an airship is determined by the volume of lifting gas required to lift the weight of the ship and the load. The lifting power of helium is approximately 58 pounds per 1,000 cubic feet (0.93 kilograms per cubic meter) under standard atmospheric conditions; of hydrogen, 64 pounds for the same volume and conditions (1.03 kilograms per cubic meter). The airship is equipped with a propulsive device and controls so that its attitude, speed, altitude, and course are under control of the pilot. This is in contrast with the free ballon, for which only altitude is controllable, velocity and direction depending essentially upon the wind. See also **Balloon**.

The requirements of navigability and aerodynamic efficiency have caused an effective aerodynamic shape to be given the airship. This shape is usually circular in cross section, with a rounded nose and a tapering tail. The ratio of length to diameter, known as the fineness ratio, varies between 5 and 8. In the past, propulsion has been obtained from air propellers driven by internal combustion engines, which are either mounted in nacelles attached to the hull, or are within the hull, and drive propellers by means of shaft and gearing extending through the skin of the hull. The latter location has been considered safe only in helium-filled airships.

There are three principal classifications of airships, i.e., the nonrigid, semirigid, and rigid. The shape of the nonrigid airship is maintained by the pressure of the lifting gas. However, the gas expends and contracts with temperature, and in the contracted state the airship would be limp (the popular name blimp is derived from a wartime designation of this as the B-limp type) were it not for an air-filled ballonet which is built inside the main covering. As the lifting gas expands it forces air out of the ballonet, and when the lifting gas contracts, air scoops fill the ballonet by virtue of the velocity of the airship. The variable volume ballonet can also be used by the pilot to regulate the altitude of the airship by using it to compress or expand the lifting gas, so changing its density and lifting power. The ballonet is emptied for ascent, and refilled for descent. The cabin and engine installations are carried in the car or in nacelles, which are suspended below the envelope.

The rigid airship has a complete metal framework, and its shape is, accordingly, independent of the degree of inflation of the lifting gas cells that are contained within. Fixed equipment, like power plants and living quarters, is rigidly attached to the structural frame. The semirigid airship resembles the nonrigid in that its shape is maintained by gas pressure, but there is a structural keel extending longitudinally from the nose to the tail,

with additional structural reinforcement at the nose and at the attachment of the control surfaces. In size, the blimps are the smallest, and the rigid dirigibles the largest, airships.

The framework of the dirigible is made of girders running longitudinally connected by parallel circumferential rings. The circumferential rings must be absolutely rigid, and if the construction is not such that their shape is self-sustaining, they must be braced diametrically. One to three of the longitudinal members at the bottom of the hull are made especially heavy and rigid to form a keel. The keel serves to strengthen and integrate the ship fore and aft, provide main walkways for access to the interior of the ship, and support heavy equipment, such as cabins, engines, and control surfaces.

One of the first dirigible balloons was designed by Henri Giffard. This craft was powered by a 3-horsepower steam engine and in mid-September 1852 flew from the Paris Hippodrome to Trappers, a distance of approximately 17 miles, at a speed of 5 miles (8 kilometers) per hour. Powered by a 3-horsepower Clement engine, the "No 9," a dirigible built by Alberto Santo-Dumont (Brazil) in Paris in the late 1890s, met with some success as a demonstration vehicle. The art of dirigible design was revolutionized by Count Ferdinand von Zeppelin (most of his designs were named after him—*zeppelins*) at the turn of the century. Zeppelin I was 426 feet (130 meters) long. Aluminum was used for the main body structure. Zeppelins were used militarily by the Germans up through World War I and for limited commercial service until 1936, at which time the hydrogen-filled dirigible Hindenburg LZ-129 burst into flames on May 6, 1936 when landing at Lakehurst, New Jersey, in which 25 of the 97 people aboard were killed. In retrospect, considering commercial aviation history, this was not an accident of great dimensions. However, coming at a time when the series of large American-built dirigibles, such as the Shenandoah, Akron, and Macon, had crashed because of weather-imposed accidents, the Hindenburg incident discouraged further dirigible developments. Some French dirigibles also had crashed during that prior period. In fairness to this mode of transportation, it should be observed that the ill-fated LZ-129 prior to its Lakehurst accident had completed ten trips to the United States and eight trips to South America, information that is not usually brought out when the disaster is mentioned. Also, in terms of speculation, it is intriguing to consider what the future of the dirigible might have been had the United States released helium for its use. Dirigible technology at that time was largely concentrated in Germany, of course, and the disaster occurred just a few years prior to the start of World War II—so the fate of dirigible technology was at least, in part, a victim of political considerations.

During the late twentieth century, some interest in attempting to apply the greatly extended know-how gained during the past 40 or 50 years to newly conceived dirigible or airship concepts was evidenced, particularly in terms of low-cost mass transportation of goods, and also as a pleasant means of low-altitude, slow-speed touring by air. Meanwhile, the technology is holding on by virtue of a very limited number of blimps in use for aerial photography, pleasure cruising, and advertising.

DISCHARGE (Coefficient of). Water discharged from an orifice, weir, pipe, etc., theoretically has a velocity which is directly proportional to the square root of the head of water causing flow through the opening. Actually, however, contractions in the stream, surface roughness, and other causes result in the actual velocity being smaller than the theoretical. The theoretical velocity is identical with that of the velocity attained by a freely falling body. It is $\sqrt{2gh}$, wherein g represents the acceleration of gravity, and h the height of fall corresponding to the pressure head creating the discharge. The ratio of the actual velocity to the theoretical is the coefficient of discharge. The coefficient of discharge from circular orifices is affected by the diameter of the orifice, the head, the sharpness of the edge, the velocity of approach to the orifice, and other minor factors. See also **Orifice**.

DISCHARGE (Gaseous). If two electrodes have a gas at low pressure between them and a gradually increasing voltage is applied across them, a series of events takes place as the voltage is raised. First a very small current (microamperes) will flow as the ions and electrons are attracted to the electrodes. These charged particles are present because various radiations (cosmic, etc.) are always present (except in specially shielded enclosures) which ionize the gas molecules. As the voltage is raised, the current finally begins to increase rapidly because the electrons being attracted toward the positive electrode have gained sufficient energy to ionize atoms of the gas and thus generate more carriers of the current. Suddenly the current increases extremely rapidly, and at the same time the voltage across the tube drops. The value of the voltage at which this occurs is the breakdown voltage and the gas has broken into a self-maintaining discharge called a glow. If the current is not limited by circuit resistance, it continues to increase almost instantaneously, while the voltage drops to a low value and the discharge becomes an arc. If the circuit has insufficient resistance the current will reach an enormous value with probable damage to the tube and other circuit elements. The glow discharge is characterized by the ability to pass moderate currents at moderate values of voltage, while the arc will pass very large currents at low values of applied voltage.

Electrodeless Discharge. A current may be maintained in a rarefied gas without the introduction of electrodes into the gas. (1) A tube containing the gas may be placed between external metal plates having a rapidly alternating, high-potential difference. The tube then acts as the dielectric in a condenser, and the gas may become luminous with a discharge across the tube similar to that with internal electrodes. (2) The tube may be surrounded by a helix through which a high-frequency current is passing. In this case, the luminosity takes the form of a ring, inside the tube, coaxial with the turns of the helix. This is due to the alternating electric intensity induced by the current in the helix. The discharge has the characteristics of the positive column in an ordinary discharge tube, except that it forms a closed ring. Striations sometimes appear, in radial planes. If the oscillations in the helix are intense, the ring discharge is confined to the space immediately inside the tube wall; if less so, it extends farther inward. The discharge is facilitated by ultraviolet radiation traversing the gas. Volatile impurities in the tube, such as sulfur or phosphorus, impair the discharge and may stop it. With some gases there is a distinct phosphorescence, called the "after-glow," persisting for some seconds after the helix oscillations cease.

Dark discharge is an electrical discharge in a gas without the production of visible light.

DISCONE ANTENNA. An antenna formed of a disk and a cone whose apex approaches and becomes common with the outer conductor or the coaxial feed at its extremity. The center conductor terminates at the center of the disk which is perpendicular to the axis of the cone. See also **Antenna (Communications)**.

DISCONFORMITY. See **Unconformity (Geological)**.

DISCONTINUITY. A point at which a function is not continuous or not defined. If the point $x = a$ is such that $f(x)$ approaches distinct finite limits as x approaches a from the left or from the right, then a is said to be a *jump discontinuity* of $f(x)$, or $f(x)$ is said to have a jump discontinuity at a. If $f(x)$ can be made continuous at a by giving a suitable definition to $f(a)$, then $f(x)$ is said to have a *removable discontinuity* at a.

DISCOVERY PROGRAM. Discovery is an ongoing program that offers the scientific community the opportunity to assemble a team and design exciting, focused science investigations that complement NASA's larger planetary science explorations. The goal is to launch many smaller missions with fast development times, each for a fraction of the cost of NASA's larger missions. The main objective is to enhance our understanding of the Solar System by exploring the planets, their moons, and small bodies such as comets and asteroids.

In the past, NASA announced plans to explore a certain planet or region of space and solicited independent bids and competitions for spacecraft, operations, and science investigations. These missions were very large in scope, carrying many instruments, involving large groups of people, taking

many years to get organized and launched, and often costing billions of dollars.

The philosophy of Discovery is to solicit proposals for an entire mission, put together by a team comprised of people from industry, small businesses, government laboratories and universities, led by a Principal Investigator (PI). The PI develops the scientific objectives and instrument payload. The team brings together the skills and expertise needed to carry out a mission from concept development through data analysis. The PI is responsible for assuring that cost, schedule and performance objectives are met.

Discovery seeks to keep performance high and expenses low by using new technologies and strict cost caps. The cost for the entire mission (design, development, launch vehicle, instruments, spacecraft, launch, mission operations, and data analysis) must be less than $425 million. The development time from mission start to launch can be no more than 36 months. The intent is to have a mission launch every 12 to 24 months.

NASA is committed to the principles of open competition and merit review as a key to excellence. Proposals are chosen through an extensive competitive peer review process. Proposals require careful tradeoffs between science and cost to produce investigations with the highest possible science value for the price.

The Space Science Enterprise Strategic Plan, published by NASA in November 2000, identifies its foremost role in support of the NASA mission as the discovery of new scientific knowledge about the universe. The Space Science Enterprise will: *Discover how the universe began and evolved, how we got here, where we are going, and whether we are alone*.

Specific goals of the Space Science Enterprise are:

- Chart the evolution of the universe, from origins to destiny, and understand its galaxies, stars, planets, and life.
- Use robotic missions as forerunners to human exploration beyond low-Earth orbit
- Develop new technologies to enable innovative and less expensive research and flight missions.
- Share the excitement and knowledge generated by scientific discovery and improve science education.

To accomplish its prime objective of enhancing our understanding of the Solar System, the unique approach of the Discovery Program is to:

- increase flight rates
- contain total mission costs
- improve performance through the use of new technology
- broaden university and industry participation, and
- increase public awareness of solar system exploration.

Discovery was among the first NASA programs to require a plan for education and public outreach, as NASA recognized the importance of communicating the excitement and meaning of space exploration to the public. Innovative methods that support national education initiatives are being developed to reach students of all ages. The vast possibilities created by the Internet greatly strengthen this effort.

Discovery advocates the testing and use of new technologies and applications. Each mission works with industry to transfer technologies used in the mission, especially those that enhance science acquisition and reduce cost.

Missions

Ten Discovery Missions have been chosen to date.

NEAR (Near-Earth Asteroid Rendezvous). On February 17, 1996, Near Earth Asteroid Rendezvous was the first Discovery Program spacecraft to be launched and is the first spacecraft ever to orbit and land on an asteroid.

Utilizing six highly specialized instruments (Fig. 1) to gather data about its primary target, asteroid 433 Eros, the NEAR mission was designed to answer many fundamental questions about the nature and origin of asteroids and comets.

NEAR's six science experiments each contributed in different ways to further our understanding of Eros:

- A magnetometer to determine whether Eros has a magnetic field
- The X-ray/gamma-ray spectrometer to measure key elements
- A near-infrared spectrometer to map mineral composition
- The laser rangefinder to read the shape of the asteroid
- A radio science experiment to determine mass and density
- A multispectral imager to study asteroid rock types and geology

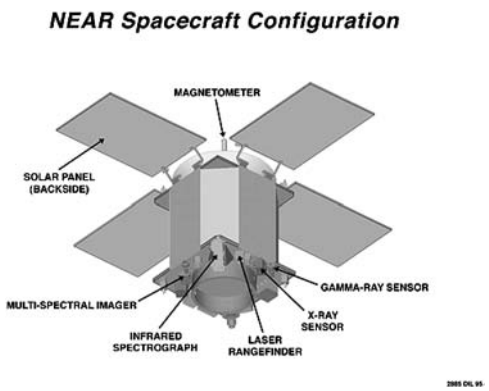

Fig. 1. NEAR's instruments. (*JHU/NASA*)

On February 14, 2000, the NEAR Shoemaker spacecraft began its year-long orbit of asteroid Eros determine its mass, structure, geology, composition, gravity, and magnetic field. Eros is the largest of the so-called near-Earth asteroids whose orbits cross that of Earth's. These bodies are of interest because of their potential for collision with Earth, as well as for the clues they hold about the nature of how small bodies, including the Earth, were formed.

During its year-long orbit, NEAR Shoemaker flew past Eros at altitudes from 3 to 35 miles (5 to 56 km), producing thousands of spectacular images and returning data that will be analyzed for years to come.

Combining digital images and data from the laser rangefinder, scientists have built the first detailed map and three-dimensional model of an asteroid.

Previously scientists had theorized that asteroids were either solid iron or cosmic rubble piles-Eros is neither. Data suggests that Eros is a cracked but solid rock, possibly a fractured chip off a larger body, made of some of the most primitive materials in the solar system.

The regolith on Eros is nearly 300 feet (91 meters) deep in places. Data indicate the regolith has moved downhill, smoothing over rough areas and spilling into craters.

The cratering on Eros has surprised scientists, with intriguing square ones and many fewer small craters than expected. More than 100,000 craters wider than 50 feet (15 meters) have been counted. Also, the large number of boulders was unexpected, with about one million house-sized or larger boulders.

The last images returned showed clusters of boulders, a mysterious area where the surface appears to have collapsed, and extremely flat, sharply delineated areas in the bottoms of some craters, indicating the story of Eros's composition is still emerging.

After a journey of more than two billion miles, NEAR Shoemaker gently landed on the tips of two solar panels and its bottom edge on February 12, 2001, at 3:01 p.m. (EST). The spacecraft snapped 69 detailed pictures during the final three miles (five km) of its descent, the highest resolution images ever obtained of an asteroid, showing features as small as one centimeter across.

The slow touchdown speed left the spacecraft intact and still sending a signal back to Earth. NASA decided to extend the mission to February 28th, to get "bonus science" from the spacecraft, which had already collected 10 times more data than originally planned. This allowed the gamma-ray spectrometer to collect data from an ideal vantage point about four inches (10 cm) from the surface, in the first gamma-ray experiment that has ever been done on the surface of a body other than Earth.

The NEAR mission returned more 160,000 detailed images that solved some mysteries and unveiled new ones. The amazing amount of data collected will be shared with scientists all over the world, to reveal facts about Eros and our solar system that no one knows today.

The NEAR mission was managed for NASA by the Johns Hopkins University Applied Physics Laboratory, in Laurel, MD. The Program Scientist was Andrew Cheng.

For complete information, including the full archive of images, science updates, news releases and a flyby movie, visit the Near Earth Asteroid Rendezvous mission home page, http://near.jhuapl.edu/.

Mars Pathfinder Mission. Launched on December 4, 1996, Mars Pathfinder demonstrated a number of innovative, economical, and highly

effective approaches to spacecraft and planetary mission design. In addition to the engineering feat of landing on Mars, the mission also served as a demonstration of key technologies and concepts for use in future missions to Mars.

The primary objective was to demonstrate a low-cost method of delivering a set of science instruments and a free-ranging rover to the surface of Mars. The rover conducted technology experiments and served as an instrument deployment mechanism.

The science objectives were to:

- Investigate Martian atmosphere, surface metrology and geology
- Characterize surface features
- Analyze the elemental composition of rocks and soil at the landing site
- Monitor atmospheric conditions as they varied over the course of the mission with photographic and analytical instruments

Pathfinder arrived on Mars on July 4, 1997, slowed in its descent by a system of parachutes and retro-rockets, falling freely the last few hundred feet, and bouncing on its inflated airbags over the Martian surface like a basketball. The airbags deflated, the petals of the lander opened, and the rover descended and began exploring and analyzing nearby rocks. The engineering design far exceeded expectations. Pathfinder's lander operated nearly three times longer than its design lifetime of 30 days, and the Sojourner rover operated 12 times its design lifetime of seven days. After sending back thousands of images and measurements, the mission ended on September 27, 1997.

Mars Pathfinder was managed by the Jet Propulsion Laboratory for NASA. Dr. Matt Golombeck of JPL was the Project Scientist. See also **Pathfinder Mission to Mars**.

For complete information about the Mars Pathfinder mission, including the archive of all images, visit their award-winning home page, http://mpfwww.jpl.nasa.gov/MPF/default.html.

Lunar Prospector. Lunar Prospector, the third Discovery mission, launched on January 6, 1998, and was successfully placed into orbit 63 miles above the lunar surface five days later. The science data returned from Lunar Prospector has enabled scientists to create detailed maps of the gravity, magnetic properties and chemical composition of the Moon's entire surface.

The studies conducted by the spacecraft and its five instruments were designed to provide insights into lunar origin and evolution and determine whether or not water ice is present in the Moon's polar regions.

Besides water, Lunar Prospector searched for other natural resources, such as minerals and gases, which could be used to build and sustain a future human lunar base or to manufacture fuel for launching spacecraft from the Moon to the rest of the Solar System.

The science data returned from Lunar Prospector has enabled scientists to create the most complete and detailed maps of the gravity, magnetic properties and chemical composition of the Moon's entire surface. While the Moon's magnetic field is relatively weak, Prospector detected large localized magnetic fields that create the two smallest magnetospheres in the Solar System.

In March 1998, mission scientists announced tentative findings of the presence of water ice in shadowed craters near the Moon's south and north poles, based on reasonable scientific assumptions from the levels of hydrogen detected, from which water ice is inferred. They estimated that up to six billion metric tons of water ice may be buried in these craters under about 18 inches of soil.

The mission originally was scheduled to end sometime in July 1999, when it would run out of fuel and randomly impact the lunar surface. However, in a dramatic attempt to find proof of water ice, scientists came up with an innovative plan to direct the spacecraft to impact the surface of the Moon inside a permanently shadowed crater near the lunar south pole. The concept was that the impact could free up to 40 pounds of water vapor that may be detectable from ground and space based observatories. A positive detection of water vapor would provide definitive proof of the presence of water ice in the lunar polar regions.

On July 31, 1999, the Mission Control team successfully ended the mission at 2:52 a.m. PDT when the spacecraft slammed into its intended target. The controlled crash produced no observable signature of water, according to data from Earth-based observatories and spacecraft such as the Hubble Space Telescope. This lack of evidence leaves open the question of whether ancient cometary impacts left ice, which is buried in permanently shadowed regions of the Moon.

Failure to prove that water ice exists in the lunar polar regions does not suggest that it is absent, but rather that this experiment, acknowledged as high payoff but with low probability of success, has not provided the conclusive evidence that was being sought. Overall, the mission provided a tremendous volume of valuable data that scientists will be analyzing for years to come.

The Lunar Prospector mission was managed by NASA's Ames Research Center. Dr. Alan Binder of the Lunar Research Institute was the Principal Investigator. The mission was implemented by Lockheed Martin Missiles and Space, Sunnyvale, California. See also **Lunar Prospector Mission**.

For complete information on the mission and the largest collection of lunar media anywhere in the world, visit the Lunar Prospector home page http://lunar.arc.nasa.gov/.

Stardust Mission. Launched on February 7, 1999, Stardust is the first space mission dedicated solely to studying a comet. For the first time ever, comet dust and interstellar dust particles will be collected during a close encounter with Comet Wild 2 and returned back to Earth for analysis by scientists worldwide.

For the Comet Wild 2 encounter, the objective is to recover more than one thousand particles larger than 15 microns in diameter. Stardust will also spend 150 days collecting particles of interstellar dust, including the recently discovered dust streaming into the solar system from the direction of Sagittarius. It is believed that these materials consist of ancient pre-solar interstellar grains left over from the formation of the solar system. Their analysis is expected to yield important insights into the evolution of the Sun and planets.

In February, 2000, the Stardust spacecraft successfully deployed its aerogel collector and began capturing interstellar dust from a stream of particles from outside our solar system that was initially detected many years ago by Earth-orbiting spacecraft. This historic first collection period lasted through May 1. The collector was then returned to its stowed position until mid-2002, when the second interstellar dust collection took place from August through December.

Stardust passed a huge milestone on January 2, 2004, when it flew within 240 kilometers (149 miles) of the nucleus of Comet Wild 2, collecting samples of comet dust and snapping detailed pictures of the comet's surface. To collect the particles without damaging them, Stardust used a collector the size of a tennis racket and a substance called aerogel, a silica-based solid with a porous, sponge-like structure in which 99 percent of the volume is empty. The collector was then stowed in the sample return capsule for the two-year journey back home.

The Stardust sample return capsule returned safely to Earth at 3:10 a.m. local time on January 15, 2006. Parachuting into the desert salt flats of the U.S. Air Force Utah Test and Training Range after a 288 billion mile journey through the Solar System, the SRC entered the Earth's atmosphere faster than any human-made object on record. It slowed from a speed of nearly 29,000 miles per hour to about 10 miles per hour in 13 minutes.

Eager science team members transported the science canister to the curation facility at NASA's Johnson Space Center in Houston, TX, to begin the process of extracting the dust particles from the aerogel.

Early analyses of the comet dust particles surprised scientists. They found high-temperature minerals in materials from the coldest place in the Solar System, suggesting that materials from the center of the solar system could have traveled to the outer reaches where comets formed. This may alter the way scientists view the formation and composition of comets. They may prove to be more diverse and complex than previously thought.

One mineral found in the material brought back by Stardust is olivine, a primary component of the green sand found on some Hawaiian beaches. It is among the most common minerals in the universe, but scientists were surprised to find it in cometary dust.

The collection of cometary particles is greater than expected, with about two dozen large tracks visible to the unaided eye. Thousands appear to be embedded in the aerogel; most are smaller than a hair's width.

The Stardust mission is managed by the Jet Propulsion Laboratory. The Principal Investigator is Dr. Donald Brownlee of the University of Washington. The Stardust spacecraft was designed and built by Lockheed Martin Astronautics of Denver, Colorado. Flight Operations during the mission will be conducted at both Lockheed Martin Astronautics and the Jet Propulsion Laboratory. See also **Stardust Mission**; and **Stardust home page**; http://stardust.jpl.nasa.gov/home/index.html.

Genesis. On August 8, 2001, the Genesis spacecraft began its journey a million miles sunward, where it will "sunbathe" in orbit around L1 for

over two years, before returning with particles of solar wind in September 2004.

The goal of the mission is to enrich our understanding of the birth and evolution of the planets and all the bodies in our solar system.

Most scientists believe the solar system was formed 4.6 billion years ago by the gravitational collapse of the solar nebula, dust and ice created from the stars. As time went on, most of the material was pulled together by gravity to form the Sun and other celestial bodies as we know them today.

Yet many mysteries remain unanswered:

- How did this transformation from solar nebula to planets take place?
- Why did some planets, like Venus, develop thick, poisonous atmospheres?
- How did the Earth's environment develop to sustain life?

Partial answers from previous studies suggest that moons, planets, and even asteroids are significantly different in composition. But without knowing what the original solar nebula was made of, complete answers are not possible. Because it is believed that the outer layers of the Sun are composed of very nearly the same material as the original solar nebula, the opportunity to compare the Sun's composition against known planetary composition data sets may provide significant answers.

On November 16, 2001, Genesis entered into halo orbit around L1. In early December the spacecraft's collector arrays were deployed, the ion concentrator was turned on, and the science of Genesis began. See Fig. 2. The concentrator and arrays collected solar wind for 26 months, through April 2, 2004. Then the collectors were re-stowed and the spacecraft headed back to Earth.

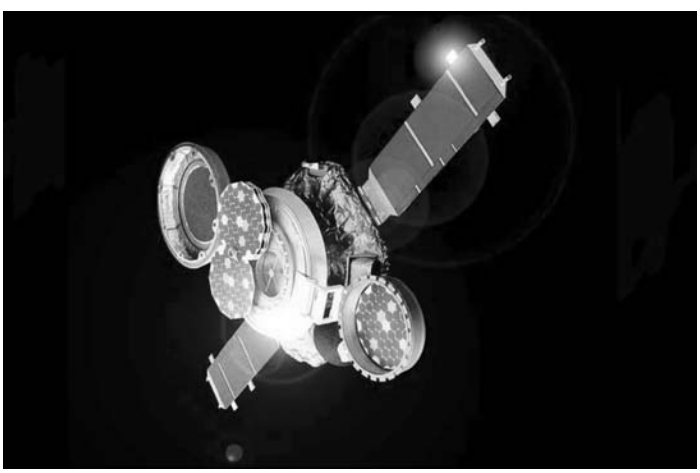

Fig. 2. This artist's conception shows the Genesis spacecraft in collection mode, opened up to collect and store samples of solar wind particles. The cover of the science canister contains one set of collection materials. It is the same kind of hexagonal silicon wafer array that comprises the stack of four arrays that were rotated out of the interior of the canister when the spacecraft began to orbit L1. The bottom three of the stacked arrays are controlled independently, and may be rotated out from the cover of the top of the stack to collect particular types of solar wind. Inside the canister is an electrostatic concentrator to increase the collection of light-weight solar wind particles. It is exposed when the array stack is rotated out. The two solar panels, shown in blue in this depiction, which extend to the side of the spacecraft bus, provide electrical energy for the functions performed by the rest of the spacecraft. (*Image courtesy of JPL*

On September 8, 2004, the sample return canister separated from the spacecraft and entered Earth's atmosphere, heading toward the preplanned entry ellipse in the Utah Test and Training Range. However, the neither the drogue parachute nor the parafoil deployed, and the Genesis capsule impacted the ground at a speed of 311 kilometers per hour (193 mph). The impact occurred near Granite Peak on a remote portion of the range.

The science canister containing the solar wind particles was transported to a specially constructed clean room at the U.S. Army Dugway Proving Ground in Utah, where team members began the tedious effort to extract the pieces and inventory the contents. See Fig. 3. There was good news when they discovered that three of the four separate segments of the concentrator target were intact. Designed to measure the isotopic ratios of oxygen and nitrogen, these segments contain the mission's most important science goal. The fourth was broken but all the pieces were there. They also discovered the gold foil collector, the number two priority for science recovery, was undamaged and in excellent condition. The gold foil is expected to contain almost a million billion atoms of solar wind.

Fig. 3. The science canister in clean room. (*NASA*)

Team members worked for two days to extract tiny pieces of the collectors from the dirt. See Fig. 4. Because this was a contingency they had prepared for, they were ready with buckets containing trowels, tweezers, and zip lock bags. The goal of the curation team from NASA's Johnson Space Center (JSC) was to maintain the scientific integrity of the samples and to make the samples safe for transport. By the time the work was completed there were an estimated 10,000 pieces documented and individually packaged.

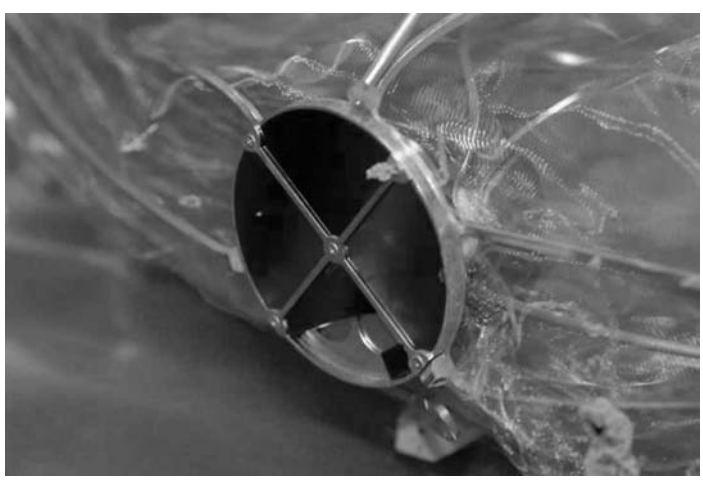

Fig. 4. One of the concentrator targets. (*NASA*)

The samples arrived at Genesis clean room at JSC on Monday, October 4, 2004, where they were numbered and packaged. The science team began work to sort the samples and deal with contamination issues.

The Mishap Investigation Board (MIB), led Dr. Michael Ryschkewitsch, identified a likely direct cause of the failure of Genesis' parachute system to open. The MIB reported in mid-October 2004 that the likely cause for the failure of the parachute system to deploy was a faulty design that resulted in the gravity switches which sense deceleration as the capsule enters the Earth's atmosphere being improperly installed on a circuit board.

In March 2005, Principal Investigator Don Burnett announced that the mission had identified ions of solar wind in one of the wafer fragments. He said molecular and particulate contamination did not impede implantation of solar wind in the collectors. The team then began accepting science community requests from its catalogue of over 10,000 samples.

Mission scientists continue to make progress in the curation of the sample collection with surface characterization, new cleaning techniques and delivery of samples to investigators. Dealing with many challenges, the team remains optimistic that the Genesis solar samples will provide important information on the history and origin of the solar system.

The Genesis project is managed by the Jet Propulsion Laboratory. Dr. Donald Burnett of the California Institute of Technology is the Principal Investigator. Lockheed Martin Astronautics, Denver, Colorado, is providing spacecraft and system integration.

For more information, visit the Genesis home page, http://genesismission.jpl.nasa.gov/.

CONTOUR (The Comet Nucleus Tour). The Comet Nucleus Tour, or CONTOUR, mission launched from Cape Canaveral on July 3, 2002. Six weeks later, on August 15, contact with the spacecraft was lost after a planned maneuver that was intended to propel it out of Earth orbit and into its comet-chasing solar orbit. Limited ground-based evidence at the time suggested the spacecraft split into several pieces.

Attempts to contact CONTOUR were made through December 20, 2002, when NASA and The Johns Hopkins University Applied Physics Laboratory concluded the spacecraft was lost.

NASA convened a CONTOUR Mishap Investigation Board with Theron Bradley Jr., NASA Chief Engineer, as chair. The purpose of the Board was to examine the processes, data and actions surrounding the events of August 15; to search for proximate and root causes; and develop recommendations that may be applicable to future missions.

After an extensive investigation, the board identified four possible causes for the failure but concluded the probable proximate cause was structural failure of the spacecraft due to plume heating during the embedded solid-rocket motor burn. For the full Mishap Investigation Board Report, See http://discovery.nasa.gov/lib/presentations/pdf/mishap board report 503.pdf.

The CONTOUR mission was timed to encounter and study two very different comets, Encke and Schwassmann-Wachmann-3 as they made their periodic visits to the inner solar system.

At each comet flyby, the spacecraft was to get as close as 60 miles (100 kilometers) to take high resolution pictures and perform a detailed compositional analyses of both gas and dust in the near-nucleus environment, as well as determine the comet's precise orbit. The science objectives were to dramatically improve our knowledge of key characteristics of comet nuclei and to assess their diversity.

The CONTOUR mission was managed for NASA by the Johns Hopkins University Applied Physics Laboratory in Laurel, MD. The Principal Investigator was Dr. Joseph Veverka of Cornell University.

MESSENGER. (**ME**rcury **S**urface, **S**pace **EN**vironment, **GE**ochemistry, and **R**anging) **mission** is a scientific investigation of the planet Mercury.

Understanding Mercury and the forces that have shaped it is fundamental to understanding the evolution of the terrestrial planets. MESSENGER will orbit Mercury for one Earth year following two flybys of that planet. The orbital phase will use the flyby data as a guide to perform a focused scientific investigation designed to answer key questions about Mercury's characteristics and environment.

MESSENGER launched on August 3, 2004, aboard a Boeing Delta II rocket from Cape Canaveral Air Force Station, FL. It will return to Earth for a gravity assist a year after liftoff; (Fig. 5), swing past Venus twice, then fly by Mercury three times before starting a yearlong orbit of the innermost planet in March 2011. MESSENGER's science goals are to provide the first images of the entire planet and collect detailed information on the composition and structure of Mercury's crust, its geologic history, the nature of its thin atmosphere and active magnetosphere, and the makeup of its core and polar materials.

Visited previously by only one spacecraft, Mariner 10, Mercury's density is the highest of any planet. Its exotic atmosphere is the thinnest among all the terrestrial planets. It is the only terrestrial planet besides Earth to possess a global magnetic field. Temperatures on this planet of fire and ice vary from nearly the highest in the solar system, at the equator, to among the coldest, in the permanently shadowed poles where ice deposits seem to lurk. See also **Mercury (Plant)**.

The MESSENGER mission's science objectives will be pursued using an optimized set of seven miniaturized instruments plus the spacecraft communication system:

Fig. 5. MESSENGER departing Earth. (*NASA*)

- What is the origin of Mercury's high density?
- What are the composition and structure of its crust?
- What is Mercury's tectonic history, and is its surface shaped by volcanism?
- What is the nature and origin of Mercury's magnetic field?
- What are the characteristics of the thin atmosphere and miniature magnetosphere?
- What is the nature of the mysterious polar caps?

The MESSENGER mission is managed for NASA by the Johns Hopkins University Applied Physics Laboratory in Laurel, MD. The Principal Investigator is Dr. Sean C. Solomon of the Carnegie Institution of Washington.

For more complete information on the mission, visit the MESSENGER home page; http://messenger.jhuapl.edu/.

Deep Impact. The Deep Impact mission was the first experiment to probe beneath the surface of a comet, attempting to reveal never before seen materials that would provide clues to the internal composition and structure of a comet. A variety of instruments, both onboard the spacecraft and at ground-based and space-based observatories around the world, observed the impact with the comet and examined the resulting debris and interior material.

The Deep Impact plan was to excavate a deep crater in a comet nucleus and:

- Observe how the crater forms
- Measure the crater's depth and diameter
- Measure the composition of the interior of the crater and its ejecta
- Determine the changes in natural outgassing produced by the crater

Mission scientists believed that observing the released gases and the crater formation would provide important information about the composition and structure of the comet.

Work on the Deep Impact mission began in January 2000. The spacecraft launched from Cape Canaveral, FL., on January 12, 2005, beginning its 268-million-mile journey to Comet Tempel 1. The two-part spacecraft consisted of a larger "flyby" spacecraft carrying a smaller "impactor" spacecraft.

On July 2, 2005, at 11:07 PDT, the impactor was successfully released at a distance of about 547,000 miles from the comet. The battery-powered, 770-lb impactor was designed to operate independently for just one day, taking over its own navigation and maneuvering into the path of the comet.

Nearly 24 hours later, at 10:52 pm PDT on July 3, traveling at a speed of 23,000 miles per hour, the impactor successfully placed itself into the path of comet Tempel 1. A camera on the impactor captured and relayed images of the comet nucleus as it approached and just before it collided with the comet. See Fig. 6.

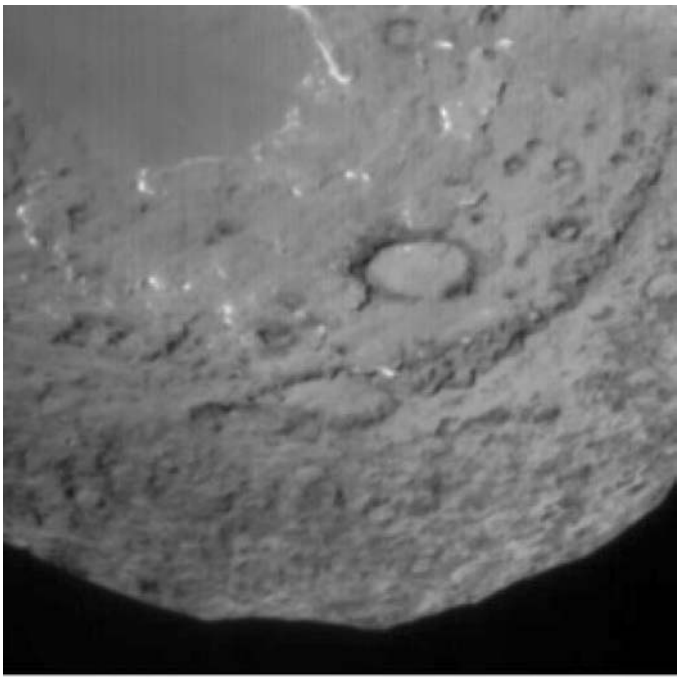

Fig. 6. This image shows the view from Deep Impact's probe 90 seconds before it was pummeled by comet Tempel 1. The image was taken by the probe's impactor targeting sensor. (*Image courtesy of NASA/JPL-Caltech/UMD*)

From 300 miles away, the flyby spacecraft observed and recorded the impact and the ejected material blasted from the crater. See Fig. 7. The collision sent a huge, bright cloud of debris upward and outward from the comet. Scientists were surprised to learn that the cloud was not composed of water, ice, and dirt. Instead, Deep Impact's instruments indicated that the huge cloud was made up of very fine, powdery material. Due to the massive amounts of dust, science team members can only estimate the size crater's size to be about 325 to 825 feet in diameter.

The flyby spacecraft collected and returned data for 14 minutes before it entered a defensive posture called shield mode to protect vital components.

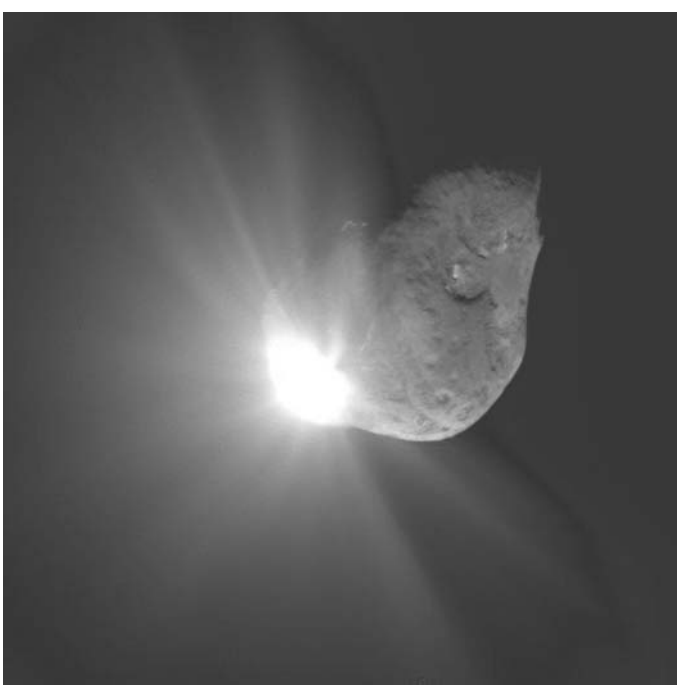

Fig. 7. Comet Tempel 1 67 seconds after it collided with the impactor, taken by the high-resolution camera on the flyby spacecraft. The image reveals ridges, scalloped edges and possibly impact craters formed long ago. (*Image courtesy of NASA/JPL-Caltech/UMD*)

It then sped away from the comet. It is now in a solar orbit with the possibility of being used again for a future mission.

Deep Impact has yielded unexpected results about the structure and composition of comets. Mission scientists found the first definitive evidence of water ice on the surface of a comet. The analysis of data also revealed that Tempel 1 has a very fluffy structure that is weaker than a bank of powder snow. The fine dust of the comet is held together by gravity. The science team was surprised to find evidence of what appear to be impact craters on the surface of the comet. Another interesting finding is the huge increase in carbon-containing molecules detected in spectral analysis of the ejection plume, indicating that comets contain a substantial amount of organic material and thus could have brought such material to Earth early in the planet's history.

Scientists learned the comet interior is well shielded from the solar heating experienced by the surface of the comet nucleus. Mission data indicate the nucleus is extremely porous, allowing the surface to heat up and cool down almost instantly in response to sunlight. This suggests heat is not easily conducted to the interior, and the ice and other material deep inside the nucleus may be pristine and unchanged from the early days of the solar system, just as many scientists had suggested.

The analyses of the vast amount of data gleaned from Comet Tempel 1 will be ongoing well into the future.

The Deep Impact mission is managed for NASA by the Jet Propulsion Laboratory, Pasadena, CA. The Principal Investigator is Dr. Michael A'Hearn of the University of Maryland. Ball Aerospace and Technologies Corporation, Boulder, CO, is responsible for all flight hardware.

For more complete information on the mission, visit the Deep Impact home page; http://deepimpact.jpl.nasa.gov/index.cfm.

Dawn. The Dawn mission will undertake a journey in both space and time by traveling to the two oldest and most massive asteroids in our solar system, Vesta and Ceres. By observing both minor planets with the same set of instruments, Dawn will provide new answers to questions about the formation and evolution of the early solar system.

Dawn will be the first purely scientific mission to be powered by ion propulsion, an advanced technology successfully demonstrated by NASA's Deep Space 1 mission. The use of solar electric ion thrusters will enable Dawn to orbit both asteroids in one mission, a feat that has not been attempted before. See also **Deep Space I Mission**.

Planned for launch in June 2007, Dawn will reach Vesta in 2011 and Ceres in 2015. These minor planets have remained intact since the earliest time of solar system formation. Their surfaces are believed to contain a snapshot of the conditions present in the solar system's first 10 million years, allowing Dawn to investigate both the origin of the solar system and its present state.

The mission's science goals are to understand the conditions and processes in place at the beginning of solar system formation. Scientists also hope to gain a new understanding of the role of water in asteroid evolution.

Dawn's science instruments will: measure the asteroids mass, shape, volume and spin state; record detailed elemental and mineral composition; determine tectonic and thermal history, magnetism and core size; and examine the internal structure to compare these two very different bodies, one cool and wet, the other hot and dry.

The Dawn mission is managed for NASA by the Jet Propulsion Laboratory, Pasadena, CA. The Principal Investigator is Dr. Christopher Russell of the University of California at Los Angeles. Orbital Sciences Corporation, Dulles, VA, will construct the spacecraft, and JPL will provide the ion engines.

For more complete information on the mission, visit the Dawn website; http://dawn.jpl.nasa.gov/.

Kepler. Are there other planets, orbiting other stars, with characteristics similar to Earth? The Kepler Mission is designed to find Earth-size planets in orbit around stars like our Sun outside of the solar system.

Planned for launch in June of 2008, Kepler will monitor 100,000 stars similar to our sun for four years. The results will be extremely important either way. If Kepler detects many habitable, Earth-size planets, it could mean the universe is full of life. Kepler would then be a stepping stone to the next extensive search for habitable planets and life, the Terrestrial Planet Finder. If nothing is found, it may mean we're alone in the galaxy. See also **Kepler Mission**; and **Terrestrial Planet Finder (TPP)**.

The Kepler mission is managed for NASA by the Jet Propulsion Laboratory, Pasadena, CA. The Principal Investigator is William Borucki

of NASA Ames Research Center. The mission team is composed of twenty-five scientists from sixteen institutions. Ball Aerospace and Technologies Corp., Boulder, CO, will build the spacecraft.

Missions of Opportunity

A Discovery Mission of Opportunity is not a complete Discovery Mission, but rather is just one piece of a larger mission. It gives the U.S. scientific community the chance to participate in non-NASA missions by providing funding for a science instrument, hardware components of a science instrument, or expertise in critical areas of a mission. Two Discovery Missions of Opportunity have been selected.

ASPERA-3. ASPERA-3 is one of seven scientific instruments aboard the Mars Express spacecraft. Mars Express is a European Space Agency mission that launched from Russia in June 2003 and entered into orbit around Mars on December 25, 2003. The main objective of the mission is to search for sub-surface water from orbit and drop a lander on the Martian surface. The instruments onboard the orbiting spacecraft will perform remote sensing measurements designed to answer questions about the Martian atmosphere, the planet's structure and geology.

The scientific objectives of ASPERA-3 are to study the interaction between the solar wind and the atmosphere of Mars and to characterize the plasma and neutral gas environment in the near-Mars space. The instrument will use a technique known as Energetic Neutral Atom (ENA) imaging to visualize the charged and neutral gas environments around Mars. ASPERA-3 will make the first ever ENA measurements at another planet.

These studies will address the fundamental question of how strongly interplanetary plasma and electromagnetic fields affect the Martian atmosphere, which is directly related to the many questions about water on Mars. Where is it? Is it lost or frozen? If lost, how did it escape? If frozen, where is it stored? Since liquid water is the key requirement for life, a clear understanding of the fate of Martian water is crucial to resolve whether or not life existed on Mars in the past.

The ASPERA-3 instrument has four sensors to gather the data, along with the data processing unit and the scanning platform. Two of the sensors, the Electron Spectrometer (ELS) and the Ion Mass Analyzer (IMA) Imaging Detector, are being funded by NASA as a Discovery Mission of Opportunity. The IMA is a separate unit connected by a cable to the ASPERA-3 experiment.

Dr. Rickard Lundin of the Swedish Institute of Space Physics is leading the development of ASPERA-3. The ELS and IMA will be built by Southwest Research Institute of San Antonio, Texas, led by Dr. David Winningham, Principal Investigator and John Scherrer, Project Manager. The instrument is being built by a large international team of 15 groups from 10 countries.

For more information, please visit the ASPERA-3 home page; http://www.aspera-3.org/.

Moon Mineralogy Mapper. The Moon Mineralogy Mapper, or M3, (pronounced M-cube) is one of eleven instruments that will fly on board Chandrayaan-1, India's first deep space mission. A project of the Indian Space Research Organisation (ISRO), the goals of the mission include expanding scientific knowledge of the Moon, upgrading India's technological capability, and providing challenging opportunities for planetary research for the younger generation.

The mission will provide high resolution remote sensing of the Moon in the visible, near infrared, low energy X-ray and high-energy X-ray regions that will be used in preparing a three-dimensional atlas and for chemical mapping of the entire lunar surface. The M3 instrument will provide the finest detail over the broadest spectral range among all of the instruments that have ever flown to the Moon.

Chandrayaan-1 is one of a series of international missions to the Moon that began in 2003. Scheduled to launch in February 2008 from a Polar Satellite Launch Vehicle (PSLV), the mission duration is planned to be two years.

M3 will characterize and map the mineral composition of the Moon at high resolution, which will dramatically improve our understanding of the early evolution of the terrestrial planets. M3 will also provide an assessment of lunar resources at high spatial resolution.

The instrument is a grating spectrometer, operating over the spectral region of 0.43 to 3 microns. It consists of three major elements: an optical bench assembly, electronics, and a thermal subassembly. M3 will produce global maps of the mineral content of the lunar surface at 70 m spatial resolution and 10 nm spectral resolution.

Specific objectives are to:

- Evaluate primary crustal components and their distribution across the highlands.
- Characterize the diversity and extent of different types of basaltic volcanism.
- Map fresh craters to assess abundance of small impacts in the recent past.
- Identify and assess deposits containing volatiles.
- Identify and evaluate concentrations of unusual/unexpected minerals.

Dr. Carle Pieters of Brown University is the Principal Investigator. Project management and instrument development are being performed at the Jet Propulsion Laboratory.

For more information, please visit the M3 home page; http://moonmineralogymapper.jpl.nasa.gov/.

DENNON CLARDY, National Aeronautics and Space Administration

DISCRETE VARIATE. A discrete or discontinuous variable is one for which only a discontinuous set of values can occur. Examples are the number of votes cast in an election, or the number of beta particles emitted by a radioactive substance.

DISCRIMINANT. A relation between the coefficients of a polynomial that is useful in the study of roots and other properties of the function. It is an invariant of the function. In the case of an nth degree polynomial in one variable, the discriminant can be written as a determinant of order $(2n-1)$ whose elements are simple functions of the coefficients of the polynomial. Vanishing of the discriminant is a condition for equality of its roots. Thus, for a quadratic equation, $ax^2+bx+c=0$, its two roots are real and equal if its discriminant, $D=b^2-4ac=0$. See also **Biquadratic Equation**; **Conic Section**; **Cubic Equation**; and **Quadratic Equation**.

DISCRIMINATOR. There are two common types of equipment designated by the name discriminator: 1. A circuit used with counters, having the property that only pulses falling between two limits of amplitude (one of which may, however, be 0 or ∞) are recorded.

2. The term discriminator is used widely for a device in which variations in amplitude are derived in response to variations in frequency or phase. A device of this kind is the detector for a frequency modulation receiver. In frequency modulation the intelligence is impressed or modulated upon the carrier by causing variations in frequency. However, our loudspeakers operate upon a change of magnitude of the current through them, so some method must be provided in the frequency modulation receiver to convert the frequency variations into amplitude variations. This is the function of the discriminator. It is a special type of balanced rectifier or detector which gives no output at the frequency for which it is tuned (the carrier frequency), but gives an output voltage whose magnitude and polarity are determined by the amount and direction of the frequency deviation of the input signal. As the received signal is varied back and forth in frequency by the modulation, the discriminator gives an output voltage whose magnitude follows these frequency changes. This output voltage may then be amplified and used to drive the loudspeaker. The discriminator is also used with appropriate circuits to tune automatically receivers having automatic frequency control. It is used in certain frequency modulation transmitter circuits as part of the frequency-stabilizing circuit.

DISCRIMINATORY ANALYSIS. Discriminatory analysis is the term used to describe the statistical methods brought to bear upon problems of allocating individuals to known classes. Given that an individual may have emanated from one of k populations, the major problem is to allocate it to the correct population with minimum error, usually on the basis of multiple measurements on the individual and a prior set of similar measurements on individuals whose origin is known.

A function of the observations used for the purpose is called a *discriminant function* or *discriminator*.

Discrimination in the exact sense arises when it is known *a priori* that different populations exist. If this is not known, and the problem is to see whether or not the data fall into distinct groups, the question is one of classification. The terms are often confused.

DISDROMETER. An instrument that measures and records the sizes of raindrops. A common type of disdrometer consists of a sensitive transponder that measures the momentum of individual drops as they fall onto an exposed horizontal surface. Size is determined from momentum through calibration, and the drop-size distribution is obtained by keeping a tally of the number of drops in different size categories that fall onto the surface in a given period of time.

DISEASES (Crop). Authorities for years have been making and continue to make estimates of the economic cost of crop losses and poor yields, circumstances that arise from a thousand and more causes. Economic losses vary from season to season, from crop to crop, and from region to region — just to cite a few of the variables involved. Hence, unless very specific in terms of crop, time, and location, such statistics tend to be of academic interest rather than of practical value.

In some regions with some crops, in a normal year and with cultural practices conventional to those regions, normal crop losses may run up to one-fourth, one-third, or one-half of what might be considered a 100% yield under essentially perfect conditions. Normal losses on some crops in some regions may run even higher. In contrast, in other regions with more favorable environments and where advanced cultural practices are reliably adhered to, a normal crop loss may approach 5% to 15% of what would be considered a 100% yield for that region under the best of conditions. In food-production systems, steady-state conditions are essentially unknown — because in any region, the prospect of total, catastrophic crop loss is always a possibility and defies scientific prediction.

Thus, across the world, where crop losses range from 10% up to total or nearly total losses, the importance of plant diseases, as well as other adverse factors, becomes self-evident. Over the years, where modern technology has been applied to food production, yields for most crops have shown marked increases. At the same time, the costs of improved cultural practices and control chemicals also have risen. Further, during the past century, as vast tracts of land have been put into food-production service for the first time, the natural balances have been greatly disturbed. Just one example of this is the tremendous alteration of the predator-prey relationship, that phenomenon of nature which tends to maintain the status quo of living organisms within a given region or ecosystem.

The major causes of crop diseases and deformities are summarized in Table 1.

TABLE 1. CROP DISEASES AND DEFORMITIES — MAJOR CAUSES

Environmental Factors — Direct	
Moisture	too much; too little
Temperature	too high; too low
Light and radiation	too much; too little
Air quality	toxic gases, aerosols, dusts
Insect population	disease-carrying insects
Implements and machines	mechanical injury

Environmental Factors — Indirect
When environmental variables exceed normal limits, conditions may become more favorable to microorganisms than to plants, thus resulting in injury and deterioration.

Nutritional Factors
Elemental and Mineral Deficiencies: boron, calcium, copper, iron, magnesium, manganese, molybdenum, nitrogen, phosphorus, potassium, sulfur, zinc.

Toxicity Factors
Presence of materials and soil in quantities beyond limits of tolerance for normal plant growth. Such conditions may result from too little or too much fertilizer, wrong fertilizer, soil poisoning by mine water, acid rain, etc.

Bacterial Diseases
Bacterial plant pathogens of such families as (1) *Pseudomonadaceae* Winslow. et al.; (2) *Rhizobiaceae* Conn; (3) *Corynebacteriaceae* Lehmann and Neumann. (4) *Enterobacteriaceae* Rahn; and (5) *Streptomycetaceae*.

Fungal and Related Diseases
Plasmodiophoral organisms — intracellular parasites, variously classified as fungi or as a separate order of microorganisms. Only a few species are of economic importance, namely, *Plasmodiophora brassicae* Woronin. 1877, which causes clubroot of cruciferous plants; and *Spongospora subterranea* Wallroth, 1841, which causes powdery scab of potato.

TABLE 1. (*Continued*)

Phycomycetes or lower true fungi, considered at a lower developmental level than the Ascomycetes, Basidiomycetes, or Deuteromycetes fungi, these microorganisms are of numerous species (1500+) and are parasitic on algae, fungi, and numerous seed plants. Important economic diseases caused by Phycomycetes include black wart of potato; brown spot of maize (corn); crown wart of alfalfa; root rot of various crop plants; late blight of potato and tomato; downy mildews of various plants, such as grape, lettuce, onion, and cucurbits; and *Rhizopus* soft rot of sweet potato.

Deuteromycetes or Fungi Imperfect i — a thousand or more species of microorganisms which resemble, but which are considered lower than the Ascomycetes and Basidiomycetes fungi. These microorganisms cause numerous plant diseases, including: gray-mold neck rot of onion; the so-called fusarial diseases arising from the genus *Fusarium*; cabbage yellows; early blight of potato and tomato; onion smudge; bean anthracnose; blackleg of crucifers; *Diplodia* disease of maize (corn); late blight of celery; and white rot of onion, garlic, and shallot.

Ascomycetes or sac fungi — several thousand species, many of which cause plant diseases, such as peach leaf curl; the powdery mildews which affect numerous plants; Dutch elm disease; blight and foot rot of pea; apple scab; bitter rot of apple; blight of chestnut; *Gibberella* diseases of maize (corn) and small grains; ergot of grains and grasses; brown rot of stone fruits; and *Sclerotinia* diseases of vegetables and field crops.

Basidiomycetes or smut fungi, rust fungi, and fleshy fungi — a large and varied group of fungi, many of which cause a rather wide range of plant diseases, including maize (corn) smut; oats smuts; loose smuts of barley; bunt or stinking smut of wheat; onion smut; black stem rust of small grains and grasses; rust of apple; flax rust; the *Rhizoctonia* diseases, such as damping-off, stem canker, and root rot; and leaf blight and white heart rot of deciduous trees.

Nematodes
Roundworms or threadworms of the phylum *Nemata* or *Nematoda* that feed and live upon and within host plants, sometimes producing cysts and galls; they take numerous forms, such as the bud and leaf nematodes; bulb and stem nematodes; the burrowing nematodes; the cyst-forming nematodes; and the root-knot and root-lesion nematodes. In addition to direct damage caused by nematodes, the latter also weaken healthy plants, making them especially susceptible to fungal infections. For example, nematodes play an important role in such significant economic diseases as the Panama disease of banana; the spreading decline disease of citrus; and the yellow disease of pepper.

Parasitic Plants (Phanerogams)
Plants which attach themselves to other plants (of greater economic value) and grow on them, depriving the host plant of nutrients, light, and moisture — in essence inhibiting normal growth of the host plant through processes of deprivation and strangulation. Notable parasitic plants include the mistletoes, dodder, Spanish moss, and bittersweet vine, among others.

Virus Diseases
Viruses are widespread, infectious, and cause many crop plant diseases, some of which are not easy to identify and to sort out from other possible causes. Two of the larger groupings of virus plant diseases are the *mosaic diseases* (named for the mosaic patterns of yellow and green on infected foliage); and the *yellows diseases*, where the infected plants display a reasonably uniform yellowing of foliage as the result of chlorophyll deficiencies. Viruses can be transmitted easily and by numerous means, including mechanical contact, as the result of grafting, by way of seed and pollen, insects, mites, nematodes, fungi, and phanerogams. Many viruses produce synergistic effects, with the damage resulting from the presence of two viruses much more severe than twice the effect of either virus operating alone. Specific virus diseases include tobacco and tomato mosaic diseases; cucumber mosaic disease; potato mosaic disease; bean mosaic disease; aster yellows disease; curly top of sugar beet; and spotted wilt.

DISINFECTANT. A substance used on inanimate objects to destroy harmful microorganisms or inhibit their activity. Disinfectants are either complete of incomplete. Complete disinfectants destroy spores as well as vegetable forms of microorganisms; incomplete disinfectants destroy vegetable forms of the organism, but do not injure spores.

Some representative disinfectants are (1) mercury compounds (mercuric chloride, phenylmercuric borate); (2) halogens and halogen compounds (chlorine, iodine, fluorine, bromine, calcium and sodium hypochlorite); (3) phenols, including cresol from coal tar, *o*-phenylphenol; (4) synthetic detergents (anionic, such as sodium alklbenzene sulfonates, and cationic, such as quaternary ammonium compounds); (5) alcolhols of low molecular weight, except methanol; (6) natural products (pine oil); (7) gases (sulfur dioxide, formaldehyde, ethylene oxide). Heat and electromagnetic waves are used as disinfectants.

A number of compounds (mercurous and mercuric chlorides, copper sulfate and carbonate, and a mixture of zinc oxide and zinc hydroxide) have been employed as seed disinfectants.

Effectiveness of disinfectants is rated by the phenol coefficient.

DISINTEGRATION (Colloidal). Passage of a metal into colloidal solution when the metal is made an electrode under certain conditions.

DISINTEGRATION (Nuclear). A transformation or change involving atomic nuclei. If the disintegration is spontaneous, it is said to be radioactive; if it results from a collision, it is said to be induced. The rate of disintegration of a radioactive nuclide is measured by a decay constant, which is the probability per unit time, λ, that it will undergo spontaneous transformation. The decay constant is the reciprocal of the mean life of the given system before undergoing transformation. Despite its literal meaning, the term nuclear disintegration refers also to radiative capture, inelastic scattering, beta transformations, and isomeric transitions. (See also **Nuclear Power Technology**.) The *nuclear disintegration energy* is the energy evolved, or the negative of the energy absorbed, in a nuclear disintegration; symbol Q. It is equal to the energy equivalence of the sum of the masses of the reactants minus the sum of the masses of the products. (For each reactant or product that is a nucleus, the appropriate mass is that of the corresponding neutral atom.) If the disintegration energy is positive, the disintegration is exoergic; if it is negative, the disintegration is endoergic. Radioactive disintegrations have positive Q-values; nuclear reactions may have values of either sign. The *ground-state nuclear disintegration energy* is the energy evolved when all the reactant nuclei enter, and all the product nuclei end, in their ground states.

DISKETTE (Computer). One form of disk storage utilizes a thin, flexible, plastic disk with one or two magnetic recording surfaces. This diskette, either 8 inches ($\sim$20 centimeters) or $5\frac{1}{4}$ inches ($\sim$13.3 centimeters) in diameter, is permanently housed in a lubricated protective paper envelope in which it rotates at speeds up to 360 rpm.

Originally conceived as the replacement for the keypunch, the first single-sided, single-density units had a capacity of 256K bytes, or the equivalent of 3200 80-column card images.

Diskettes are suited to data-entry, word processing, and personal computer applications, in which data rates are low, response time requirements are modest, and required storage capacities are fairly low.

Synonymous with flexible disk, floppy disk.

DISK STORAGE (Computer). In this form of storage, a magnetic coating on a rotating disk is used. Data are recorded on the surface of the rotating disk by magnetizing the surface in accordance with the pattern of binary data and are read by detecting the magnetic flux. Data are recorded on cylindrical tracks on the top and bottom surfaces of the disk.

A magnetic head for each of the two data surfaces performs the reading and writing functions. The write portion of the read/write head consists of a coil of wire which magnetizes the magnetic surface of the disk when a current flows through the coil. The read portion of the head consists of a similar coil of wire into which a voltage is induced as it intercepts the magnetic flux on the disk.

DISLOCATION. In crystallography, a type of lattice imperfection whose existence in metals is postulated in order to account for the phenomenon of crystal growth and of slip, particularly for the low value of shear stress required to initiate slip. One section of the crystal adjacent to the slip plane is assumed to contain one more atomic plane that the section on the opposite side of the slip plane. Motion of the dislocation results in displacement of one of the sections with respect to another.

DISORDER PRESSURE. The contribution to the pressure that arises through the existence of a contribution to the entropy of a liquid through molecular disorder, i.e., from the communal entropy.

DISPERSION. 1. A two-phase system where one phase consists of finely divided particles (often in the colloidal size range) distributed throughout a bulk substance, the particles being the disperse or internal phase, and the bulk substance the continuous or external phase. Under natural conditions, the distribution is seldom uniform; but under controlled conditions, the uniformity can be increased by addition of wetting or dispersing agents (surfactants) such as fatty acid. The various possible systems are: gas–liquid (foam), solid–gas (aerosol), gas–solid (foamed plastic), liquid–gas (fog), liquid–liquid (emulsions), solid–liquid (paint), and solid–solid (carbon black in rubber). Some types, such as milk and rubber latex, are stabilized by protective colloid that prevents agglomeration of the dispersed particles by an abherent coating. Solid-in-liquid colloidal dispersions (loosely called solutions) can be precipitated by adding electrolytes that neutralize the electrical charges on the particles. Larger particles will gradually coalesce and either rise to the top or settle out, depending upon their specific gravity.

See also **Colloid System**; **Surfactants**; and **Suspension**.

2. In the field of optics, dispersion denotes the retardation of a light ray, usually resulting in a change of direction as it passes into or out of a substance, to an extent depending on the frequency. Dispersion is a critically important property of optical glass.

See also **Refraction**.

DISPERSION (Radiation). The process (or resulting condition) of separating a radiation, a complex sound wave, etc., in accordance with some characteristic such as frequency, wavelength, or energy, into components. The process may be due to diffraction, refraction, or scattering. For example, a prism or diffraction grating disperses white light by sending light of different wavelengths in different directions. Quantitatively, a general measure of such dispersion is the derivative of the deviation with respect to that variable (wavelength, frequency, etc.). Dispersion of a medium is also expressed as the rate of change of refractive index with wavelength (or frequency, etc.).

The dispersion of light may be accomplished through refraction by a prism, diffraction by a grating, or other means. Refractive dispersion is due to the fact that the velocity of light in a given medium, and hence the refractive index, varies with the frequency. In any case, if the deviation Δ produced by the dispersion apparatus is expressible as a function of the wavelength λ, then the measure of the dispersion may be taken as

$$D = \frac{d\Delta}{d\lambda}$$

For example, for a plane diffraction grating at normal incidence, the deviation in the first order is given by $\sin \Delta = \lambda/s$, in which s is the grating space; from which it follows that the dispersion is $D = (s^2 - \lambda^2)^{-1/2}$.

Refractive dispersion is not so simply expressed. For a single refraction at angle of incidence i and with refractive index n, it may be shown that the dispersion is equal to

$$D = \frac{\sin i}{n\sqrt{n^2 - \sin^2 i}} \cdot \frac{dn}{d\lambda}$$

Various attempts have been made to express n as a function of λ, for example, by the Cauchy dispersion equation or by the Sellmeier equation. See also **Anomalous Dispersion**.

Different media are commonly compared through some arbitrarily defined "dispersive power." The spectroscopist generally finds it convenient to express dispersion in terms of the number of angstroms corresponding to a distance of 1 millimeter on a photographic plate. Such a linear dispersion will vary with wavelength for a prism spectrograph but will be constant for a grating instrument.

DISPERSION (Statistics). A measure of dispersion is a quantity indicating the extent to which a set of observations scatters about some central value. Examples are the standard deviation or variance, the mean deviation, and the range. In advanced theory the measure almost always used is the standard deviation or its square, the variance. For a set of variables $x_1, x_2, \ldots, x_n$, the matrix whose element in the ith row and jth column is the covariance of x_i and x_j, is called the *dispersion matrix* or the *variance-covariance matrix*.

DISPERSIVE POWER. If n_1 and n_2 are refractive indexes for wavelengths λ_1 and λ_2 and n is the mean refractive index, the dispersive power is $d = (n_2 - n_1)/(n - 1)$. The refractive indexes n, n_1, n_2 are frequently taken as those of the Fraunhofer D, F, C lines, respectively. The reciprocal of the dispersive power is often called the Abbe number or v-number.

DISPLACEMENT CURRENT. Consider a capacitor hidden in a "black box" with two terminals. Charging or discharging the capacitor requires a charge flow, or current, in the external connections. Viewed externally, let a current of positive charges flow into one terminal; the equal current of negative charges into the second terminal appears to be a positive current out of the second terminal. It is logically awkward to think of a current into one terminal and out of the other that doesn't go through the box. Hence, to maintain continuity of current, a "displacement" current is postulated in the capacitor, equal to the "conduction" current in the external connections.

This concept of displacement current was invented by Maxwell to simplify the mathematical equations of electromagnetism; it led to the prediction of electromagnetic waves.

The displacement current is more than a convenient fiction, as is indicated by the fact that the Biot-Savant law holds when the circuit surrounds a displacement current as well as when it surrounds a conduction current. Part of the displacement current can be accounted for as the movement of bound charges within the dielectric, i.e., the creation or reorientation of dipoles. The balance, which is exhibited even in a vacuum, may be better understood as quantum electrodynamics is further developed.

Precisely, the displacement current through a surface is defined as the integral of the normal component of displacement current density over that surface. The displacement current density is the time derivative of the electric induction.

DISPLAY TECHNOLOGIES (Other).

Flat-Thin Cathode Ray Tubes. The major reason for the low cost of a CRT is that the manufacturing process has been developed over many years and is now routine. CRTs meet stiff competition from display applications that require thinness, light weight, or low power consumption. Consequently, considerable research over the past 30 years has been devoted to eliminating these disadvantages. However, the development of flat, thin CRTs has not reached the stage of even modestly replacing conventional types.

Several types of small, flat-thin CRTs have been developed over the years by Sony, Sanyo, Sinclair/Times, and Hitachi; only the Sony device became a commercial product. Sony introduced 2-inch, flat, monochrome CRTs in 1982, followed by 3- and 4-inch (7.6 and 10.2 centimeter) models a few years later. Sony's technology involved bending the electron beam through 90° to impinge on the phosphor screen; an opposing transparent electrode was used for focusing purposes. Sony still sells some handheld, portable, black-and-white televisions (Watchman) with these flat, thin CRTs, which are undoubtedly the most successful type in the market several million have been produced over the years.

The original flat CRT is attributed to W. Ross Aiken. The Aiken thin tube was conceived in 1951 at the University of California, Berkeley (Lawrence Radiation Lab). http://www.lbl.gov/ The idea was to use a series of electron deflectors to steer a beam along a very tortuous path. The gun was located at the bottom and the side of the thin tube. The beam was centered as it left the gun, then directed to a series of horizontal deflector plates. A series of vertical deflector plates covering the rear of the tube made the beam scan vertically. Aiken left the University and pursued development at Kaiser. Work continued for another five years, until it became apparent that a large amount of money would be needed to build a manufacturing plant.

Shortly thereafter, the Gabor tube was developed by Dennis Gabor at the Imperial College of Science and Technology in England. In the Gabor tube, the gun was located in the rear of the tube, facing downward at the center. The beam was swept in an arc from side to side, bent into a hairpin turn at the bottom, directed upward, and then directed into the phosphor screen over the viewing surface. Although a British patent was awarded, no commercial production ever began.

Matsushita Electric Industrial Co., of Osaka, Japan, (http://www.panasonic.co.jp/global/Mtop/main e.html) developed a color flat panel display for use in prototype flat color televisions featuring first a 10-inch, then a 14-inch (diagonal) screen, with a depth of less than 10 centimeters. The color, flat, CRT-like panel was developed using Matsushita's Matrix Drive and Deflection System. The panel's screen consisted of 3,000 picture cells arranged in a matrix: 200 units horizontally and 15 vertically. Each picture cell was scanned by one electron beam, which excited phosphor stripes. These television sets made it to the marketplace, but were eventually dropped when it became apparent that consumers would not pay a high price (25 times the price of a comparable CRT-based television) for the thin profile. See also **Cathode-Ray Tube**.

Electromechanical Displays

There are two main types of electromechanical display technologies: split-flap and flip-disk. Variations include roller-band and flip-segment displays. For night visibility, either backlighting or front floodlighting can provide illumination. Using a fluorescent pigment increases display contrast.

Electromechanical displays consume far less power than large-area incandescent and LED (light emitting diode) displays for outdoor applications. A bulb requires continuous power to remain illuminated, but electromechanical displays only need to be written once-afterwards they retain the state. Electromechanical displays use far less power for night lighting than do incandescent displays, even when dimmed. Furthermore, if low-power fluorescent tubes are used, power consumption is reduced even more.

The disadvantages of electromechanical displays are that they cannot display any type of animation and they are subject to frequent breakdowns. The dependence on mechanical structures imposes serious limitations on display performance. They are used in situations in which the message is relatively static, not changing more than a few times a minute. High-resolution graphic displays based on electromechanical operation are not on the horizon. In spite of this, they continue to be made and installed.

Rotatable Dipole Displays

Rotatable dipole displays-have been around more than 30 years. They are made with crystals of iodoquinine sulfate (heraphathite) or related compounds suspended in various organic solvent media. These crystals act as dipoles in the presence of an electric field, and the application of a high-frequency signal enables them to align in the direction of the applied field. Because these crystals are dichroic, the difference in optical density between the randomized and the aligned crystals is quite large. Thus, the electrically activated portions of the cell will be colorless, while the inactivated portions will be dark blue. Displays based on this effect, therefore, have a very high contrast.

The main problems are somewhat high voltage requirements (35 volts at 3 kHz) and instability of the suspension. Research Frontiers, Plainview, New York, is working on an improved version of this device as both an information display and a light control device for architectural and other types of glass. The latter is the main application today.

Electrophoretic Imaging Displays (EPID)

The principle of operation of this passive matrix display technology involves moving small charged particles of a particular color, suspended in a dye solution of a second color, in a uniform applied electric field. The use of an electrophoretic process as a reversible nonemissive display was first reported by Evans. In 1973 Ota and his coworkers at Matsushita Electric Industrial Co. introduced an electrophoretic display that was reflective; it is known as an EPID display. Based on this initial work and that of others, the EPID concept became a promising new nonemissive display technology with a number of desirable features.

The operation of a simple electrophoretic display device is explained by assuming that the pigment particles are white in color and positively charged in a dark suspending liquid. When an D.C. voltage is applied

between a pair of transparent electrodes in such a way that the front transparent electrode is negative, the white pigment particles move electrophoretically toward the front electrode (viewing side). Consequently, the panel becomes white in reflective color. On the other hand, when the transparent electrode is positive, the reflective color becomes dark, because the white pigment particles move to the opposite (rear) transparent electrode and are hidden behind the dark suspending liquid.

This technology has been dormant. Also, E Ink Corporation is pursuing electrophoretic technology for use in electronic books.

The Reverse Emulsion Electrophoretic Display (REED) is a variation of the solid/liquid electrophoretic display under development by Zikon Corporation of San Jose, California. Although it shares some properties with the electrophoretic displays developed in the past, the principles of operation are different. The inventors claim that it will not suffer from the insurmountable problems that have historically been attributed to electrophoretic displays.

The basic components that make up the REED are two glass plates, each with etched ITO electrodes, and a colored reverse emulsion. The glass plates are sandwiched together, leaving a space of a few tens of microns in between. The reverse emulsion is then injected in the space, and the sandwich is sealed. Appropriate voltages are then applied across the emulsion through the ITO electrodes to change the color of the display. Currently, two methods of addressing have been developed: frequency addressing and electrophoretic addressing.

The patented reverse emulsion is the key to the new technology. It is composed of a mixture of a polar solvent (a liquid with properties like water), a nonpolar solvent (a liquid with properties like oil), one or more *types* of surfactants (detergents), and a dye. The dye is soluble in the polar solvent and insoluble in the nonpolar solvent. When all components are mixed, the two types of solvents do not dissolve in each other. Instead, surfactant molecules concentrate along the boundary between the two solvents, reducing surface tension.

Under certain circumstances, the polar solvent forms droplets, or *micelles*, in the nonpolar solvent, forming a stable suspension. The dye is concentrated inside the droplets, since it is only soluble in one solvent and not in the other. The result is a lot of colored droplets floating in a clear liquid. Due to some rather complex processes that occur in the mixing, the droplets can be charged or can be otherwise responsive to electric fields. This property of the droplets is used to arrange them in such a way as to make them more spread out (display on) or more compact and transparent (display off).

Electrochromic Displays

The phenomenon of electrochromism consists of changing the light-absorption properties of certain materials by an externally applied electric field. Ordinarily, these materials are completely colorless. However, on applying a moderate electric field, the material develops a color that remains even after the field has been removed. However, when the polarity of the applied field is reversed, the system returns to its original state. This effect is typically used for displays in the reflective mode, with tungsten trioxide (WO_3) as the active matrix electrochromic material. This material, initially colorless, becomes deep blue when 0.5 to 1.5 volts D.C. is applied across electrodes, between which the tungsten trioxide is sandwiched.

In addition to tungsten trioxide, electrochromic materials include other transition metal oxides, such as iridium oxide (IrO_2) and molybdenum oxide (MoO_3), as well as tin nitride (SnN_x). Devices have been made in both liquid and solid states. In the liquid typean electrolyte such as water, sulfuric acid, or an organic solvent with a saltlike lithium perchlorate ($LiClO_4$) dissolved in it is used to make a cell. The electrochromic material is then oxidized or reduced according to the current direction applied to the cell.

The liquid systems have not been reliable due to corrosion of the electrochromic materials, detachment of the electrodes, or leakage of the liquid from the cell. It has been very difficult to make a matrix-addressed (multiplexed) electrochromic display. Most of the systems investigated were plagued with very slow response times and a lack of a sharp switching threshold. These two characteristics have made it very difficult to build high information content displays capable of use in video or monitor applications. Many of the applications are limited to large-area message displays and single-pixel switching displays (electronically dimmable mirrors for automobiles).

Electrochromic technology can make a readable and pleasant-looking public information display. Response times of 600 milliseconds for coloring and 410 milliseconds for bleaching were reported. The displays have been tested for approximately 1,000,000 cycles and up to 1,000 hours of storage without distinguishable degradation.

Another ECD effort that used a composite of several thick films based on the reduction to bismuth metal from a bismuth-bromine system has been developed Segmented displays, as well as small matrix displays, were demonstrated, and unlike other types of ECDs then display changed from white to black with a very high contrast ratio. See also family of articles catalogued under **Flat Panel Display Technology**.

DISPOSAL (Waste). See **Air Pollution**; **Nuclear Power Technology**; **Wastes and Pollution**; and **Water Pollution**.

DISSIPATION. This term has three related uses in physics, as follows: 1. The interaction between matter and energy incident upon it, such that the portion of the energy used up in the interaction is no longer available for conversion into useful work. 2. A persistent loss of mechanical energy because of the presence of frictional or friction-like forces. 3. In free oscillatory motion, a persistent loss of mechanical energy due to presence of friction-like resistance to motion which eventually exhausts the total energy of the system and causes it to come to rest. Such motion is said to be damped.

DISSOCIATION. This can be broadly defined as the separation from union or as the process of disuniting. In chemistry, dissociation is the process by which a chemical combination breaks up into simpler constituents due, for example, to added energy as in the case of the dissociation of gaseous molecules by heat, or to the effect of a solvent upon a dissolved substance, as in the action of water upon dissolved hydrogen chloride. Dissociation may occur in the gaseous, liquid or solid state or in solution.

Elementary substances, if polyatomic in the molecule, will dissociate under conditions of sufficient energy. Chlorine and iodine, which are diatomic, are half dissociated at 1700 °C and 1200 °C, respectively. Just above the boiling point the molecule of sulfur is S_8. Its molecular weight decreases from 250 at 450 °C TO 50 at 2070 °C. Thus there are some monatomic sulfur molecules at 2070 °C. The dissociation probably takes place in reversible steps and can be represented by the equation:

$$S_8 \rightleftharpoons 4S_2 \rightleftharpoons 8S. \tag{1}$$

Many chemical compounds dissociate readily upon heating or otherwise supplying them with energy. Acetic acid vapor consists of double molecules just above the normal boiling point, but dissociates completely into single molecules at 250 °C. nitrogen tetroxide (N_2O_4) is a pale reddish brown gas at temperatures near its normal boiling point of 21.3 °C. On heating the density of the gas becomes less and the color becomes darker until it is almost black. At 140 °C the molecular weight is 46 which is that of NO_2 molecules. The dissociation can be written:

$$N_2O_4 \rightleftharpoons 2NO_2. \tag{2}$$

If one mole of gas yields ν moles of gaseous products, and α is the fraction of the one mole which dissociates, then the total number of moles present is:

$$1 - \alpha + \nu\alpha = 1 + \alpha(\nu - 1). \tag{3}$$

Now the density of a given weight of gas at constant pressure is inversely proportional to the number of moles, and if d_1 is taken as the density of the undissociated gas and d_2 that of the partially dissociated gas, then:

$$\frac{d_1}{d_2} = \frac{1 + \alpha(\nu - 1)}{1} \tag{4}$$

or

$$\alpha = \frac{d_1 - d_2}{d_2(\nu - 1)} \tag{5}$$

Therefore the *degree of dissociation* of a substance can be found by measuring the densities of the undissociated and partially (or completely) dissociated substance in the gaseous state. Molecular weights may be substituted for densities giving

$$\alpha = \frac{M_1 - M_2}{M_2(\nu - 1)} \tag{6}$$

The degree of dissociation can be used to calculate the *equilibrium constant* for dissociation. The equilibrium constant may be expressed in terms of concentrations, for example, moles per liter (K_c), or in terms of partial pressures (K_p). The degree of dissociation and equilibrium constants are important theoretically and practically, e.g., the latter can be used to ascertain the extent of a chemical process.

The temperature dependence of dissociation is expressed in terms of the equilibrium constant and is

$$\frac{d\ln K_p}{dT} = \frac{\Delta H}{RT^2} \quad \text{or} \quad \frac{d\ln K_c}{dT} = \frac{\Delta H}{RT^2} \tag{7}$$

where ΔH is the heat of dissociation. Integrating between the limits T_1 and T_2 one obtains

$$\ln\frac{K_{p_2}}{K_{p_1}} = \frac{\Delta H}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right)$$
$$\ln\frac{K_{c_2}}{K_{c_1}} = \frac{\Delta H}{R}\left(\frac{T_2 - T_1}{T_1 T_2}\right) \tag{8}$$

Electrolytes, depending upon their strength, dissociate to a greater or less extent in polar solvents. The extent to which a weak electrolyte dissociates may be determined by electrical conductance, electromotive force, and freezing point depression methods. The electrical conductance method is the most used because of its accuracy and simplicity. Arrhenius proposed that the degree of dissociation, α, of a weak electrolyte at any concentration in solution could be found from the ratio of the equivalent conductance, Λ, of the electrolyte at the concentration in question to the equivalent conductance at infinite dilution Λ_0 of the electrolyte. Thus

$$\alpha = \frac{\Lambda}{\Lambda_0} \tag{9}$$

This equation involves the assumption that mobilities of the ions coming from the electrolyte are constant from infinite dilution to the concentration in question. From the degree of dissociation and the concentration, the ionization constant or protolysis constant of a weak electrolyte can be obtained.

Water is a weak electrolyte, ionizing according to the equation:

$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^- \tag{10}$$

The specific conductance L, of water at 25° is 5.5×10^{-8} mho cm^{-1}, and the equivalent conductance of water at infinite dilution is found from the equivalent conductance of its constituent ions (H_3O^+ and OH^-) to be 547.8 mhos. The equivalent conductance Λ of water at 25° is LV, where V is the volume of water (18 ml) containing 1 gram equivalent of water. Hence $\Lambda = LV = 5.5 \times 10^{-8} \times 18 = 9.9 \times 10^{-7}$. Therefore $\alpha = \Lambda/\Lambda_0 = 9.9 \times 10^{-7}/547.8 = 1.81 \times 10^{-9}$. Now $C_{H_3O^+} = C_{OH^-} = 55.5 \times 1.81 \times 10^{-9} = 1.00 \times 10^{-7}$ and

$$K = \frac{C_{H_2O^+} \times C_{OH^-}}{C_{H_2O}^2} \tag{11}$$

but C_{H_2O} is a constant, namely 55.5 moles/l and therefore

$$K_\omega = (55.5)^2 K = C_{H_3O^+} \times C_{OH^-}$$
$$= 1.00 \times 10^{-7} \times 1.00 \times 10^{-7} = 1.00 \times 10^{-14}$$

The ionization constant of pure water varies with temperature as shown below.

Temperature°C	0	10	25	40	50
$K_\omega \times 10^{14}$	0.113	0.292	1.008	2.917	5.474

Inserting corresponding values of K_ω and absolute temperature into Eq. (8) and solving for ΔH one finds the heat of ionization per mole of water to be 13.8 kilocalories.

Ionization or dissociation in general can be repressed by adding an excess of a product of the dissociation process.

The acid formed when a base accepts a proton is called the conjugate acid of the base and the base formed when an acid donates a proton is the conjugate base of the acid. Thus in the reaction

$$HA + H_2O \rightleftharpoons H_3O^+ + A^- \tag{12}$$

HA and A^- are conjugate acid and base and H_2O and H_3O^+ are conjugate base and acid, respectively.

The common ion effect then can be found as the following example shows. When using ammonium hydroxide to which the common ammonium ion in the form of ammonium chloride has been added, the ionization can be represented by the equation

$$NH_3 + HOH \rightleftharpoons NH_4^+ + OH^- \tag{13}$$

Ammonium ion NH_4^+ is the conjugate acid of the ammonia molecule. The ionization constant can be written

$$K = \frac{C_{NH_4^+} \times C_{OH^-}}{C_{NH_3}} \tag{14}$$

and

$$C_{OH^-} = K\frac{C_{NH_3}}{C_{NH_4^+}} \tag{15}$$

Now the base NH_3 is such a weak base that in the presence of NH_4Cl the concentration of unionized base, C_{NH_3}, is equal to the total concentration of base represented by C_{base}, and $C_{NH_4^+}$ coming from the weak base is so small as to be negligible. Hence the NH_4^+ ions can be considered as coming exclusively from the NH_4Cl. Therefore Eq. (15) can be written

$$C_{OH^-} = K\,\frac{C_{base}}{C_{salt}} \tag{16}$$

or

$$pOH = pK + \log\frac{C_{salt}}{C_{base}} \tag{17}$$

Thus C_{OH^-} and hence the degree of ionization of the base NH_3 is decreased with increasing concentration of salt. The salt effect of adding electrolytes with no common ion to a solution of incompletely ionizable substance can be seen from the following considerations and using the equilibriums represented by Eq. (14) which in terms of activities becomes:

$$K = \frac{a_{NH_4^+} \times a_{OH^-}}{a_{NH_3}} = \frac{C_{NH_4^+} \times C_{OH^-}}{C_{NH3}} \cdot \frac{f_{H_3O^+} \times f_{OH^-}}{f_{NH_3}} \tag{18}$$

This ionization constant in terms of activities is called the true or thermodynamic ionization constant. It does not differ too much from the K in Eq. (14) for sufficiently low ionic strengths. The two differ more markedly for appreciable ionic strengths. Now suppose a salt with no common ion is added to the solution. The ionic strength of the solution will be increased. This increase in ionic strength causes a decrease in the activity coefficients of the ions except in very concentrated solutions. Thus for K of Eq. (18) to stay constant the concentrations of the ions must increase to offset the decrease in their activity coefficients. The ammonia must therefore increase in ionization and K as defined by Eq. (14) must increase. This is known as a salt effect.

Ampholytes in solution give equal concentrations of a weak acid and a non-conjugate weak base. The amino acids are ampholytes which contain within their molecules equal amounts of a weak acid, the COOH group and a weak non-conjugate base, the NH_2 group.

According to Arrhenius those substances which yield the hydrogen ion in solution are acids, whereas bases produce the hydroxyl ion. As long as water was considered the only "ionizing" solvent these definitions were relatively simple. In the case of nonaqueous solvent chemistry at least three other concepts have been advanced. These are: (1) Franklin's *solvent system concept*, first limited to water and ammonia but since extended to nonprotonic media and defining an acid as a substance yielding a positive ion identical with that coming from auto-ionization of the solvent and a base as a substance yielding a negative ion identical with that coming from auto-ionization of the solvent (2) the *protonic concept* of acids as proton donors and bases as proton acceptors advanced by Brønsted and by Lowry and (3) Lewis' electronic theory according to which an acid is a molecule, radical or ion which can accept a pair of electrons from some other atom or group to complete its stable quota of electrons, usually an octet, and forming a covalent bond, and a base is a substance which donates a pair of electrons for the formation of such a bond.

In liquid ammonia as in water auto-ionization takes place. Ammonium and amide ions are formed by the dissociation or protolysis according to the following equation

$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^- \tag{19}$$

The acid and base analogs of ammonia as a solvent is specified by this equilibrium as NH_4^+ and NH_2^- ions. All substances which undergo ammonolysis and hence bring about an increase in the ammonium ion concentration yield acid solutions. Thus P_2S_5 dissolves in liquid ammonia to give an acid solution as follows.

$$P_2O_5 + 12NH_3 \rightarrow 2PS(NH_2)_3 + 3(NH_4)_2S. \tag{20}$$

The solution is acid since an ammonium salt is formed and also because a solvo acid is obtained.

Many substances dissolve in liquid sulfur dioxide to yield ionic, conducting solutions. It has been found that such conductance data extrapolated to very high dilution yield the limiting conductance of sulfur dioxide. Both the Ostwald dilution law and the law of independent mobility of ions hold for "strong" electrolytes in highly dilute solutions.

The order of increasing dissociation and conductivity of salts in liquid sulfur dioxide apparently parallel the order of increasing cationic size. Probably because of solvation effects a similar relationship does not hold with respect to anion size. The mobilities of various ions in liquid sulfur dioxide have been studied. The van't Hoff *i* factors or mole numbers have been obtained by the ebullioscopic method for a wide variety of solutes in liquid sulfur dioxide. For non-electrolytes the mole number is one within experimental error. In liquid sulfur dioxide, univalent electrolytes give mole numbers which indicate large effects of ion-association of some kind. As would be expected the mole numbers of these electrolytes approach two in very dilute solutions. See Jander and Mesech, Z. physik. Chem., *A183*, 277 (1939). The mole number in general can be found from the ratio of the value of a colligative property of the solute is solution to the value of the same colligative property for a normal solute such as sugar, both solutes being at the same molal concentration.

The protonic concept of acid and bases is applicable to many of these high temperatures solvent systems such as the fused ammonium salts which possess the "onium" ion or solvated proton, and the fused anionic acids which are salts possessing a metallic ion and a hydrogen containing anion. One of the most useful of the anionic acids is KHF which is used to dissolve ore minerals containing silica, titania and other refractory oxides.

In many high temperature reactions there is an absence of hydrogen-containing ions. The Lewis electron pair concept of acid and bases can be used to advantage in such systems. In such systems strong anion bases such as the $O^=$ ion coming from basic compounds such as metallic oxides, hydroxides, carbonates or sulfates react with acidic oxides such as silica through the intermediate formation of polyanionic silicate complexes. The average ionic size of these complexes depend no doubt upon the temperature and the amount of added base.

Anion bases include the sulfide and fluoride ions coming from the corresponding alkali metal compounds. Likewise, metaphosphate and metaborate melts are acid in nature. Also proton-like character can be ascribed to any positive ion. The smaller the positive particle and the higher its charge, the greater is its polarizing tendency in bringing about deformation of negative ions, and the more reasonably can such an ion be looked upon as an acid analog.

When the potential energy of a diatomic molecule is plotted versus the distance separating the nuclei in the molecule, the potential-energy curve shows a minimum of zero in the energy at the distance separating the nuclei where the molecule is most stable, that is, where the nuclei are at the equilibrium internuclear separation. Energy is required to force them closer together or to pull them farther apart. The energy required to separate the nuclei to an infinite distance is D', the dissociation energy measured from the minimum of the potential energy curve. The spectroscopic dissociation energy D is smaller than D' by the zero point energy $\frac{1}{2}h\nu_0$. This results in the relationship,

$$D' = D + \frac{1}{2}h\nu_0 \tag{21}$$

The spectroscopic dissociation energy D is the dissociation energy of an ideal gas molecule at absolute zero, where all the gas molecules are in the zero potential energy level, h is Planck's constant (6.62×10^{-27}erg second), and ν_0 is the frequency of vibration of the nuclei at the lowest vibrational level, which is above the point of zero potential energy at the equilibrium internuclear separation. Thus, for the hydrogen molecule, $D = 4.476$ electron volts, $\nu_0 = 1.3185 \times 10^{14} sec^{-1}$, and since 1 electron volt = 23.06 kilocalories per mole we calculate D' using Eq.(21) as follows:

$$D' = (4.47 \text{ eV})(23.06 \text{ kcal mole}^{-1} \text{ eV}^{-1}) + \frac{6.023 \times 10^{23} \text{ mole}^{-1} \times 6.62 \times 10^{-27} \text{ erg sec} \times 1.3185 \times 10^{14} \text{ sec}^{-1}}{(2)(4.184 \times 10^{10} \text{ ergs kcal}^{-1}).}$$

$$= 109.5 \text{ kcal mole}^{-1}$$

E. S. AMIS, University of Arkansas, Fayetteville, Arkansas

DISSOLVED OXYGEN (DO). One of the most important indicators of the condition of a water supply for biological, chemical, and sanitary investigations. Adequate dissolved oxygen is necessary for the life of fish and other aquatic organisms, and is an indicator of corrosivity or water, photosynthetic activity, septicity, etc.

DISSONANCE. In acoustics, when two or more musical tones played simultaneously produce an unpleasant effect (due to beats) on the listener, the tones are said to be in dissonance. In optics, dissonance means the formation of maxima and minima by the superposition of two sets of interference fringes from light of two different wavelengths.

DISTAL. As used in anatomy, a position distant, or farthest away, from the source of any part.

DISTANCE MARKER. A reference marker indicating distance, particularly such a marker on a radar indicator, to indicate distance of a target from the radar antenna. On a plan position indicator it is usually one of a series of concentric circles. Also called *range marker*.

DISTANCE MODULUS. If the apparent magnitude and absolute magnitude of a star, cluster, or galaxy are known, one may calculate the distance to the object in parsecs by means of the relation

$$m - M = -5 \log D - 5$$

When plotting distances, the value $m - M$ (instead of calculating D) is often used, and hence, this quantity is referred to as the distance modulus. See also **Stellar Magnitude**.

DISTILLATES. See **Petroleum**.

DISTILLATION. This is one of the most important and widely used of the chemical unit operations, both in the laboratory and on a large industrial scale, for separating the components of a liquid mixture. Distillation provides a means for partially vaporizing the mixture and separately recovering the vapor and residue. Consequently, the method is dependent upon the vapor pressures of the components making up the mixture. The vapor pressure of a pure substance is a constant, but varying with temperature. In distillation, the lighter, more volatile components of the original mixture (*distilland*) concentrate in the vapor when heat is applied. Advantage is taken of the fact that the ratios of the component substances in the vapor and liquid phases, except for special situations, are different. The less volatile components concentrate in the liquid residue (*bottoms*). The vapors evolved by distillation are condensed and are termed the *distillate*.

Distillation should be contrasted with evaporation wherein the vapor (frequently water) is not usually condensed (except where it is desired to conserve water). The principal product desired in evaporation is the solid material which remains in the evaporator vessel. Thus distillation would be used to separate two or more miscible liquids, such as glycol and water, whereas evaporation would be used to separate solid sodium chloride from brine.

The effectiveness of separation by distillation is largely determined by differences in the boiling points of the starting components. Where these are widely separated, as in the case of water (100 °C) and ethylene glycol (197.6 °C), the separation is relatively easy and redistillation is not required. Closer-boiling mixtures, such as the isomers of xylene, are much more difficult to separate by distillation. As the boiling points of the components approach each other, effective separation by distillation becomes more difficult.

Boiling-point diagrams or what also are termed boiling and condensation curves, usually experimentally determined, are useful guides in the design of distillation equipment. Fig. 1 is the phase diagram of a binary system forming a liquid and a vapor phase at constant pressure. Curve I is the boiling curve, which gives the coexistence temperature as a function of liquid composition; and curve II is the condensation curve, which gives the coexistence temperature as a function of the composition of the vapor phase. If the temperature is increased, vaporization begins when the boiling curve is crossed. Inversely, condensation begins when the temperature is decreased below the condensation curve. The use of boiling-point diagrams in still design will be discussed later.

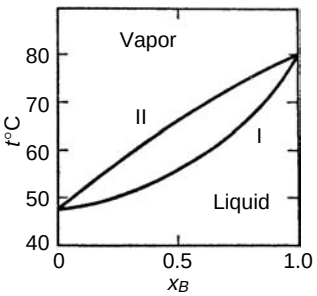

Fig. 1. Temperature-composition of a liquid-vapor system at constant pressure.

Major Types of Distillation

Distillation can be a batch or a continuous operation. Batch distillation is frequently used in the laboratory for determining the chemical composition of mixed liquids, such as hydrocarbons. In the majority of industrial processes, distillation is continuous. In a batch operation, the charge material is boiled and vapors are removed continuously, condensed, and collected until such point is reached where there is the desired average composition. The separation is not sharp. This type of operation is also termed *simple* or *differential distillation*. In another approach, the mixture may be heated until a definite fraction of the liquid batch is vaporized, during which time the liquid and vapor are kept in intimate contact, i.e., with no vapors being removed. At the prescribed temperature and after the liquid and vapor have had opportunity to reach full equilibrium, the vapor is suddenly withdrawn and condensed. This approach is known as *equilibrium* or *flash distillation*. The method finds wider application in connection with multicomponent systems than with simple binary systems.

In the majority of industrial distillation systems, some of the distillate will be continuously returned to the distillation column. The returned condensate is contacted countercurrently with the rising vapors, thus bringing about an enrichment of the vapor in the more volatile components than otherwise would be accomplished with a single distillation and most often obviates the need for one or more redistillations to obtain the degree of purity desired. This approach is known as *rectification* or *fractional distillation*. The material returned is termed *reflux*. In most rectifying columns, the raw feed to the column is introduced at about the mid-level of the tower or column. The portion of the column above the point of feed is called the *rectifying section*; the portion below, the *stripping section*. Where the feed may be introduced at the top of the column, the entire column then is usually referred to as a *stripping column*, with no reflux used.

Dephlegmation is a means for increasing the efficiency of fractional distillation by forcing the vapors from the still to bubble through shallow layers of condensate in a column or dephelgmator. Thereby, the amount of low-boiling component in the vapor is increased and a substantial portion of the higher-boiling components is retained in the condensate.

Steam distillation is a process whereby compounds that are sparingly soluble in water may be distilled by heating with water or by blowing steam through the mixture. Compounds of relatively high boiling point may be distilled at lower temperatures by this method and thus prevent degradation.

A representative fractional distillation column of which there are thousands in use in the process industries, notably in the petroleum and petrochemical industries, is shown in Fig. 2. The material balance of the column is:

$$F = W + D$$

$$Fx_F = Wx_F + Dx_D$$

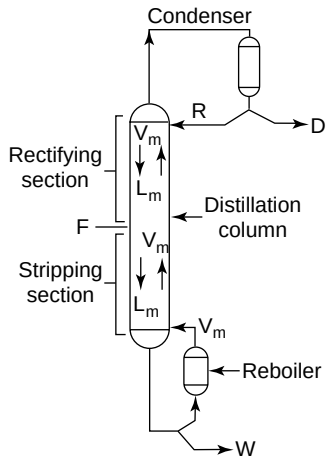

Fig. 2. Typical distillation column.

where F = feed rate, weight-moles/unit of time
W = bottom product, weight-moles/unit of time
D = distillate, weight-moles/unit of time
x_F = mole fraction of low boiler in feed
x_D = mole fraction of low boiler in distillate
x_W = mole fraction of low boiler in bottom product

In this balance, the assumption is made that the molar heat capacities and the latent heats of vaporization of all components are identical. It is also assumed that heat losses from the column and heats of mixing are negligible. With these assumptions, the upward vapor flow and the downward liquid flow in both the rectifying and stripping sections will be invariant within the sections. It is also assumed that accounting for the column heat balance is independent of the compositions of the product streams. Within these qualifications, the internal material balance is:

$$L_n = (1 + b)R$$

$$V_n = D + (1 + b)R$$

$$L_m = L_n + qF$$

$$V_m = L_m - W$$

$$x_W = f\left(\frac{L_m}{V_m}\right)$$

$$x_D = g\left(\frac{L_n}{V_n}\right)$$

where V_n = vapor rate in rectifying section, weight-moles/unit of time
V_m = vapor rate in stripping section, weight-moles/unit of time
L_n = liquid rate in rectifying section, weight-moles/unit of time
D = distillate rate, weight-moles/unit of time
R = external reflux, weight-moles/unit of time
b = a numerical factor, depending upon the reflux enthalpy or temperature. (It should be noted that b is greater than zero whenever the reflux temperature is below that at the top of the column.)
q = a numerical factor, depending on the feed enthalpy whose value satisfies certain constraints
$q < 0$, when feed temperature is below feed plate temperature.
$q = 1$, when feed temperature and composition are identical with those of feed plate.
$1 > q > 0$, when feed enters column partially vaporized.
$q = 0$, when feed is fully vaporized and is at saturated temperature.
$q < 0$, when feed is superheated vapor.

f and g are factors which account for several functional relationships which depend upon such column design criteria as the number of

plates in column, location of control plates, location of feed plate, and temperature and other conditions specified for control plates.

The foregoing type of material balance is of large value in determining the best form of automatic control to apply to the column in order to maximize yields.

Distillation Calculations. In determining the type of packing or trays to be used in a fractionating column, the diameter, height, location of feed, location of reflux return, vapor and liquid rates, and all other specifications for a column to effect a given separation, equilibrium diagrams of the type shown in Fig. 3 are important. Prior to the availability of high-speed computers, distillation column designers depended heavily upon graphical solutions, notably McCabe-Thiele diagrams, named after the early developers of this concept. A typical diagram of this type for a simple binary distillation is shown in Fig. 4. Oversimplifying the method, first an equilibrium curve of the type of Fig. 3 is constructed. Next a 45° diagonal line is drawn. With knowledge of desired final composition, i.e., composition of the liquid received by the top plate from the condenser, X_p, calculate the intercept of an *operating line* with the Y-axis of the chart. This is indicated as #1 on Fig. 4. The term $X_p/O + 1$ is this Y-intercept of the operating line. O is the reflux ratio. Next, the intersection of the diagonal line with the ordinate X_p is marked. This is indicated as #2 on Fig. 4. The operating line is then drawn in by joining #1 and #2. Now, commencing at #2, rectangular steps between the operating line and the equilibrium curve are drawn in until it crosses the line $X = X_s$. X_s is the starting composition of the mixture. The number of horizontal steps counted (in this case, five) indicates the number of *theoretical plates* required to accomplish the separation desired. A theoretical plate may be defined as a plate wherein complete equilibrium is reached between the vapor rising from the plate and passing to the plate above — with the liquid leaving the plate and passing to the plate below. An actual plate, of course, will not perform with this efficiency. Thus, the designer, depending upon past experience with plates of certain designs, will include an appropriate margin in specifying the number of actual plates needed.

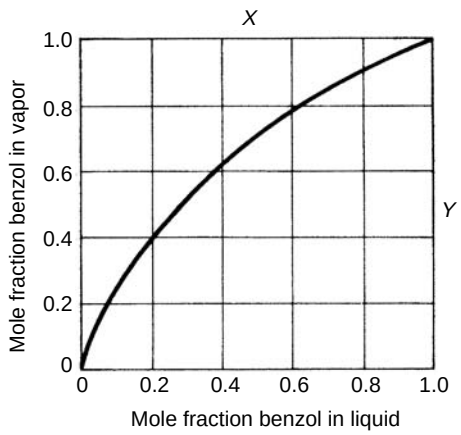

Fig. 3. Equilibrium diagram for the benzol-toluol system.

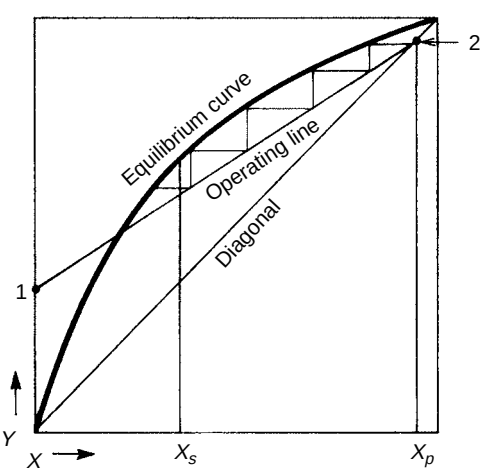

Fig. 4. Representative solution for theoretical plates in rectifying part of a distillation column.

Numerous computer software programs are available today to streamline design calculations. Of course, such software can be structured only after very careful analysis is made of the chemical dynamics of a given application. Calculations are particularly complex and difficult in the instances of azeotropic and reactive distillation. Software programs are described in some detail in the Kumana, Morris, and Venkataramkan references listed.

Azeotropic Systems. An azeotropic system is one wherein two or more components have a constant boiling point at a particular composition. Such mixtures cannot be separated by conventional distillation methods. If the constant boiling point is a minimum, the system is said to exhibit *negative azeotropy*; if it is a maximum, *positive azeotropy*. Consider a mixture of water and alcohol in the presence of the vapor. This system of two phases and two components is divariant. Now choose some fixed pressure and study the composition of the system at equilibrium as a function of temperature. The experimental results are shown schematically in Fig. 5.

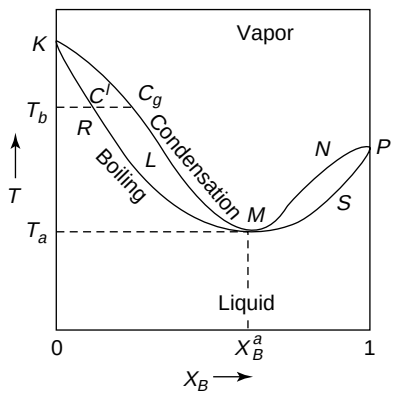

Fig. 5. Boiling-point diagram of an azeotropic system exhibiting negative azeotropy.

The vapor curve *KLMNP* gives the composition of the vapor as a function of the temperature T, and the liquid curve *KRMSP* gives the composition of the liquid as a function of temperature. These two curves have a common point M, where the curves are tangent. Because of the special properties associated with systems in this state, the point M is called an *azeotropic point*. In an azeotropic system, one phase may be transformed to the other at constant temperature, pressure and composition without affecting the equilibrium state. This property justifies the name azeotropy, which means a system that boils unchanged.

Because a number of industrially important liquid mixtures are azeotropic systems, means had to be found whereby they may be separated by distillation. Two approaches, *extractive distillation* and *azeotropic distillation*, are used. In either case, a *separating agent* is added to the column so as to alter favorably the relative volatilities of the feed components. Usually, water or polar organic compounds are found most effective. They increase the liquid-phase non-ideality of one feed component more than another.

In extractive distillation, the agent (sometimes termed solvent) is significantly less volatile than the regular feed components. The agent will be added near the top of the column. The agent behaves as a *heavier-than-heavy* key component. It is also conveniently separated from the product streams. Because the agent usually must be added in fairly substantial amounts, this means that column diameters and heat loads are increased, while plate efficiencies are lowered.

In azeotropic distillation, an agent is selected that will form an azeotrope with one of the feed components. In essence, separation is accomplished between this "new" azeotrope (as an overhead product) and the other feed component as bottoms product. An agent will be selected preferably that will permit easy separation after distillation.

Agrada, et al. (see reference listed), describes the manufacture of high-purity methyl acetate via *reactive distillation*. This operation is difficult because of reaction equilibrium limitations and formation of methyl acetate-methanol and methyl acetate-water minimum-boiling azeotropes. The researchers point out, "Conventional processes use schemes with

multiple reactors in which a large excess of one of the reactants is used to achieve the high conversion of the other reactant. Some use a series of vacuum and atmospheric distillation columns to change the composition of the methyl acetate-water azeotrope. The refined methyl acetate is separated from the uncoverted reactants, and the methyl acetate-methanol azeotrope is then recycled to the reactors. Other schemes use several atmospheric distillation columns and a column with an extractive agent, such as ethylene glycol monomethyl ether, to act as an entrainer to separate the methyl acetate from methanol."

In the process described by Agrada, et al., the concept of a countercurrent reactive distillation column (Fig. 6) is used.

Trays and Packing. Trays with bubble caps or other suitable configurations for enhancing a maximum intermingling of rising vapors with falling liquid in a column are usually used where efficiency and close separations are major considerations. Packed columns, filled with ceramic shapes of various types, such as Berl saddles and Raschig rings, are used primarily where cost and acid-resistance are factors. The sectional view of a form of bubble cap is shown in Fig. 7. A tunnel cap is much more shallow and replete with peripheral performations through which vapor and liquid flow. One column tray, incorporating several hundred tunnel caps, is shown in Fig. 8. In some very tight separations, several trays separated a few feet apart up the vertical length of the column may be required.

A petroleum crude atmospheric distillation column is illustrated in Fig. 9. This unit separates the crude into three major fractions which then are subjected to later separations: (1) a light straight-run fraction, consisting primarily of C_5 and C_6 hydrocarbons, but also containing any C_4 and lighter gaseous hydrocarbons dissolved in the crude; (2) a naphtha fraction having a nominal boiling range of 200–400 °F (93–204 °C); and (3) a light distillate with boiling range of 400–650 °F (204–343 °C).

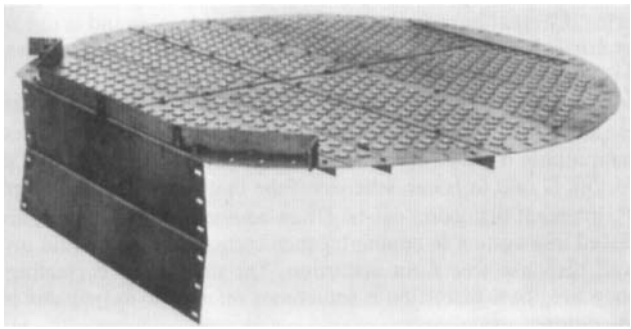

Fig. 8. Distillation tray incorporating several hundred shallow, tunnel-type caps.

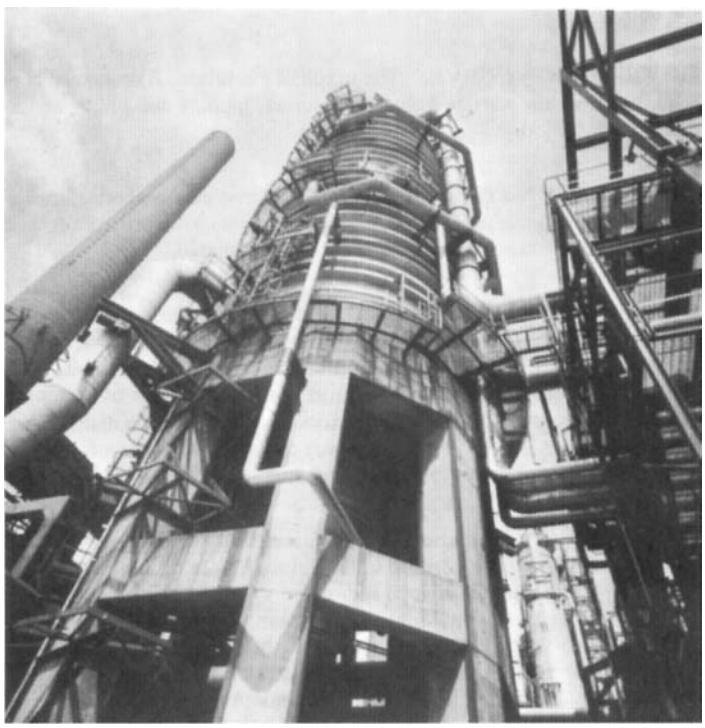

Fig. 9. View from base upward of atmospheric crude distillation tower.

Parastillation. This relatively new approach to distillation, as proposed by A.E.O. Jenkins in 1983, is a method for multistage, counter-current contact between vapor and liquid and is reputed to provide 33% more ideal stages than traditional factional distillation at the same tray spacing. The differences between the old and the proposed methodologies are shown in Fig. 10. This is a schematic of the vapor and liquid flows in the distillation column. In parastillation, the vapor is divided into two parts by a partition running the full height of the column; liquid entering the top of the column flows from one vapor side to the other. As pointed out by Canfield, a secondary advantage of the parastillation process over traditional distillation is that the liquid on a given vapor side of the column always flows in the same direction. Analysis of other advantages of the Jenkins system is outlined in the Canfield reference.

The literature is rich in descriptions of numerous improvements that have been made in distillation equipment over the past few years. For those readers desiring more detail, refer to the articles listed.

DISTORTION (Acoustic). A change in waveform. Noise and certain desired changes in waveform, such as those resulting from modulation or detection, are not usually classed as distortion. No acoustic or electroacoustic communication system or receiving apparatus is free from distortion. By this is meant that the waveform of the acoustic output is not strictly similar to that of the acoustic input, so that the quality of the sound is somewhat altered. The human ear is no exception. Vibrations received in the cochlea, with the consequent sensations, do not accurately represent the periodic variations of air pressure in the auditory canal, and we hear subjectively sounds that have no external physical existence. The most important aspect of this auditory distortion is the fact that when two pure musical tones are sounded, which are not of too nearly the same pitch, many persons can distinctly hear other tones in addition to the two actual ones. These subjective sensations are called combination tones, from the fact that they correspond in pitch to tones having frequencies equal to the difference, to the sum, or to other simple combinations of the two actual frequencies.

In the following discussion, tone frequencies are stated in hertz (cycles per second). Thus 528 means 528 hertz.

By far the most conspicuous of these subjective tones is the difference tone. Thus if one plays on a piano the two notes e (333) and c (528), many listeners hear, in addition to these, the note g (195), in the octave below, which is equal to 528−333. It was formerly supposed that the difference tone was the effect of beats, but Helmholtz detected sum tones and showed, further, that the difference tone sensation is too loud to be attributed to beats.

The cause of distortion in the case of the ear is believed to lie in the fact that the eardrum, or tympanic membrane, does not vibrate symmetrically. Mathematical analysis shows that if the tympanum moves farther inward than outward from its normal position during vibration, the waves passed on from it to the cochlea will contain other frequencies than those making up the original sound, and that in the case of a sound composed of two pure tones of frequencies n_1 and n_2, there will arise also the frequencies $n_1 - n_2, n_1 + n_2, 2\,(n_1 - n_2)$, etc.

The existence of difference tones is of value in electroacoustic apparatus such as the telephone and amplifier systems, and also in the pipe organ, the deficiencies of which in the lower frequency range are partially offset by the low difference tones that the listener thinks he hears. There is evidence that the "striking note" of certain chime bells is really a difference tone and does not exist among the partials of the complex sounds of these bells. The occurrence of combination tones can hardly fail to be of importance also in the effect on the ear of chords in musical harmony.

DISTORTION (Electromagnetic). An undesired change in waveform. This kind of distortion is one of the major limiting factors in any communications system, being a measure of the failure of the system to reproduce exactly at the receiver the signal which was applied at the transmitter. The amount of this distortion that can be tolerated varies with the different types of communication, and both for electrical and for economic reasons a system is usually not made much better than necessary.

When a sinusoidal signal is passed through a communications system, in general the output signal differs in amplitude and phase from the input signal. For convenience in discussing different kinds of distortion, let the ratio of the output amplitude to input amplitude be designated G and the phase shift between output and input be denoted by θ.

Distortion may be divided into three types: frequency distortion, which is caused by the system and responding to all frequencies equally, that is, G varies with the frequency of the input signal; amplitude distortion, which is caused by the system not responding to amplitude of signal linearly, that is, G varies with the amplitude of the input signal; and finally, phase distortion, which is caused by different frequencies being shifted in phase by varying amounts, that is, θ varies with frequency in such a manner that relative phase relations among the various sinusoidal components of a complex input signal are not maintained. The first two are important in sound communication while all three are important in television.

Frequency distortion is determined by the circuit's ability to respond to a wide frequency band. The average human ear will respond to a range of about 20 to 15,000 Hz, but all of this range is not necessary for most services so the systems are not designed to respond to such a wide range. For telephone service the range from about 250 to 2,800 Hz gives ample articulation and is the usual band employed. A wider band is not necessary and would greatly increase the cost of apparatus and the difficulties from

interference. Radio broadcast service requires a much wider band since it is designed for entertainment and must give a fair reproduction of the original music. Amplitude modulation systems are usually limited to an upper value of about 5,000 Hz to keep the side bands within the allowed channel and to avoid the excessive noise pick-up a wider band would introduce. Frequency modulation, being inherently more noise-free, uses a much wider band, going to the upper limit of audibility. When any system fails to reproduce the applied frequency range linearly it gives frequency distortion, which may or may not be objectionable.

Amplitude distortion usually results from some component saturating when a large signal is applied, frequently the distortion occurring for one polarity of the signal current or voltage and not the other. This has the effect of introducing new frequencies that are harmonics of the original ones.

Phase distortion does not appear to be important for sound since the ear is not sensitive to it, but in picture work it produces very noticeable distortion in the reproduced picture. It is caused by circuit elements offering different impedances at different frequencies and is one of the most difficult forms to eliminate when the frequency range of the system is very wide.

For the absence of phase distortion, it is necessary that the curve of phase shift θ vs. frequency be a straight line intersecting the θ axis at some multiple of 180°. If the slope of the curve is not constant, delay distortion is said to occur, whereas if the intercept is not a multiple of 180°, intercept distortion exists. Often compensating networks are introduced in a system to counterbalance certain distortions and give an overall response free from distortion. The process of correcting frequency and phase distortion is sometimes referred to as gain and phase equalization.

DISTORTION (Optics). One of the five geometrical aberrations with spherical surfaces. This aberration is due to the variation in magnification with distance from the axis.

DISTRIBUTED CAPACITANCE (Coil). The capacitance that is inherent in any coil because of the adjacent turns, layers, windings, etc. that are separated by some dielectric material and that have voltage differences between them. The result of this is a capacitance action, which lowers the effective inductance of the coil. This capacitance is often considered as lumped and in parallel with the true inductance of the coil.

DISTRIBUTION CURVE. The graph of cumulated frequency as ordinate against the variate value as abscissa, namely the graph of the distribution function.

DISTRIBUTION-FREE METHODS. Statistical methods, mostly in the theory of inference, which are independent of the precise form of the parent distribution from which the data emanated.

DISTRIBUTION FUNCTION. The distribution function $F(x)$ of a variate x is the total frequency of members with variate values less than or equal to x. As a general rule the total frequency is taken to be unity, in which case the distribution function is the proportion of members bearing values $\leq x$. Similarly, for p variates $x_1, x_2, \ldots, x_p$ the distribution function $F(x_1, x_2, \ldots, x_p)$ is the frequency of values less than or equal to x_1 for the first variate, x_2 for the second and so on.

DISTRIBUTION (Statistical). The manner in which a set of individuals is classified according to the values of one or more variables: for example, the number of men in a given town, classified into ranges according to height (a univariate distribution), or the same men classified into a two-way table by height and weight (a bivariate distribution).

Theoretical statisticians recognize a great many distributions expressed in mathematical form, both discontinuous (e.g., binomial distribution, Poisson distribution) and continuous (e.g., normal distribution, exponential distribution, Pearson family of distributions).

DISTRIBUTIVE LAW. If $A(f_1 + f_2 + \cdots) = Af_1 + Af_2 + \cdots$ then the operator A obeys this law when it is applied to a sum of functions. Normally, arithmetic and algebraic operations behave in this way but it is easy to find exceptions to the law. Thus, $\sin(x + y + z + \cdots) \neq \sin x + \sin y + \sin z + \cdots$, which is typical of trigonometric functions.

DISTURBANCE. In general, any agitation or disruption of a steady state.

In meteorology, this has several rather loose applications: 1) used for any low or cyclone, but usually one that is relatively small in size and effect; 2) applied to an area where weather, wind, pressure, etc., show signs of the development of cyclonic circulation; 3) used for any deviation in flow or pressure that is associated with a disturbed state of the weather, that is, cloudiness and precipitation; and 4) applied to any individual circulatory system within the primary circulation of the atmosphere.

DIURETIC AND URICOSURIC AGENTS. These are substances that increase the volume of urine excreted, causing a condition known as *diuresis*. some natural drugs, such as caffeine, act as diuretics. Some other substances, known as "saline diuretics," when filtered through the renal capsule are incapable of being reabsorbed by the tubules. These substances thus increase the concentration of salts within the tubule so that little of the urine can diffuse back into the blood stream. Some drugs, such as mercurial diuretics, act at the tubules, thus preventing reabsorption. Other drugs, such as digitalis, cause diuresis because of their specific actions on the circulatory system.

Diuretics are among the most frequently prescribed therapeutic agents for the treatment of edema, hypertension, and congestive heart failure and act primarily by inhibiting the reabsorption of sodium ions from the renal tubules in the kidney. This diverse class of therapeutic agents includes organomercurials, polyols, sugars, thiazides, phenoxyacetic acids, aminomethylphenols, xanthines, aromatic sulfonamides, pteridines, pyrazines, and steroids. These agents have been classified in a variety of ways including; chemical structure, mechanism of action, tubular site of action, magnitude of natriuretic effect, and by their effect on electrolyte depletion. Today no single classification system is commonly used; however, diuretics are often grouped as *loop*, *potassium-sparing*, *thiazide*, and *osmotic* diuretics. See also **Congestive Heart Failure (CHF)**; and **Kidney and Urinary Tract**.

Uricosuric agents increase the excretion of uric acid, one of the principal products of purine metabolism. These compounds are used in the treatment of gout, a condition in which plasma levels of uric acid are elevated and, as a result, deposits of crystalline sodium urate form in connective tissues. Hyperuricemia is an adverse effect sometimes observed with diuretic treatment and arises from decreased extracellular volume and increased urate reabsorption. Today, a heterogeneous array of diuretic compounds possessing different structures and sites of action are available for safe and effective treatment of edema and cardiovascular diseases including compounds that have combined diuretic and uricosuric properties. This modern era of diuretic therapy began in 1949, when sulfanilamide was discovered to possess diuretic and natriuretic properties. Since the 1950s, significant advances have been made in the discovery of new diuretic agents and their precise cellular mechanism of action.

Clinical Aspects of Diuretics

In a healthy human subject, changes in dietary intake or variations in the extrarenal loss of fluid and electrolytes are followed relatively rapidly by adjustments in the rate of renal excretion, thus maintaining the normal volume and composition of extracellular fluid in the body. Edema is an increase in extracellular fluid volume. In almost every case of edema encountered in clinical medicine, the underlying abnormality involves a decreased rate of renal excretion. One of the factors influencing the normal relationship between the volume of interstitial fluid and the circulating plasma is the pressure within the small blood vessels. In diseases of hepatic origin (e.g., cirrhosis), the pressure relationships are disturbed primarily within the portal circulation and ascites results. In congestive heart failure, pressure-flow relationships may be disturbed more in the pulmonary or systemic circulation and edema may be localized accordingly.

There is overwhelming evidence to indicate that the primary disturbance of the kidney is in its ability to regulate sodium excretion, which underlies the pathogenesis of edema. Three approaches are available when edema fluid accumulates because of excessive reabsorption of sodium and other electrolytes by the renal tubules. First, one can attempt to correct the primary disease if possible; second, one can reduce renal absorption of electrolytes by the use of drugs; and third, one can restrict sodium intake to a level that corresponds to the diminished renal capacity for sodium excretion. Cardiac decompensation is one of the most common causes of edema. Treatment consists of full digitalization, which should

be considered the primary therapeutic agent. Diuretic drugs have a secondary though very important role because it has been shown that blocking excessive electrolyte reabsorption in the renal tubule alleviates the symptoms of cardiac failure and also improves cardiac function. Diuretics are also used in the treatment of hypertension.

Diuretic therapy may lead to a number of metabolic and electrolyte disorders. In general, these disturbances are mild but can be life-threatening in certain cases. Some of the common adverse effects observed with diuretic treatment are hypokalemia, hyperuricemia, and glucose intolerance. Diuretics that possess a site of action proximal to the collecting tubules, such as the loop and thiazide diuretics, induce potassium loss; an average loss of 0.5–0.7 meq/L generally results with long-term therapy. In most young hypertensive patients, this reduction does not present any problem; however, in older patients or patients with preexisting heart disease, it may lead to the occurrence of ventricular arrhythmias. Combinations with potassium-sparing diuretics are frequently used to minimize the effect. Dietary potassium supplements may also be prescribed. In patients receiving long-term diuretic therapy, serum uric acid concentrations increase on average 1.3 mg/L as the result of a decrease in extracellular volume and increased urate reabsorption from the filtrate. Some patients may experience an attack of gout, or those with preexisting gout or excessive uric acid production may experience more frequent attacks. A number of studies have shown that some patients who have undergone long-term diuretic therapy have elevated blood levels of glucose and that their tolerance to glucose decreases. The mechanism of the diuretic-induced glucose intolerance is unknown. Some other side effects that are observed with diuretic treatment are increases in cholesterol levels in men and postmenopausal women, ototoxicity, and hypomagnesemia. See also **Kidney and Urinary Tract**.

Pharmacology and Mechanism of Action

Osmotic Diuretics. Osmotic diuretics all have several key features in common:

1. They are passively filtered at the glomerulus.
2. They undergo limited reabsorption in the renal tubules.
3. They are usually metabolically and pharmacologically inert.
4. They have a high degree of water solubility.

These agents all function as diuretic agents by preventing the reabsorption of water and sodium from the renal tubules. The addition of a nonreabsorbable solute prevents water from being passively reabsorbed from the tubule, which in turn prevents a sodium gradient from forming and thereby limiting sodium reabsorption. These actions hinder salt and water reabsorption from the proximal tubules; however, it has also been proposed that these agents have multiple sites and mechanisms of action.

Most of the osmotic diuretics are sugars and polyols (Table 1.) Mannitol is the prototype of the osmotic diuretics and has been studied extensively. The compound is poorly absorbed after oral administration and is therefore administered by intravenous (i.v.) infusion. It is freely filtered at the glomerulus and reabsorption is quite limited. The usual diuretic dose is 50–100 g given as a 25% solution.

These compounds are not prescribed as primary diuretic agents to edematous patients. One of the most important indications for the use of mannitol is the prophylaxis of acute renal failure. After cardiovascular operations or severe traumatic injury, for instance, a precipitous fall in urine flow may be anticipated. Administration of mannitol, under such conditions, exerts an osmotic effect within the tubular fluid, inhibiting water reabsorption. A reasonable flow of urine can thus be maintained, and the kidneys can be protected from damage. Osmotic diuretics have also been prescribed in the relief of cerebral edema after neurosurgery, to lower intraocular pressure in ophthalmologic procedures, and after a drug overdose to maintain urine flow.

Mercurial Diuretics. For approximately 30 years, mercurial diuretics were the most important diuretic agents. Since the introduction of orally active, potent, less toxic, nonmercuiral diuretics, beginning in 1950 with acetazolamide, their use has greatly declined. Today they represent only a small fraction of the injectable diuretics used, and injectable diuretics in turn are only a small portion of the total diuretic market. Organomercurials are generally given intramuscularly. The usual dose is a 1-mL solution containing 40 mg Hg. In responsive, edematous patients, an increase in urine flow is evident in 1–2 h and reaches a maximum in 6–9 h. The effect is usually over within 24 h. A loss of about 2.5% of body weight represents an average response. Mercury is eliminated from the body in the urine, as a complex with cysteine. These diuretics therefore should not be prescribed to patients with renal insufficiency marked by adequate excretion of the mercury-cysteine complex.

TABLE 1. OSMOTIC DIURETICS

Generic Name	Trade Name	Structure

Glycerine	Osmoglyn	Glucose		Isosorbide	Ismotic	Mannitol	Osmitrol	Sorbitol		Sucrose		Urea	Ureaphil	H_2NCONH_2

Before the development of the loop diuretics, the organomercurials were the most potent diuretics available. Further studies have found that the major effect of organomercurials appears to be in the ascending limb of Henle. Organomercurials inhibit active chloride reabsorption in the thick ascending limb of Henle. During diuresis, the urine contains a high concentration of chloride ion matched by almost equivalent amounts of sodium ion. The effect of mercurial diuretics on potassium excretion is complex. They depress the tubular secretion of potassium and, for this reason, the diuresis is accompanied by significantly less potassium loss than occurs with other diuretics that do not inhibit the secretory mechanism. However, mercurials can have a paradoxical effect of increasing potassium excretion when initial excretory rates are low.

Side effects, such as diarrhea, gingivitis, proteinuria, and stomatitis, can occur with organomercurial treatment. As with other diuretics, electrolyte imbalances are common after long-term use (hypochloremic alkalosis, hypokalemia, hyponatremia). In some cases after intravenous administration, severe hypersensitivity reactions may develop. The structural characteristics of mercurial diuretics and the most important mercurial diuretics are shown in Table 2.

Carbonic Anhydrase Inhibitors. Acetazolamide is the prototypical carbonic anhydrase inhibitor (Table 3). It is rapidly absorbed from the stomach, reaches a peak plasma level within 2 h, and is eliminated unchanged in the urine within 8–12 h. The efficacious dose is 250 mg to 1 g daily. During continuous administration of acetazolamide, the excretion of HCO_3^- leads to the development of metabolic acidosis. Under such acidic conditions, the diuretic effect of carbonic anhydrase inhibition is much reduced or completely absent, and therefore the effect of the drug is self-limiting. This is attributed to the fall in the level of plasma

and filtered bicarbonate, given that the latter is lost in the urine. A state of equilibrium is reached when the small amount of hydrogen ion that is secreted in spite of carbonic anhydrase blockade is sufficient to reabsorb the reduced amount of filtered bicarbonate ion. Because of the development of kaliuresis, metabolic acidosis, and their self-limiting nature, these inhibitors are not generally prescribed for diuretic therapy. Their most common use today is to lower intraocular pressure in the treatment of glaucoma. There is a great deal of current research in this area. Carbonic anhydrase inhibitors also have some therapeutic utility in epilepsy, congestive heart failure, mountain sickness, gastric and duodenal ulcers, and more recently in the area of osteroporosis, antitumor agents, and as diagnostic tools.

Carbonic anhydrase is a zinc-containing enzyme that was first discovered in erythrocytes by Roughton in the early 1930s. This enzyme was subsequently found in many tissues, including the renal cortex, gastric mucosa, pancreas, eye, and central nervous system. Carbonic anhydrase catalyzes the reversible hydration of carbon dioxide and the dehydration of carbonic acid. These reactions can occur in the absence of the enzyme, although the rates are too slow for normal physiological function to occur. Normally the enzyme is present in the tissue in high excess. Because of the levels of this enzyme in the kidney, approximately 99% of the enzyme's activity must be inhibited for physiological activity to be observed. To date, 14 different isozymes or carbonic anhydrase-related proteins have been identified in humans and higher vertebrates.

There are two main classes of compounds that inhibit carbonic anhydrase: unsubstituted sulfonamides and metal-complexing inorganic anions (e.g. azide, cyanate, cyanide, hydrogen sulfide, etc.). The inorganic anions have served as tools for better understanding of the catalytic and inhibitory mechanism of carbonic anhydrase inhibition. The sulfonamide class has led to the development of several useful therapeutic agents. After the discovery of the carbonic anhydrase inhibitory activity of sulfanilamide, a variety of aromatic sulfonamides were found to exhibit the same type of activity. Aliphatic sulfonamides were much less active; substitution of the sulfonamide nitrogen in aromatic sulfonamides eliminated the activity.

Thiazides. Thiazides are a major class of diuretic agents that have been used for over 30 years. It was this group of therapeutic agents that first challenged and then replaced the mercurial diuretics that were used in the first half of the twentieth century. Treatment of 4-amino-6-chlorobenzene-1,3-disulfonamide with formic acid resulted in the formation of the cyclic benzothiadiadiazine derivative, chlorothiazide. This compound was the first orally active, potent diuretic that could be used to the full extent of its functional capacity as a natriuretic agent without upsetting the normal acid-base balance. Chlorothiazide is saluretic with minimal side effects and fulfilled a clinical need. In addition to diuretic activity, chlorothiazide and its congeners exert a mild blood pressure-lowering effect in hypertensive patients.

Thiazide diuretics arose as an outgrowth of the carbonic anhydrase inhibitor area, in particular from the work of Novello and Sprague. Research in this area was based on the conviction of Beyer that it should be possible to find a sulfonamide derivative that was saluretic and that increased Na^+ and Cl^- excretion in approximately equal quantities; in other words, a compound that did not act as a classical carbonic anhydrase inhibitor, which increased water, Na^+, and HCO_3^- elimination. A saluretic diuretic should permit a substantial reduction of edema without affecting the normal acid-base balance.

Hydrothiazides. The thiazide diuretics have their greatest usefulness in the management of edema of chronic cardiac decompensation. In hypertensive disease, with or without overt edema, the thiazides have a mild antihypertensive effect. They are used with caution in patients with significantly impaired renal function. In some patients with nephrosis they have been effective, but their therapeutic usefulness in such cases has been unpredictable. The side effects observed with thiazide treatment can be divided into two types: hypersensitivity reactions and metabolic complications. Some of the common metabolic complications of these diuretics are hypokalemia, magnesium depletion, hypercalcemia, hyperuricemia, and hyperlipidemia. Thiazides may also induce hyperglycemia and can aggravate a preexisting diabetic state. With respect to hypersensitivity, dermatitis, purpura, and necrotizing vasculitis have been observed. The thiazide diuretics are available as tablets; the wide range of dosages of the individual preparations are shown in Table 4. To minimize the possibility of potassium depletion, fixed combinations with potassium-sparing diuretics have been made available (e.g., hydrochlorothiazide-triamterene and hydrochlorothiazide-amiloride).

As a class, the thiazides have an important action on potassium excretion. In most patients, a satisfactory chloruretic and natriuretic response is accompanied by significant kaliuresis; this is also seen in dog diuretic studies. At low doses, with some selected thiazides, a separation of natriuretic and kaliuretic effects have been observed, although at higher doses and repeated administration these differences disappear. The

kaliuresis, although enhanced by the carbonic anhydrase activity of many of these compounds, is probably a consequence of increased delivery of sodium and fluid to the distal segment of the nephron. Elevated serum uric acid levels, which may be associated with gout resulting from decreased uric acid excretion during chronic thiazide administration, have been well documented. Calcium excretion is decreased, and the excretion of magnesium is enhanced by the administration of thiazide diuretics in normal subjects and in patients. Thiazide treatment has also been observed to increase plasma levels of cholesterol and triglycerides.

Other Sulfonamide Diuretics. This group of diuretics (see Table 5) includes compounds that produce a pharmacological response similar to that seen with the thiazide diuretics (i.e., they are saluretics), and the maximally attainable level of urinary sodium excretion is in the same range as that of hydrochlorothiazide. The compounds in this group

differ in chemical structure; however, most of them are derivatives of *m*-sulfamoylbenzoic acid.

High Ceiling Diuretics. The term *high ceiling diuretics* has been used to denote a group of diuretics that have a distinctive action on renal tubular function. As suggested by their name, these drugs produced a peak diuresis far greater than that observed with other diuretics. These agents act primarily by inhibiting the reabsorption of sodium in the thick ascending loop of Henle and, thus, they are also commonly referred to as *loop diuretics*. This class of diuretic agents holds few structural features in common. Because they are most alike in potency and with respect to their renal site of action, they represent more a pharmacological rather than a chemical class of agents. The high ceiling or loop diuretics now in use or currently being studied are shown in Table 6.

TABLE 6. HIGH CEILING DIURETICS

Generic Name	Trade Name	Clinical Dose p.o. (mg/kg)	Structure

It is currently believed that the renal site of action for these diuretics is the $Na^+/K^+/2Cl^-$ cotransporter located in the thick ascending loop of Henle. By binding to the chloride site of the cotransporter, these drugs inhibit the reabsorption of sodium, thus promoting their diuretic action. The carboxyl group common to many of these diuretics is essential for the binding activity, and it has only been successfully replaced by a sulfonamide. Most of these drugs are readily absorbed in the gastrointestinal tract. For example, furosemide and bumetanide have bioavailabilities of 65 and 100%, respectively. Generally these compounds are secreted from the blood to the urine through the organic acid transport system in the proximal tubule and travel through the renal tubule to their more distal site of action. Increased potassium excretion and the elevation of plasma uric acid levels, as was observed with the thiazides, are also seen with the loop diuretics. These diuretics also increase calcium and magnesium excretion. The calciuric action of these agents has led to their use in symptomatic hypercalcemia. Many of the hypersensitivity and metabolic disorders seen with the thiazides are also seen with loop diuretics. The development of transient or permanent deafness is a serious but rare complication observed with this class of agents. It is believed to arise from the changes in electrolyte composition of the endolymph. It usually occurs when blood levels of these drugs are very high.

Steroidal Aldosterone Antagonist. Spironolactone (see Table 7) is the most extensively studied aldosterone antagonist. It promotes diuresis by competing with aldosterone at the receptor sites responsible for sodium ion reabsorption and best clinical results have been obtained from those patients suffering from cirrhosis and nephrotic syndrome, in whom the aldosterone secretion rate is very high. After administration for several weeks to hypertensive patients, the compound exhibits a modest antihypertensive effect; however, in normotensive subjects no reduction in blood pressure is seen.

Cyclic Polynitrogen Compounds. The diuretic actions of alkylxanthines, such as caffeine and theophyline (see Table 8), have been known for more than a century. They have been of limited clinical utility because of their low potency, development of tolerance after repeated administration, and side effects such as psychomotor effects and cardiac stimulation. It has been proposed that the pharmacological basis for their mechanism of action is adenosine receptor antagonism. Adenosine produces antidiuretic and antinatriuretic responses in several species. These effects can be competitively antagonized by theophylline. There are four adenosine receptor subtypes, A_1, A_{2A}, A_{2B}, and A_3. It is believed that the renal actions of adenosine are the result of its stimulation of the adenosine A_1 receptor. It has been shown that compounds that antagonize the A_1 receptor exhibit diuretic effects. Compounds that are adenosine A_2 antagonists do not show any diuretic or natriuretic properties.

There are three structurally different classes of potassium-sparing diuretics: steroids, pyrazines, and pteridines. These diuretic agents inhibit sodium reabsorption mainly in the principal cells of the collecting tubules. The steroidal aldosterone antagonists interact with the aldosterone cytoplasmic receptors, which interaction causes a series of events leading to sodium excretion and potassium reabsorption. The pyrazines and pteridines, on the other hand, inhibit the actions of the sodium channels located on the luminal side of the principal cells. These compounds are thought either to block this channel or to switch them from an open to a closed state. As a result, the apical cell membrane becomes hyperpolarized, and the transepithelial potential is decreased. This reduces the driving force for potassium to exit the luminal side by way of potassium channels, thus decreasing renal potassium loss. On average, the human body contains about 140 g of potassium. A calculation has shown that 98% of potassium is intracellular and only about 2% is in the extracellular compartment. Therefore, removal or addition of a small amount of potassium to this extracellular pool is very evident.

Frequently potassium-sparing agents, although themselves weak diuretics, are combined with other diuretics. In particular, these agents enhance the actions of the thiazides and loop diuretics, increasing the urinary loss of sodium while decreasing the excretion of potassium. Representative of these agents are spironolactone and triamterene.

The carbonic anhydrase inhibitors, such as acetazolamide also decrease the absorption of sodium, bicarbonate, and chloride, but are too weak in their effect to be useful as single agents.

In addition to their use in congestive heart failure and angina pectoris, diuretics are widely prescribed in the treatment of hypertension (high blood pressure), acute respiratory failure, hypercalcemia (in cancer patients), hypertrophic cardiomyopathy, and the syndrome of inappropriate ADH secretion, among others. See also **Hypertension (High Blood Pressure)**.

Uricosuric Agents

In humans, one of the principal products of purine metabolism (i.e., uric acid) is implicated in several human diseases such as gout. Guanine and adenine are both converted to xanthine (1); oxidation, catalyzed by xanthine oxidase, yields uric acid (2). In humans, uric acid is the excretory product and most of it is excreted by the kidney. In most mammals, uric acid is further hydrolyzed by uricase to allantoin (3), a more soluble excretory product. Allantoin, in turn, is further degraded to allantoic acid

TABLE 8. CYCLIC POLYNITROGEN COMPOUNDS

Generic Name	Trade Name	Structure
Theophylline (aminophylline)		In combination with diaminoethane 2:1 Aminometradine	Mictine	Amisometradine	Rolicton	Chlorazanil	Daquin, Diurazine, Orpisin	Triameterene	Dyrenium	Amiloride	Collectril	Clazolimine		
(4) by allantoinase, and then to urea and glyoxylic acid (5) by allantoinase (Fig. 1). Uric acid is not the major pathway of nitrogen excretion in humans. Instead, the ammonia nitrogen of most amino acids, the major nitrogen source, is shunted into the urea cycle. Uric acid is mostly insoluble in acidic solutions, although alkalinity increases its solubility. At the pH of blood (pH 7.44), uric acid is present as the monosodium salt, which is also very highly soluble and tends to form supersaturated solutions.

Uric acid forms from purines, which are liberated as a result of enzymatic degradation of tissue and dietary nucleoproteins and nucleotides, but it is also formed by purine synthesis. When the level of monosodium urate in the serum exceeds the point of maximum solubility, urate crystals may form, particularly in the joints and connective tissues. These deposits are responsible for the manifestations of gout. Serum urate levels can be lowered by decreasing the rate of production of uric acid or by increasing the rate of elimination of uric acid. The most common method of reducing uric acid levels is to administer uricosuric drugs, which increase the rate of elimination of uric acids by the kidneys. See also **Gout**; **Purines**; and **Water**.

DIURNAL. Daily, especially pertaining to actions that are completed within 24 hours and that recur every 24 hours; thus, most reference is made to diurnal cycles, variations, ranges, maxima, etc.

The diurnal variability of nearly all of the meteorological elements is one of the most striking and consistent features of the study of weather. The diurnal variations of important elements at the earth's surface can be summarized as follows: 1) temperature maximum occurs after local noon and minimum near sunrise; 2) relative humidity and fog are the reverse of temperature; 3) wind generally increases and veers by day and decreases and backs by night (*see* heliotropic wind, land and sea breeze, mountain and valley wind); 4) cloudiness and precipitation over a land surface increase by day and decrease at night; over water the reverse is true, but to a lesser extent; 5) evaporation is markedly greater by day; 6) condensation is much greater at night; 7) atmospheric pressure varies diurnally or semidiurnally according to the effects of atmospheric tides.

AMS

DIVERGENCE LOSS (Sound). That part of the transmission loss due to the divergence or spreading of sound rays in accordance with the geometry of the system (e.g., spherical waves emitted by a point source).

DIVERGENCE (Mathematics). The scalar product of the differential operator del (∇) and a vector. In Cartesian coordinates

$$\nabla \cdot \mathrm{V} = \div \mathrm{V} = \frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y} + \frac{\partial V_z}{\partial z}$$

The divergence of a position vector is constant; $\nabla \cdot \mathbf{R} = 3$; $\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$.

If **V** represents at each point in space the direction and magnitude of flow of some fluid, such as water or a gas, thermal, or electrical flux, then div **V** equals the rate of increase of flow per unit volume.

If the divergence of a vector function of position vanishes everywhere in a certain region, the function is said to be a solenoidal vector in that region. It follows that if **V** is a solenoidal vector so that $\nabla \cdot \mathbf{V} = 0$, then $\mathbf{V} = \nabla \times \mathbf{W}$, or **V** is the curl of some vector **W**. See also, for relations sometimes known as the divergence theorem, **Gauss Theorem** and **Green Function**.

DIVERSITY RECEPTION. Fading has been found to vary from place to place at a given time. Thus if a radio signal is received simultaneously at points separated by a few wavelengths' distance it is found that the outputs of the receivers do not all fade together. Diversity reception is a method of utilizing this effect to minimize the fading. Basically such a system consist of 2 or more (3 is quite common) antennae separated by several wavelengths (at least 10 times the wavelength of the received wave is desirable and 3 antennae placed at the vertices of an equilateral triangle give the best positioning) feeding separate radio-frequency receiver

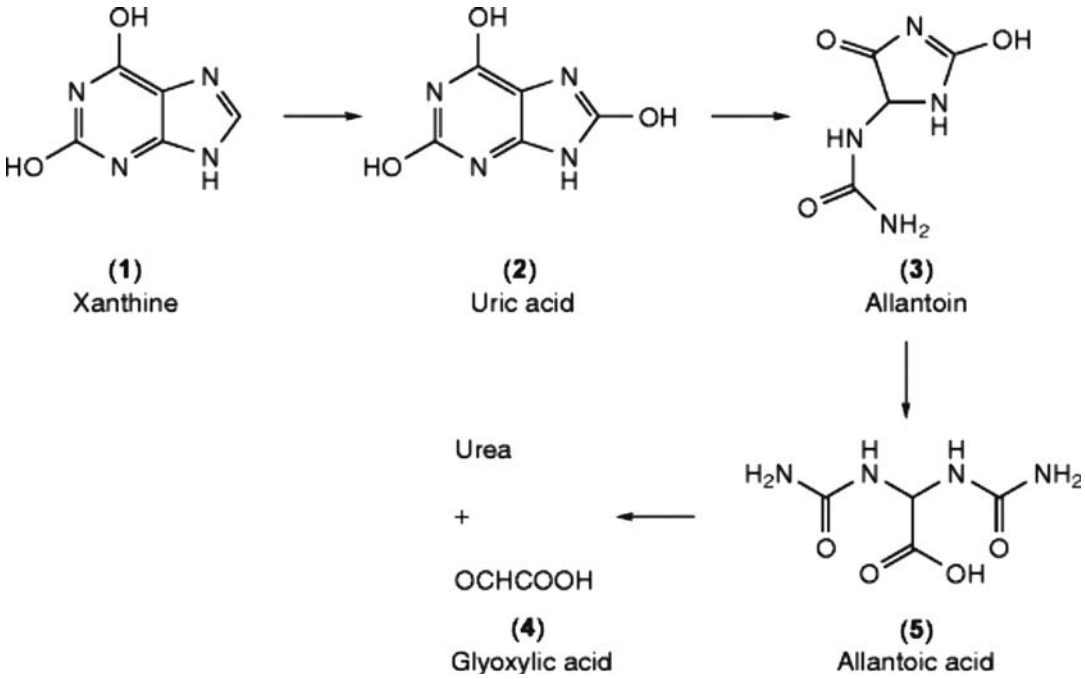

Fig. 1. Purine metabolism.

channels. The outputs of these channels are then combined to give a single output. By means of automatic volume control circuits, the antenna receiving a non-faded signal supplies most of the output and as the signals at the different antennae fade out and back in, the control system acts to maintain a constant output level.

A system of this type is used for the reception of overseas broadcasts and for transoceanic telephone reception.

DIVERTICULOSIS AND DIVERTICULITIS. Diverticula are small sacs or pockets (outpouchings) which occur in the colonic mucosa. When diverticula are present, even without symptoms, the disorder is called *diverticulosis*. When inflammation develops, which particularly occurs in the sigmoid colon, the condition is called *diverticulitis*. Diverticula are formed by a spreading of the muscular coat (mucosa and submucosa) of the bowel wall (a type of herniation), causing the bowel to protrude through the wall as a blind pocket. Diverticula may range from as small as 1 to 2 millimeters up to 5 centimeters in diameter. In routine barium enema x-ray examinations, somewhat less than 10% of adults are found to have some colonic diverticula, although the incidence rises to 30–60% among persons over 60 years old. Only a small percentage of persons with diverticula develop the complications of inflammation, i.e., diverticulitis. Nevertheless, 2% of the population of a large country represents a few million cases and thus physicians find diverticulitis, in varying degrees, to be a rather common complaint. Diverticulosis occurs less frequently in countries where people consume less-refined foods that contain appreciable amounts of indigestible fibers, as in Asia and Africa. However, in urban populations of developing countries where dietary habits have altered, the incidence of diverticulosis is increasing. See also **Diet**.

In diverticulitis, early symptoms include lower abdominal aching and cramping with pain usually regionalized to the left lower abdomen. Fever is not uncommon. Chills may indicate bacteremia. Watery diarrhea may develop; defecation may be more frequent. Pericolitis may develop, possibly causing painful defecation and, in some cases, complete obstruction. The most common site of inflammation is a narrow-necked diverticulum located in the sigmoid colon. Microperforation may be present. Where there is rebound tenderness, probably indicating a localized peritonitis, a barium enema examination is usually delayed until the acute process has subsided. It is very important that the mass involved in the difficulty be located. There are a number of diseases, particularly in older people, which tend to mimic acute diverticulitis, including Crohn's disease, ulcerative colitis, and pseudomembranous colitis, among others. See also **Colitis and Other Inflammatory Bowel Diseases**. In the absence of detailed history, an accurate differential diagnosis is required.

It is estimated that about 70% of patients with acute attacks of diverticulitis can be treated with supportive measures and that they will not experience subsequent attacks. Treatment includes nasogastric suction, fluid and electrolyte replacement, and antibiotic therapy, where the inflammation is severe or where peritonitis is suspected. A broad-spectrum antibiotic, such as ampicillin is frequently the drug of choice. Usually when a patient does not respond to medical supportive measures within 24 to 48 hours, surgical correction is indicated. There are several criteria considered as bases for surgery, including: where barium enema x-ray examinations and colonoscopy do not fully rule out carcinoma of the colon; where attacks of diverticulitis occur frequently; where a fistula is present; where there is chronic infection of the urinary tract coupled with deformity of the bladder; where a giant (measuring from 8 to 25 centimeters) sigmoid diverticulum is present; and where there is persistent low-grade intestinal obstruction. When emergency surgery is required, the mortality rate is about 6%; with elected surgery, about 1 or 2%, with the rate increasing with age of the patient. For some years, it was traditional to perform this surgery in two or three stages. A large number of surgeons today prefer a one-stage procedure.

DIVISION. An operation that is the inverse of multiplication. To divide a number a by a number b is to find a number c, such that $a = bc$. The number a is called the *dividend*, b the *divisor*, and c the *quotient*. The symbols, a/b, and $a \div b$ frequently are used to denote division. Division by zero is excluded from algebra in order that all quotients exist and be unique. The symbols, $b^{-1}a$ and ab^{-1} indicate the products of a and the inverse of b. In algebra, multiplication is commutative and both

products equal c. Therefore, dividing a by b is equivalent to multiplying a by b^{-1}(where$b^{-1}b = bb^{-1} = 1$). Multiplication by b^{-1} is meaningful in many applications where $a \div b$, or the other symbols interpreted in the sense of arithmetic or algebra are not well defined (for example, matrices). See also **Synthetic Division**.

DONALD R. HODGE, Alexandria, VA

DNA (Recombinant). See **Genetics and Gene Science (Classical)**.

DOBSON SPECTROPHOTOMETER. A photoelectric spectrophotometer used in the determination of the ozone content of the atmosphere. The instrument compares the solar energy at two wavelengths in the absorption band of ozone by permitting the two radiations to fall alternately upon a photocell. The stronger radiation is then attenuated by an optical wedge until the photoelectric system of the photometer indicates equality of incident radiation. The ratio of radiation intensity is obtained by this process and the ozone content of the atmosphere is computed from the ratio.

DOBSON UNIT. The standard way to express ozone amounts in the *atmosphere*. One DU is 2.7×10^{16} (10 to the 16th power) ozone molecules per square centimeter. One Dobson unit refers to a layer of ozone that would be 0.001 cm thick under conditions of standard temperature (0 °C) and pressure (the average pressure at the surface of the Earth). For example, 300 Dobson units of ozone brought down to the surface of the Earth at 0 °C would occupy a layer only 0.3 cm thick in a column. Dobson was a researcher at Oxford University who, in the 1920s, built the first instrument (now called the Dobson Spectrophotometer) to measure total ozone from the ground. See also **Dobson Spectrophotometer**.

DOBZHANSKY, THEODOSIUS (1900–1975). Dobzhansky was a Russian-born American naturalist and evolutionist, who pioneered the field of population genetics.

Theodosius Dobzhansky was brought up in Ukraine, where his father taught mathematics. While still a schoolboy he became a serious collector of *Coccinellidae* (ladybirds). Just too young to be drafted for World War I, he took an undergraduate degree course at the University of Kiev and then worked as a zoology instructor at Kiev Polytechnic. His work on the pleiotropic effects of *Drosophila* genes attracted attention and in 1924 he moved to Leningrad University as an assistant to Iurii Filipchenko.

In 1927 Dobzhansky was awarded an International Education Board fellowship to study *Drosophila* genetics in Thomas Hunt Morgan's laboratory at Columbia University, New York. He never returned to the USSR, moving with the Morgan group to the California Institute of Technology and becoming first Assistant Professor and then Professor of Genetics. In 1940 he moved back to New York as Professor of Zoology at Columbia University. See also **Morgan, Thomas Hunt (1866–1945)**.

The taxonomy of Coccinellidae had already convinced Dobzhansky of the importance of geographical races in the process of evolutionary divergence ('Geographical variation in lady-beetles', 1933). Within the Morgan group Dobzhansky began working on the geographical races of *Drosophila pseudoobscura* and in 1936 he was asked to give the Jesup lectures at Columbia University. These were published as *Genetics and the Origin of Species* (1937), an enormously influential book which was the first attempt to summarize the existing quantitative data on natural populations and interpret them in terms of theoretical population genetics. See also **Genetics and Gene Science (Classical)**.

Genetics and the Origin of Species integrated Mendelism and Darwinism and played a key role in the evolutionary synthesis of the 1930s and 1940s. However, one factor in its immediate success was Dobzhansky's popularization of Sewall Wright's hypothesis of genetic drift, which provides a mechanism for nonadaptive evolution. After his move to New York, Dobzhansky collaborated with Wright in an attempt to test the hypothesis. The data suggested that random factors are less important than natural selection and that heterozygosity confers a selective advantage. This last finding led to a lengthy dispute with H. J. Muller.

Dobzhansky's pathbreaking papers founded the field of experimental population genetics in the United States. To some extent this field already existed in Russia and many of the most influential ideas in *Genetics and the Origin of Species* (biological species defined by reproductive isolation; isolating mechanisms) were already familiar withinthe Russian biological community. The novelty of Dobzhansky's approach lay in its attempts to measure the mathematical variables of population genetics and in its use of the new technology of salivary gland chromosomes. Both innovations owed much to his collaboratorsin the Morgan group but Dobzhansky's 'grand mix' was all his own.

Genetics and the Origin of Species was revised three times and Dobzhansky also published popular books on evolution, for example *Mankind Evolving* (1962). He traveled widely throughout his career and founded a school of population genetics in Brazil.

DODO. See **Pigeons and Doves**.

DOG DAYS. The period of greatest heat in summer. Although the name is popularly supposed to have been derived from the period when dogs are especially liable to go mad, it is actually taken from Sirius, the Dog Star. In ancient Greece and Rome the heliacal rising of Sirius was associated with, and believed to cause, the hot, dry, sultry season of summer. The loss of human energy and the wilting of vegetation caused by this weather led to a belief in the baleful effect of Sirius on all human affairs. No formal meteorological or climatological definition exists. In the United States dog days are considered to persist for four to six weeks between mid-July and early September; in western Europe they last from about the third of July to the eleventh of August, and also are associated with the period of greatest frequency of thunder.

DOGFISH. See **Bowfin**; and **Sharks**.

DOGWOOD SHRUBS AND TREES. Probably best known for its beautiful trees, the dogwood family (Cornaceae) is predominantly made up of shrubs which have toothless leaves, except Cornus alternifolia, and staminate and pistillate flowers found on separate plants. The dogwood is found in Europe, Asia, and the United States. The C. florida is a small-to-medium size tree, achieving a height of from 20 to 40 feet (6 to 12 meters) and a trunk diameter of from 4 to 6 inches (10 to 15 centimeters). It is an extremely ornamental tree, particularly at springtime. Also known as the flowering dogwood, the C. florida has a rather flat top, with essentially horizontal branches. The twig is thin and the foliage is not dense. The leaf is about 4 to 5 inches (10 to 12.7 centimeters) long and clustered at the end of the branch. The flower is large and showy, about 3 to 4 inches (7.6 to 10 centimeters) across. The flowers are four-bracted, creamy white, sometimes tinged with pink. The fruit is a deep scarlet color. The wood is hard, heavy, and close-grained, weighing 46 pounds per cubic foot (737 kilograms per cubic meter). The heart wood has a slight red tinge. The wood has been used where a hard wood of fine quality is desired, but the availability is limited. Applications have included shuttles, skate rollers, golf club heads, and pulleys. The tree is found in woodlands and frequently in large gardens and parks from Maine and Quebec west to Wisconsin and Minnesota and south to Florida and southwest to Texas. It is probably found in the largest numbers in the mountains of North Carolina. The Japanese dogwood (C. kousa) is quite similar to the tree just described.

Record dogwood trees in the United States are indicated in Table 1. The C. alternifolia generally is considerably smaller than the record specimen described in the table. Often it may be a shrub only 6 to 10 feet (1.8 to 3 meters) in height, with a small trunk of perhaps 9 inches (22.9 centimeters) in diameter. The alternating leaves are an exception to the rule of the genus. The flowers of this shrub/tree are white and occur in broad, flat clusters. The fruit is a dark grayish-blue of pea-size. The plant prefers moist thickets and occurs from Quebec westward into Ontario and Minnesota and southward to Alabama and Georgia.

Although the C. florida does not do well in Britain, the C. kousa appears to be well suited. Both species have performed well in parts of Europe,

TABLE 1. RECORD DOGWOOD TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters

[1]From the "National Register of Big Trees," American Forest (by permission).
[2]At 4.5 feet (1.4 meters).

notably France. The Chinese dogwood (C. controversa) is found in Europe and the United States. Although this tree does not feature the large white bracts characteristic of the other species, it does display small flowers and the tree definitely has the general bearing of a dogwood. There are approximately fifty other species of dogwoods.

In the late 1970s, dogwood anthracnose was first noted on wild dogwoods in the United States and Canada. As of the early 1990s, the disease had spread to urban dogwood species in 18 states and British Columbia. Robert Anderson (U.S. Forest Service) reports that "for urban trees, we have pruning, fertilizing, mulching, and watering methods that can help" to control the disease. Forest dogwoods are more susceptible than trees in the open, which receive more sunlight and air circulation. With mortality reaching 90% in some areas, there is concern that the wild dogwood may succumb to a fate equivalent to the American chestnut with the passage of time. However, some species of dogwood appear to be naturally resistant.

The disease commences as purple-rimmed leaf spots. Even with urban planted trees, the disease ultimately will kill the tree unless treated early. Where found, further details from the U.S. or Canadian forest services should be consulted.

DOISY, EDWARD ADELBERT (1893–1986). Edward Doisy was born in Hume, Illinois in 1893. On graduation from the Universityof Illinois in 1916, he studied for a PhD at Harvard University, graduating in 1920. From 1919 to 1923 he taught at the Washington University School of Medicine, St Louis, wherehe worked with the distinguished embryologist Edgar Allen. In 1923 he was appointed Professor of Biochemistry at St Louis University, a post that he held until 1965.

Much of his career was devoted to the study of endocrinology, especially the ovarian hormones. In 1929 he isolated oestrone, followed by oestriol in 1930 and oestradiol in 1935. In 1936 at the University of Kansas he gave a series of lectures on "Sex Hormones," the culmination of his research on this subject.

Doisy received public recognition for his work on the isolation and synthesis of the K vitamins. He shared the 1943 Nobel Prize for Physiology or Medicine with Henrik Dam, for his discovery of the chemical nature of vitamin K. Vitamin K_1 was isolated from alfalfa, and vitamin K_2 from fish meal. The chemical structure of the K vitamins was then quickly ascertained, which aided their commercial production. They were to prove invaluable in the treatment of diseases of the liver. Doisy was adamant that he should not benefit from the commercial exploitation of his work; he donated all the profits from the patents of oestrone, oestradiol and vitamin K to St Louis University. See also **Vitamin K**.

DOLDRUMS. See **Winds and Air Movement**.

DOLERITE. The term dolerite, derived from the Greek meaning deceitful, was originally applied to all dark, heavy, fine-grained igneous rocks of doubtful character. It is now used to indicate gabbroid or basaltic types occurring as dikes or sills whose mineralogical composition is plagioclase, feldspar, hornblende or pyroxene or both, olivine and perhaps biotite, magnetite or ilmenite and pyrite. Included in the dolerites are the diabases, which display plagioclase laths in a somewhat radial arrangement, and from this circumstance we have the textural term diabasic which is synonymous with ophitic.

DOLOMITE. The mineral dolomite, the carbonate of calcium and magnesium, corresponds to the formula $CaMg(CO_3)_2$ and closely resembles calcite. Its crystals, rhombohedral in habit, fall in the hexagonal system. Like calcite, it may be massive or granular, some marbles being dolomite rather than calcite. It displays a perfect cleavage parallel to the

rhombohedron; subconchoidal fracture, brittle; hardness, 3.5–4; specific gravity, 2.85; luster vitreous to pearly; color varies widely, white, reds, greens, black, browns, yellows or colorless; transparent to translucent. Unlike calcite, dolomite dissolves very slowly if at all in dilute cold hydrochloric acid; powdered dolomite will dissolve in warm acid. This is the common test for the two minerals.

Much dolomite occurs as stratified rocks where it is believed to have been formed by a secondary process, probably by the action of waters charged with magnesium compounds. Dolomite also is found as a vein mineral, as is calcite. Iron or manganese, rarely zinc or cobalt, may replace some of the magnesium. Ankerite is the name given to a mineral whose composition is essentially a calcium-magnesium-iron carbonate. Among the many noted localities for dolomite are Saxony, Switzerland, Italy, France, Spain, Brazil, Mexico; in the United States, Roxbury, Vermont; Lockport, New York, Phoenixville, Pennsylvania; Alexander County, North Carolina; Hancock County, Illinois, and the Joplin District, Missouri, Dolomite was named for Deodat deDolomieu, who first described its characteristics. See also **Limestone**.

DOLPHINS *(Osteichthyes)*. Of the order *Percomorphi*, suborder *Percoidea*, and family *Coryphaenidae*, a dolphin is a marine game fish with a deep head, short snout, and long tapering body. In general form, these fishes appear like the mammalian dolphins. However, the marine dolphin is not to be confused with the air-breathing porpoise also referred to as a dolphin.

Mammalian dolphins and porpoises are described under **Whales, Dolphins, and Porpoises** (*Mammalia, Cetacea*).

There are two species of marine dolphins: (1) *Coryphaena hippurus*, and (2) *Coryphaena equiselis*. *C. hippurus* is the common dolphin which, as an adult, may reach a length of 5 feet (1.5 meters). It is possessed of a long fin and up to 65 rays extending along the back. The color is a beautiful blue and the tail is forked. Adult males may weigh up to nearly 70 pounds (32 kilograms) and have a markedly square-like head. The head of the female is more pleasingly rounded. Females rarely exceed a weight of 35 pounds (16 kilograms). Records of Hawaiian catches indicate an average of about 17 pounds (8 kilograms). Very fast, the dolphin can travel up to 37 miles (60 kilometers) per hour. Dolphins travel singly or in schools and feed on quite a range of fishes. Along the tropical American coasts and the Philippines, the dolphin is not highly regarded as a food fish, whereas in the Hawaiian Islands, *mahi mahi* (*C. hippurus*) is well regarded and is often considered a premium fish. *C. equiselis* is also referred to as the pompano dolphin. The latter is a considerably smaller fish (maximum length of about 30 inches; 76 centimeters) and has fewer rays on the dorsal fin, but otherwise is quite similar to *C. hippurus*.

DOMAGK, GERHARD JOHANNES PAUL (1895–1964). Domagk was a German pathologist and bacteriologist who discovered the first of the sulfa drugs or sulfonamides.

The son of a schoolteacher, Domagk was born in Lagow, Germany. His medical studiesat the University of Kiel were interrupted by his enlistment in the army during World WarI, but he returned to Kiel after the war to obtain his medical degree in 1921. In 1925, Domagk married Gertrude Strube, by whom he had four children. After university appointments in Kiel, Greifswald and Münster, in 1927 he accepted the position of Director ofthe Bayer Laboratory for Experimental Pathology and Bacteriology of the I.G. Farbenindustrie at Wuppertal-Elberfeld, a position which he held until the end of his career. From 1928, he also served as Professor of General Pathology and Pathological Anatomy at the University of Münster.

One of Domagk's tasks at the Bayer laboratory was the screening of various chemicals for antibacterial properties. Paul Ehrlich's introduction of Salvarsan for the treatment of syphilis had stimulated a search for other chemicals to combat infectious diseases. By 1930, the successful chemotherapeutic agents that had been developed were largely effective against protozoa-like organisms, such as the trypanosome that causes sleeping sickness, and there had been little progress made in the drug therapy of diseases caused by most pathogenic bacteria. The I.G. Farbenindustrie decided to embark upon a search for antibacterial drugs with Domagk in charge. See also **Ehrlich, Paul (1854–1915)**; **Protozoa**; and **Syphilis**.

Domagk did not have any significant success until he turned to a series of azo dyes that contained the sulfonamide group. These compounds had been synthesized by the Bayerchemists Fritz Mietzsch and Joseph Klarer. Experiments with mice in December 1932 indicated that one of the dyes, later named Prontosil, was extremely effective against haemolytic streptococcal infections, but the results were not published until 1935. Clinical trials established the value of Prontosil against a number of bacterial infections.

Scientists at the Pasteur Institute in Paris soon discovered that Prontosil is broken down in the body to yield sulfanilamide, which is the active therapeutic ingredient. The discovery that sulfanilamide was the active agent also led the various investigators to synthesize and test different derivatives of the compound. Several of these so-called*sulfa drugs* or *sulfonamides*, such as sulfathiazole and sulfapyridine, proved to be useful chemotherapeutic drugs against such diseases as puerperal (childbirth) fever, cerebrospinal meningitis, and pneumonia. Although later supplanted to a large extent by the antibiotics, the sulfonamides were wonder drugs in their time and responsible for saving countless lives.

In 1939, Domagk was awarded the Nobel Prize in Physiology or Medicine for his work on Prontosil, but the Nazi government of Germany forced him to decline it. He eventuallyreceived the medal in 1947, but it was too late to claim the prize money. Domagk continued his research in chemotherapy, giving particular attention to tuberculosis. He was responsible for the introduction of the thiosemicarbazones, which found some use in the treatment of cases of tuberculosis that proved resistant to the standard course of therapy. In his later years, he devoted much of his time to cancer chemotherapy, although without notable success. See also **Antibiotics**; and **Tuberculosis**.

JOHN PARASCANDOLA, U.S. Department of Health and Human Services, Rockville, MD

DOMAIN. 1. A region of space, together with its bounding points, curves, or surfaces.

2. The range of the independent variable for which a function is defined. See also **Mapping (Mathematics)**.

3. A region of spontaneous electric or magnetic polarization in a ferroelectric or ferromagnetic crystal. The size and shape of a domain depend on the material and its treatment. The boundary between domains is known as a Bloch wall. See also **Domain Structure**.

DOMAIN STRUCTURE. The theory of the macroscopic behavior of ferromagnetic and ferroelectric crystals depends on their consisting of large numbers of domains, each polarized to saturation but pointing in different directions so as to minimize the energy. An applied field tends to make those domains grow which are already favorably oriented, at the expense of those opposed to the field. Due to anisotropy energy, domains tend to be oriented along certain directions of easy magnetization, but the detailed arrangement of domains in a crystal is a complicated compromise between the tendency of each domain to be as large as possible and the necessity of creating closed loops of magnetic flux.

DOME. As used by the geologists, this term has several meanings. It is principally applied to mounds of viscous lava, which are squeezed out of volcanoes and solidify without forming lava flows. When portions of the older lavas or ashes are pushed up by the pressure of later lavas, the resulting structure is called a volcanic dome.

DOMINANCE (Ecology). In ecological communities, certain organisms may exert a much greater influence on the community than the other parts of the community. Those organisms, which, in essence, determine the basic nature of a community, are referred to as *dominants*. In terrestrial communities, plants are frequently the dominants. It is established, for example, that in a beech-maple community, the amount of shade cast by

these trees limits the maturation of shorter plants and the absence of the latter may, in turn, limit the animal species that can survive in the area.

DOMITE. The term proposed by Von Buch for the trachyte lavas of the volcanic Puy de Dôme district of France. More specifically, trachytes that contain appreciable amounts of oligoclase and hematite.

DONKEY. See **Horses, Asses, and Zebras**.

DOPING (Semiconductor). See **Semiconductors**.

DOPPLER BROADENING. A spreading of radiation frequencies with a resulting broadening of the corresponding spectral line, which takes place when radiating nuclei, atoms or molecules do not all have the same velocity relative to the observer, so that they give rise to different Doppler shifts. For example, since molecules of luminous gases obey the Maxwell distribution law, these effects produce a range of observed frequencies symmetrically distributed about the frequency of the atoms at rest. This range increases with increasing temperature, and there is a distribution of intensities throughout the broadened line that is determined by the Maxwell distribution of velocities. In absorption spectra, a similar broadening of the lines can result from the motions, relative to the observer, of the absorbing atoms or molecules. In nuclear physics, thermal motions of the nuclei in the material under examination can contribute appreciably to the widths of resonance lines, many of which (for instance, in slow neutron absorption) have natural widths of about 1 eV. See also **Broadening of Spectral Lines**.

DOPPLER EFFECT. In 1842, Christian Doppler predicted that the frequencies of received waves were dependent on the motion of the source or observer *relative to the propagating medium*. His predictions were promptly checked for sound waves by placing the source or observer on one of the newly developed railroad trains. In his original article on the special theory of relativity, Einstein developed the expression for the Doppler shift of light waves, which was dependent upon the velocity of the source relative to the observer. From the photon hypothesis for light, Schrödinger obtained the same results. Thus, the Doppler effect provides one of the illustrations of the equivalence of the wave and particle descriptions of light.

Classroom demonstrations of the Doppler effect for water waves are made in shallow glass-bottom ripple tanks. Instead of giving the vibrating source a constant velocity, one lets the sheet of water as medium flow continuously by the source.

The circles of Fig. 1 are snapshots of the crests of a water wave or compressions in a sound wave observed when the source is moving at constant velocity v to the right relative to the medium. Points 1 and 2 are positions of the source one and two periods after passing O. The largest circular crest originated at O, the next at 1 and the smallest at 2. A crest is about to leave point 3 at the time the snapshot is taken. If the position P of the observer is a large distance from the source compared to the distance the source moves in one period, then with good approximation we may assume that two successive crests are moving in the same direction as they pass P. If v is the velocity of the source in the direction OA, the source moves a distance vT in one period T. In one period, the source comes closer to P by the amount $vT\cos\theta$, where θ is the angle between the direction of the velocity of the source and the line from the source to the observer at P. Now λ_0 is the wavelength and ν_0 the frequency when the source is at rest; λ is the observed wavelength and ν the observed frequency when the source is in motion. Because of the motion of the source, the wavelength received at P is reduced by $vT\cos\theta$.

$$\lambda = \lambda_0 - vT\cos\theta$$

If c is the velocity of the wave, $T = \lambda_0/c$ and $\lambda = \lambda_0[1 - (v/c)\cos\theta]$, but $\lambda = c/\nu$ and $\lambda_0 = c/\nu_0$. Therefore,

$$\frac{\nu}{\nu_0} = \frac{1}{1 - \dfrac{v}{c}\cos\theta} \tag{1}$$

when the *source is in motion relative to the medium*.

In Fig. 2 the source is at rest, but the observer at P has a velocity v with respect to the medium. The velocity of the wave relative to the observer is equal to the vector sum of the velocity of the wave relative to the medium

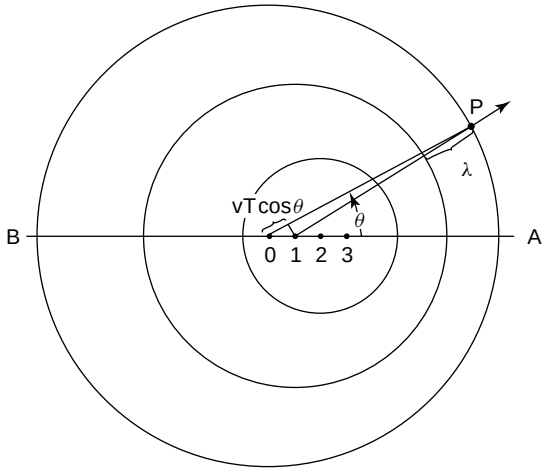

Fig. 1. The source is moving relative to the medium along the line BA. The circles represent crest of the wave of an instant. (*Andrews, "Optics of the Electromagnetic Spectrum," Prentice-Hall*.)

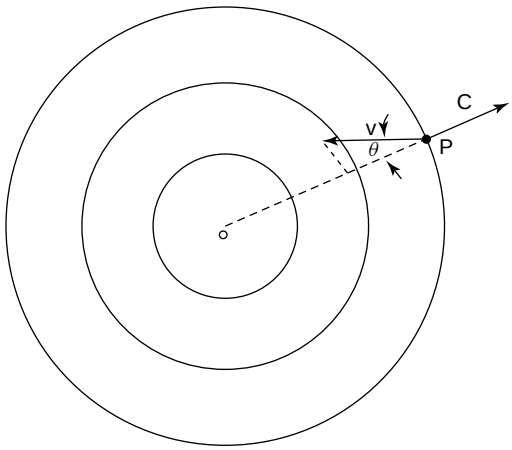

Fig. 2. The source is at rest at point O and the observer at point P is moving with velocity v relative to the medium. (*Andrews, "Optics of the Electromagnetic Spectrum," Prentice-Hall.*)

and the velocity of the medium relative to the observer. In Fig. 2, c is the velocity of the wave and v the velocity of the observer relative to the medium. Let λ_0 be the wavelength, ν_0 the frequency of the source, and ν the frequency received by the moving observer. The radial velocity of the wave relative to the observer is $c + v\cos\theta$ so that

$$\nu\lambda_0 = c + v\cos\theta$$

For an observer at rest $\nu_0 = c/\lambda_0$. Substituting for λ_0, we obtain

$$\frac{\nu}{\nu_0} = 1 + \frac{v}{c}\cos\theta \tag{2}$$

when the *observer is in motion relative to the medium*.

By a postulate of relativity, the velocity of light is the same relative to all observers. The theory of relativity yields the frequency

$$\frac{\nu}{\nu_0} = \frac{1 + \dfrac{v}{c}\cos\theta_0}{\sqrt{1 - \dfrac{v^2}{c^2}}} \tag{3}$$

in which $v\cos\theta_0$ is the component of the velocity of the source toward the observer. The angle θ_0 is measured in the source system. If θ is the angle measured in the observer's system, then

$$\cos\theta_0 = \frac{\dfrac{v}{c}\cos\theta}{\dfrac{v}{c}\cos\theta - 1} \tag{4}$$

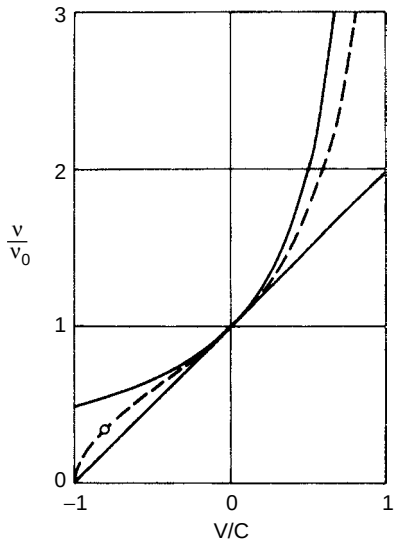

Fig. 3. Graphical plots of the ratio of the observed frequency to the frequency at the source against the ratio of radial velocity to the velocity of the wave for three cases: (1) Sound waves from a moving source; (2) sound waves to a moving receiver; (3) electromagnetic waves. The circle represents the red shift of light received from the most distant galaxies observed.

Figure 3 is a graphical plot of v/v_0 against v/c for the radial motion in the three cases we have treated. (1) The linear relation is that for the observer in motion relative to the medium that propagates sound or other mechanical waves. (2) The other solid curve is for the source of sound in motion. (3) The broken curve represents the Doppler effect for electromagnetic waves such as x-rays, light, and radio waves.

By comparing several spectral lines of elements observed in a star with a laboratory spectrum of the same elements, astronomers use the Doppler effect to measure the radial components of velocity of astronomical bodies toward or away from the earth. Spectra of the edges of the sun's disk are measured to determine the velocities toward and away from the earth. The radial velocities of the principal stars of our galaxy have been recorded. The spectral lines of some of the stars are doublets, which periodically come together and separate again, indicating that the light comes from two stars revolving about a common center of gravity.

In the expanding universe, the radial velocities of other galaxies away from our galaxy are proportional to their distances from the observer. Thus, the Doppler red shift provides a means of determining the dimensions of the observed universe. In 1964, some of the most intense radio sources were located with high precision by observing these sources when the moon passed in front of them. With this knowledge of position, the same sources were located with a light telescope. The measured red shift was surprisingly high. The sources were not stars as previously thought but the most distant galaxies known. One of them, 3C-9 in the catalogue of radio sources had a red shift $\Delta\lambda/\lambda_0$ equal to 2.0. If this shift were due solely to the Doppler effect, the astronomers had to conclude that the source was moving from us with 80% of the velocity of light. The Doppler frequency and velocity of this source is indicated by a circle on the broken line of Fig. 3.

If a microwave beam is reflected from a moving microwave mirror, such as a person, an automobile or a man-made satellite, the image of the primary source may be considered as another source moving with twice the velocity of the mirror. Since the speed is small compared with the speed of light, the squared terms of Equation (3) may be neglected. Thus

$$v = v_0\left(1 + \frac{2v}{c}\cos\theta\right)$$

Direct frequency measurements cannot be made to enough significant figures to distinguish ν from ν_0. However, if the two frequencies are combined they give beats or the difference frequency

$$\Delta v = v_0\frac{2v}{c}\cos\theta$$

Since the beat frequency is proportional to the radial velocity, a frequency meter may be calibrated in miles per hour. The precision of such a speed detector depends upon the frequency of the source being so stable that it varies less than the Doppler frequency shift during the time that the wave travels from the source to the mirror and back. The same phenomena of beats between the direct wave from the source and the wave reflected from a moving mirror may be observed with light. If one of the mirrors of Michelson's interferometer is moved at constant speed, the frequency with which dark bands pass the cross hair is the difference in frequency of the two waves.

The numerator of Equation (3) contains a term for the radial component of velocity. However, the second-order term in the denominator is independent of direction. Thus, as v/c approaches unity, one may expect to detect a *tangential Doppler effect*. Ives and Stilwell have measured the predicted value for the Doppler shift in frequency due to a stream of radiating molecules for which v/c was 10^{-2}. This experiment was a direct proof of time dilatation for the transverse case. In order to separate the tangential from the radial effect, Ives and Stilwell produced a sharply collimated beam of molecules. In order that θ be precisely 90°, they set a mirror accurately normal to the line of observation and altered the line of observation until nearly the same wavelengths were given by direct and reflected light.

DOPPLER ERROR. The error in measurement of the radial velocity of a radar target. The error is due to 1) noise in the measurement system; 2) fluctuations in the signal itself, which are a characteristic of echoes from distributed targets such as precipitation; 3) limited measurement time; and 4) atmospheric refractive effects (usually negligible) that modify the ray path and the speed of light.

DOPPLER RADAR. In a system of this type, use is made of the Doppler shift of an echo caused by the relative motion of target and radar. Differentiation between fixed and moving targets is made possible by observing a shift in frequency. Highly accurate determination of the velocity of moving targets is made possible by measurement of the frequency shift. Both continuous-wave and pulsed Doppler radar configurations are used. See also **Radar**.

DOPPLER SHIFT. The magnitude of the change in the observed frequency of a wave due to the Doppler effect. Expressed in cycles, the magnitude is also termed *Doppler frequency*. See also **Red Shift**.

DORAB *(Osteichthyes).* A member of the order *Isospondyli*, suborder *Clupeidae* (herrings), and family *Chirocentridae*, the dorab is also known as the wolf herring. It is a slender marine fish of Oriental origin, of large size and vicious habits with powerful jaws and formidable dentition. It differs from all other herrings by the presence of a spiral valve in the intestine. Normally, this is found only in rays and sharks and possibly a limited number of primitive bony fishes. The dorab has much of the outward appearance of a very large herring, but unlike other herring-type fishes, the dorab is an aggressive carnivore. The fish has the typical herring-type knife-edge on the underside of the abdomen. Records indicate the maximum length of the dorab is about 12 feet (3.6 meters), thus several times larger than other herrings. The waters of the central Pacific are its habitat.

DORMOUSE. See **Rodentia**.

DOSIMETER (Radiation). Most commonly, a device worn by persons working around radioactive material to indicate the "dose" of radiation to which they have been exposed. Photographic film badges have long been used because of the sensitivity of photographic emulsions to radiation and the comparatively low cost of this type of detector. The electroscope also has been used for personnel monitoring. In the common form of the

instrument, an insulated fiber is supplied with a static charge relative to another electrode. The electrostatic force on the fiber causes it to deflect. The deflection corresponding to a fixed reference voltage is determined as zero dose on the scale. As the electroscope is exposed to radiation, the charge leaks away through the gas and the fiber deflection decreases. The scale of the instrument is calibrated in terms of total radiation dose received. Although primarily used for personnel monitoring, the electroscope also finds application in radiation measurement where the integrated dose at a point location is desired over a long exposure, such as hours or days.

Various chemical dosimeters have been developed based on the ability of ionizing radiation to induce chemical reactions. Among these are the ferrous-ferric dosimeters and the cerous-ceric dosimeters. The latter is used for very high radiation doses. The ferrous dosimeter is one of the most thoroughly studied of the chemical types. This involves the conversion of ferrous ions to ferric ions in an 0.8-normal sulfuric acid solution by radiation-induced oxidation. The detector is most useful for high radiation levels. The yield of the dosimeter usually is expressed in *G* units, which are the number of molecules produced or converted per 100 electron-volts absorbed.

Colorimetric dosimeters involving the effect of radiation upon degradation of dye colors also have been used for less accurate determinations of radioactivity. Dysprosium, a rare-earth element, in the form of metal foil and also the oxide, Dy_2O_3, also have been used in dosimeters.

DOUBLE-DABBLE. A technique for binary to decimal conversion. Starting with the most significant bit, proceed, bit-by-bit, as follows: If the next bit is 0, double what you have (double); if the next bit is 1, double what you have and add 1 (dabble).
Thus, 111 (binary) = 7 (decimal)
10111 (binary) = 23 (decimal).

DOUBLE SALT. A hydrated compound resulting from crystallization of a mixture of ions in aqueous solution. Common examples are the alums, made by crystallizing from solution either potassium or ammonium sulfate and aluminum sulfate; Rochelle salt (potassium sodium tartrate), made from a water solution of potassium acid tartrate treated with sodium carbonate; and Mohr's salt (ferrous ammonium sulfate), crystallized from mixed solutions of ferrous sulfate and ammonium sulfate.

DOUBLE STAR. A pair of stars, both of which, seen from the earth, are so nearly in the same direction that they appear as a single star to the unaided eye, but which may be seen as separate stars through a telescope. Double stars may be either one of two kinds. In cases where the two stars are only apparently close to each other (i.e., lie in approximately the same direction from the earth, but are separated by a great distance in the radial direction), the pair is known as an optical double. In the great majority of cases, however, the stars are actually close enough together to exert strong gravitational attractions on each other, and are in orbital motion relative to each other. Such physically connected stars form what is known as a binary star, and are the chief source of stellar masses. Optical doubles may be distinguished from binaries by observing the pair in a telescope over a period of years. If the distance between the two stars changes progressively over a long period of time, but the position angle remains constant, it may be safely assumed that the motion is due to proper motion alone, and that an optical double is under observation. In the case of a binary, position angle changes progressively, and distance oscillates between a maximum and minimum.

The first recorded discovery of a double star (Zeta Ursae Majoris) was made by Riccioli (1650). The search has continued. During the early part of the present century, the study of double stars and binary stars was central to much astronomical research. At the time when a 36-inch refracting telescope was a highly sophisticated instrument, it was observed by Aitken that "at least 1 in every 18, on the average, of the stars in the northern half of the sky, which are as bright as 9.0 magnitude, is a close double star." Since that time, aided by advanced astronomical equipment and techniques, the estimate has been revised upward.

Binary star systems are further described in entries on **Binary Stars; Eclipsing Binary; Spectroscopic Binaries**; and **Visual Binaries**.

STEVEN N. SHORE

DOUBLET. 1. Two elements that are shared by two atoms so as to form a nonpolar valence bond.

2. A pair of spectral lines resulting from transitions between a common state and two states which differ only in total angular momentum (J), i.e., have identical values of orbital (L) and spin (S) angular momenta.

3. Two stationary states having common values of (L) and (S), but different values of (J).

DOUBLET LENS. Particularly an achromat having two components. See also **Petzval Surface**.

DOUGLAS FIR. See **Fir Trees**.

DOVE. See **Pigeons and Doves**.

DOWN-GRADIENT DIFFUSION. A random molecular process where there is net movement of variables such as chemicals, temperature, moisture, or momentum, from regions of high concentration toward lower concentration.

A classic example is heat flowing from the hot end toward the cold end of a metal rod. Gradient refers to the change of mean variable across a distance, such as the temperature change across the metal rod. Down-gradient refers to movement from high to low concentration, such as from hot to cold (as opposed to counter-gradient, meaning from cold to hot). Many turbulence theories such as K-theory and mixing-length theory assume that turbulent transport is caused mostly by small eddies, resulting in a local transport (down-gradient turbulent diffusion). Such small eddy local turbulent transport is not a law, but is a turbulence closure assumption that works well for those atmospheric situations where small eddies dominate (such as in the atmospheric surface layer), but that usually fails for situations where large eddies dominate (such as in the atmospheric mixed layer where large convective thermals cause nonlocal turbulent transport).

AMS

DOWN'S SYNDROME. This syndrome is sometimes referred to as *trisomy 21* because this genetic disorder involves chromosome 21, the smallest of the human chromosomes. This error occurs in about one out of every 700 newborn infants. The incidence increases with the age of the mother: mid-30s, one in 300 children; early 40s, one in 30 children; middle-40s, one in 10 children.

Children born with this disorder suffer a range of physical and mental problems, including varying degrees of mental retardation. The syndrome is the leading cause of mental retardation in the United States. Physical features include epicanthic folds of the eyelids, a broad face, and flattened nose. Other features may include the open mouth, a protruding tongue, and poor posture associated with weak muscle tone. Prior to the present designation of the disorder, the word *Mongoloidism* (because of appearance characteristics) was commonly used. This designation is now considered obsolete.

The disorder has been known for several centuries, but was not formally recognized until 1866, when John Langdon Down, a physician at the Earlswood Asylum in Surrey, England prepared a comprehensive paper describing the disorder. Down's syndrome was one of the first disorders to be identified as one of genetic origin. In 1909, G.E. Shuttleworth (Royal Albert Asylum, Lancaster, England) referred to the disorder as the result of "uterine exhaustion" because it was noted that an exceptional number of patients were the youngest of a long line of children of the same mother. That hypothesis no longer holds, but the relationship of the disorder with the age of the mother is now widely accepted.

The concept that the syndrome may involve the nondisjunction of chromosomes, that is, the failure of chromosomes to separate properly during meiosis, was suggested in the early 1930s by Adrian Bleyer (Washington University School of Medicine, Saint Louis, Missouri). At that time, from the study of plants, it was established that certain plant deformities occurred when there were 15 rather than the normal number of 14 chromosomes present. However, relating plant genetics to those of humans was difficult then because an accurate count of the number of human chromosomes had not been established. This remained for the research of Tjio and Levan (Institute of Genetics, Lund,

Sweden), who established the total human count at 46 chromosomes. Other researchers supported the nondisjunction concept in Down's syndrome subjects because of their having a total of 47 chromosomes rather than the normal count of 46 chromosomes.

Over the intervening years, a number of scenarios have been developed by researchers. Statistics have implicated the abnormality to eggs, not sperm. More recently, it has been suggested that the aberration is related to the role of estrogen in reproduction. Eggs are developed only to the prophase stage of cell division until puberty. At that time, the cyclic rise in estrogen triggers one egg, once a month, to ovulate or resume cell division (miosis). Thus, in some very young mothers, the normal cycle may not have commenced at the time she became pregnant. In older women, the estrogen concentration decreases, thus decreasing the rate of miosis. Some researchers have suggested that if miosis is too slow, the spindle does not attach to both ends of the chromosomes by the time the chiasmata (which holds the chromosomes together) have terminalized and thus the dividing cells will have unequal numbers of chromosomes. One cell may lose the 21st chromosome and will not survive. But the extra chromosome may be added to another cell, giving it one extra chromosome. This cell can go on to regular fertilization by the sperm, subsequently resulting in Down's syndrome in the offspring.

With the rapid expansion of gene science (see also **Genetics and Gene Science (Classical)**), more definitive causation scenarios will emerge. As reported by Patterson (see reference), investigators are currently addressing four basic questions: (1) What genes occupy the region of the chromosome that is specifically responsible for Down's syndrome? (2) Which of these genes are responsible for the pathogenesis of the syndrome? (3) Exactly what proteins are encoded by the genes? (4) By what mechanism(s) does the presence of three copies of the genes (instead of the normal two) lead to Down's syndrome? Researchers at present are concentrating on preparing high-resolution gene maps. One tentative hypothesis proceeds along these lines. If there are three copies of each gene instead of two, it would seem logical that each gene would produce half again as much of a particular gene product as found in normal individuals. Thus, the detection of a particular protein or particular enzyme activity may be a good indication that the protein or enzyme is encoded by a gene on a trisomic chromosome. When the scenario is understood at the gene and even molecular level, many encouraging avenues of treatment may be suggested.

In addition to the mental and physical characteristics previously mentioned, the Down's syndrome patient faces a shortened life span. However, because of advancements in general medicine for treating Down's syndrome patients, the life span of 9 years, the estimate widely used as recently as 1929, has been extended to more than 30 years, with an estimated 25% of Down's syndrome patients living to age 50 years. Conditions related to the syndrome include evidence of abnormal microscopic senile plaques and neurofibrillary tangles as found in Alzheimer's disease. This condition may account for part of the mental retardation occurring at birth and in early years instead of in later years as experienced in Alzheimer's disease. See also **Alzheimer's Disease and Other Dementias**. An estimated 40% of Down's syndrome persons are born with congenital heart defects and have increased chances of developing cataracts and other visual impairments. It has been established that Down's syndrome patients have elevated levels of purines which can cause neurological impairment and immune-system deficiencies as well as mental retardation. The patients are abnormally susceptible to infection and statistics indicate that these patients have a 20- to 50-fold chance of developing leukemia.

On the positive side, much has been learned over the last few decades to improve the life of the Down's syndrome patient, not only in terms of extending life expectancy, but also in increasing the quality of life. Parental interest and enthusiasm are major ingredients. Forms of therapy can be commenced as early as age 4 weeks. Speech therapy at an early age is paramount and influences intellectual development. With a realization that increased knowledge at the gene and molecular level is forthcoming in the near future, it seems reasonable to assume that improved therapy will result.

Questionable Therapy. Niehaus (Switzerland) in the 1930s proposed that fetal sheep and rabbit cells contain unidentified substances that stimulate growth in aging human cells. The concept was revived in the 1960s by Schmid (Germany), suggesting that a preparation made up of the aforementioned freeze-dried animal cells for subcutaneous or intramuscular injection into Down's syndrome patients could improve some of the manifestations of the syndrome, including intelligence and motor and social skills. Although support for the concept continues, the consensus of professional therapists has been and continues to be very negative and warns against possible side effects, including allergies, that could result from such procedures.

DOWNWASH. See **Aerodynamics and Aerostatics**; and **Helicopters and V/STOL Craft**.

DOWNWELLING. The process of accumulation and sinking of warm surface waters along a coastline. A change of airflow of the atmosphere can result in the sinking or downwelling of warm surface water. The resulting reduced nutrient supply near the surface affects the ocean productivity and meteorological conditions of the coastal regions in the downwelling area.

DRACONTIC MONTH. The average period of revolution of the moon about the earth with respect to the moon's ascending node, a period of 27 days 5 hours 5 minutes 35.8 seconds, or approximately $27\frac{1}{4}$ days. Also called *nodical month*.

DRACO (the dragon). A northern constellation that lies between Ursa Major and Ursa Minor.

DRAFT. 1. The draft of a ship or boat is its depth of flotation; also, the minimum depth of water in which navigation is possible.

2. In foundry practice, in making a pattern which is to be molded in sand, a certain small taper is necessary where the pattern is of such shape as to be rather deeply imbedded in the sand. When the pattern is rapped or jarred loose from the sand, a slight taper, called draft, allows the pattern to pull free during its removal from the mold, without disturbing the side walls.

3. As applied to a gaseous system, *draft* is a pressure-differential that operates to move the gases. *Combustion* requires oxygen — and therefore air. To move this air through the fuel bed and to produce a flow of the gaseous products of combustion out of the furnace, then through the boiler, economizer, etc., requires a difference of pressure equal to that necessary to accelerate the gases to their final velocity, plus friction head losses. This difference of pressure is called draft whether measured above or below atmospheric pressure. The range of pressures required is most easily measured by manometers reading in inches of water.

4. In meteorology, a manometer measures pressures in terms of a displaced column of water. The pressure may be obtained from the manometer reading by employing the factor relating a head of water to the pressure produced at its base. It requires 2.31 feet (0.693 meter) of water to result in a pressure of 1 psi (0.07 atmosphere). The ordinary draft gage is a variation of the U-tube manometer.

5. In heating engineering, requisite draft can be obtained by use of chimneys, fans, steam or air jets, or combinations of these. The chimney is probably the most common, but the least understood of any of them. At one time the chimney was universally used as the sole means for producing a draft and even now it is relied on entirely in many small plants and partially in most of the large ones.

Mechanically draft may be classified as *forced* or *induced*, the former having the combustion air placed under a plenum, the latter referring to gas movement into a region of partial vacuum. With forced draft alone, furnace gases seep outward through cracks in walls, and blow through opened doors and ports. Induced draft alone allows considerable undesirable dilution of the products of combustion unless furnace, casings, ducts, etc., are maintained airtight. A logical compromise is to use both systems in a *balanced draft* adjusted to maintain atmospheric pressure (or a slight vacuum) in the furnace. Thereby, expansion cracks, opened doors, etc., will not cause undesirable gas or air flows.

DRAG. The frictional impedance offered by air to the motion of bodies passing through it. More precisely, the component of aerodynamic force parallel to the direction of mean flow. At very low speeds, most of the drag exerted by the air on a body moving through it is due to viscous drag (or skin friction) acting through a fairly thin boundary layer. In the case of spheres, the low-speed air resistance is given by Stokes's law. For higher speeds, so-called form drag or pressure drag arises as a result of separation of the laminar boundary layer creating a wake region of chaotic flow in which the pressure is reduced. In general, for large Reynolds numbers, form drag is far more significant than viscous drag. The velocity dependence of air resistance changes more or less continuously from linear dependence in the viscous range to velocity-squared dependence at high speeds. The latter dependence is given by Rayleigh's formula,

$$\text{drag} = \tfrac{1}{2} C_D \rho L^2 U^2$$

where ρ is the density of the medium, L a characteristic linear dimension of the body, and U the speed of the body relative to the fluid. The drag coefficient C_D is proportional to an experimentally determined power of the Reynolds number. At speeds approaching that of sound, an additional source of drag arises out of the formation of shock waves. See also **Aerodynamics and Aerostatics**; **Airplane**; **Helicopters and V/Stol Craft**; and **Supersonic Aerodynamics**.

DRAG COEFFICIENT. A dimensionless ratio of the component of force parallel to the direction of flow (drag) exerted on a body by a fluid to the kinetic energy of the fluid multiplied by a characteristic surface area of the body.

In symbols, the drag coefficient C_D is

$$C_D = \frac{\text{force of resistance}}{\frac{1}{2}\rho U^2 L^2},$$

where is the fluid density, U the speed, and L a characteristic length of the body. Rayleigh's formula expresses the drag coefficient as proportional to a power of the Reynolds number (Re),

$$C_D = \text{const.}(\text{Re})^n.$$

For Couette flow, $n = -1$ and the constant is 2. In most aerodynamic experiments n lies between $-1/4$ and $-1/2$. The drag coefficient for the force exerted by the atmosphere on the earth is called the skin-friction coefficient.

AMS

DRAG EFFECT. The effect of interionic attraction in reducing the freedom of an ion to move in an electrical field, because of the interference of the ions of opposite charge by which a given ion is surrounded. The drag effect is an essential part of the explanation of the Debye-Hückel theory of the anomalous properties of concentrated solutions of strong electrolytes. See also **Electrochemistry**.

DRAG FOLD. In geology, a smaller fold included in major folds. Produced by the shearing stresses set up within a fold by the relative movements of strata parallel to their bedding planes.

DRAG LAW. The relationship between wind speed and force caused by the wind against objects or along surfaces.

Force per unit area of the wind parallel to the ground is called surface stress, τ, resulting in a drag law of the form

$$\tau = C_D \rho M^2 \text{ or } u_*^2 = C_D M^2,$$

where C_D is a drag coefficient, M is wind speed, is air density, and u^* is friction velocity, which when squared equals the kinematic surface stress $\tau/$. Most atmospheric flows near the surface are turbulent, resulting in drag coefficients that must be determined empirically rather than by using molecular properties such as viscosity or Reynolds number. See also **Drag**.

AMS

DRAG LINE. The drag line excavator consists of a turntable on wheels or caterpillar treads, which supports the excavating machinery. A long boom is pivoted at its lower end to the turntable, and guyed at its outer end by a rope sheave. Extra-long booms are characteristic of the drag line excavator because the loading of the bucket is by scraping action in contrast to the shoveling action of a grab bucket. By the use of the boom, to which is attached the scraper, with the intermediary of a block and tackle, the operator can place the scraper bucket at a distance of 25–100 feet (7.5–30 meters) from the position of the excavator. The scraper has attached to it a drag line that is wrapped around a powered drum in the cab. As this drag line is reeled in, it drags the scraper bucket and fills it, after which it is hoisted and dumped wherever wished. The drag line excavator has been built in very large capacities, and is especially suitable for such work as levee building, borrow pit work, etc.

The drag line scraper is a means for stocking-out bulk material to storage and reclaiming the same. Drag lines also are used in large coal-mining operations where the coal is near the surface. It is comparatively low in first cost, and adaptable to a storage lot of irregular area. A head post and machinery house is located at the point from which stocking-out begins, and to which reclamation moves. A movable tail tower may be operated at different points along the edge of the storage lot farthest from the head post. Between the tail tower and head post is an endless wire cable, to which is attached a scraper bucket. This passes over the drive sheave in the head tower. The drive may be reversed, and the bucket caused to move out on the stock pile and then be returned, scraping up a full load of loose material as it comes. See also **Coal**.

DRAGONETS *(Osteichthyes)*. Of the order *Percomorphi*, suborder *Callionymoidea*, and family *Callionymidae*, dragonets are a rather ugly-appearing fish with a sharp spine of a hook-like nature. The gill opening is very small and located on the upper portion of the head. These fishes are frequently very colorful with slender, flattened bodies. They are found worldwide in both tropical and temperate waters and prefer the bottom. They range from 4 to 8 inches (10 to 20 centimeters) in length. A separate family, the *Draconettidae*, embraces the dragonets of a more primitive nature. These fishes have a somewhat different anatomy, including very broad gill openings. They usually frequent reasonably deep water.

DRAGON FLY *(Insecta, Odonata)*. Large insects of powerful flight that eat other insects caught in the air. The immature insect is aquatic and predacious. The order is composed of dragon flies and damsel flies only. All have four slender net-veined wings and long slender bodies, but the dragon flies have fore and hind wings of slightly different shape and hold them extended when at rest. Also called devil's darning needles.

The dragon fly is considered one of the ancient insects, along with grasshoppers, cockroaches, and crickets. Fossil evidence indicates that some of the early dragon flies measured two feet from wing tip to wing tip. The period of development of the dragon fly ranges from 1 to 4 years, with 10 to 15 larvae stages. The wings appear after the third or fourth molt. Swift, graceful insects that patrol the banks of ponds and lakes, dragon flies are harmless.

DRAINAGE SYSTEMS. Designing an effective drainage system is an important aspect in the civil engineering of numerous structures, notably airport runways, railroad, highways, tunnels, and sport arenas, as well as conventional commercial, industrial, and residential structures. In addition to assuring the convenience, comfort, and safety of non-flooded surfaces, adequate drainage is required to stabilize slopes, prevent mud slides during

periods of excessive rainfall, assure dry basements (thus protecting an inventory of stored goods), and to prevent the weakening of underlying foundations and ultimate collapse of all or parts of a structure. As water content increases, the strength of soil generally decreases. Attention to drainage is particularly important in areas that may be arid for months, but subject to excessively heavy storm conditions for but brief periods.

Before the best suited drainage system can be proposed, a soil and topographical study of the site is required. The availability of natural channels to provide the most economic means for conveying surface drainage must be ascertained. Careful estimates must be made of the amounts of water that may have to be carried away during the worst possible conditions, such as 50- and 100-year storms. Preliminary studies, while an item of cost which a developer or builder might prefer to put into actual construction rather than planning, frequently will alter plans in a way to conserve total project funding. In some instances, it may be found that provision for adequate draining may be excessively costly and that selection of an alternate site would be the most economical solution. Once construction is commenced and it is found that severe drainage problems are encountered which were not a part of the original plan, drainage system costs may become several fold what they might have been if part of an original plan.

A useful formula for estimating rainfall runoff is

$$Q = CIA$$

where Q = quantity of runoff, cubic feet/second
C = average runoff coefficient. This is affected by slope, soil, land cover, and time of concentration, and essentially is the percentage of rain that appears as direct runoff
I = intensity of rainfall, inches/hour
A = area under consideration, acres

(Where Q is expressed in cubic meters/second; I in centimeters/hour; and A in hectares, if using coefficients of Table 2, use a multiplying constant (k) of 0.082.)

Where exact land use is known, a precise runoff coefficient can be established. Unfortunately, this is not usually the case, particularly where a variable land use in the lower reaches of the area may not yet be planned or even postulated. Thus, frequently a calculated composite coefficient must be used.

Assumptions made in calculating a composite coefficient include: (1) the maximum rate of runoff considering that a specific rainfall intensity will occur if the duration of the rainfall equals or is greater than the time of concentration; the time of concentration is defined as the time period needed for the water to flow from the far distant point of a drainage basin to a point of flow measurement; (2) the maximum rate of runoff, considering a specific rainfall intensity (the duration of which equals or is greater than the time of concentration), will be directly proportional to the rainfall intensity; (3) the peak discharge (per unit area) will decrease as the drainage area increases, and the intensity of rainfall will decrease as its duration increases; and (4) the coefficient of runoff will remain constant for all storms on a given watershed.

Common runoff coefficients are given in Table 1. Some refinements to runoff coefficients are made by special agencies, such as the Los Angeles County Flood Control District which provide runoff coefficients as a function of the soil and area type and of the rainfall intensity for the time of concentration.

The Steel formula is one of the most useful tools for determining the factor I in the foregoing runoff formula. The Steel formula is

$$I = \frac{K}{t + b}$$

where K and b depend on the storm frequency and region of the United States in which the site is located. The United States is broken down into seven regions which take into consideration the 50- and 100-year storm occurrences. See Fig. 1.

In planning a drainage system, the height of the water table at the site is of paramount importance. It is very costly to lower the water table even temporarily during construction. Thus, wherever possible, the new construction should not penetrate the water table. Sometimes it is possible to lower the water table permanently through the use of gravity draining or automatic pumping. These are usually quite costly approaches. In some instances, it may be best to alter the overall development plan and relocate the planned structure to a better-suited site.

TABLE 1. COMMON RUNOFF COEFFICIENTS FOR URBAN AREAS

Category of Drainage Area	Runoff Coefficient C
Industrial	
Light areas	0.50–0.80
Heavy areas	0.60–0.90
Railroad-yard areas	0.20–0.40
Business	
Downtown areas	0.70–0.95
Neighborhood areas	0.50–0.70
Streets	
Asphaltic	0.70–0.95
Concrete	0.80–0.95
Brick	0.70–0.85
Drives and walks	0.75–0.85
Residential	
Single-family dwelling areas	0.30–0.50
Detached multiunits	0.40–0.60
Attached multiunits	0.60–0.75
Suburban	0.25–0.40
Apartment building areas	0.50–0.70
Parks and cemeteries	0.10–0.25
Playgrounds	0.20–0.35
Unimproved areas	0.10–0.30
Roofs	0.75–0.90
Lawns	
Sandy soil, flat (2%)	0.05–0.10
Sandy soil, average (2–7%)	0.10–0.15
Sandy soil, steep (7%)	0.15–0.20
Heavy soil, flat (2%)	0.13–0.17
Heavy soil, average (2–7%)	0.18–0.22
Heavy soil, steep (7%)	0.25–0.35

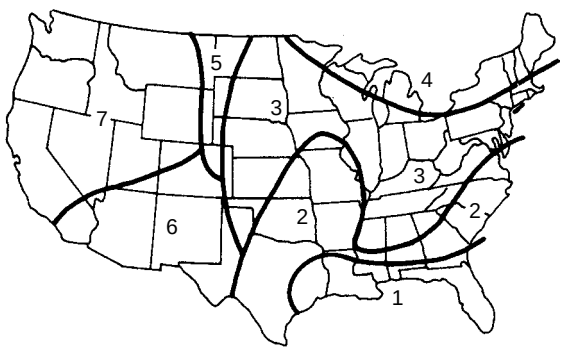

Fig. 1. Geographical regions referred to in Table 2.

Necessary to planning a drainage system is a full understanding of the permeability and drainage characteristics of the underlying soil. Permeability is dependent upon the density of the soil, the degree of water saturation, and particle size of the soil. The coefficient of permeability is defined by Darcy's law

$$Q = kiA$$

where Q = rate of flow of water through a soil mass, cubic centimeters/second
i = hydraulic gradient (or total head lost) per unit of flow distance, centimeters/centimeter
A = total cross-sectional area of soil through which flow occurs, square centimeter

The Darcy law is useful for estimating gravitational flow, but does not take into consideration the movement of water by capillary action, water held by adsorption, or flow of water by osmosis. For inclusion in the Darcy formula, values of k are given in Table 2.

Numerous drainage designs are available. The simplest and least costly solutions provided they are adequate include the laying of intercepting drains along the contours of the site and, alter construction, covering these areas with heavy mulching and planting to prevent percolation of water downward into the soil. Gravity flow systems are usually best to achieve the permanent stabilization of slopes. If there is artesian pressure present, then vertical wells may be used. In some instances, sand drains

TABLE 2. VALUES OF K AND b FOR STEEL FORMULA

$$I = \frac{K}{t + b}$$

Storm Frequency (Years)	Coefficients	Region of the United States 1	2	3	4	5	6	7
2	K	206	140	106	70	70	68	32
	b	30	21	17	13	16	14	11
5	K	247	190	131	97	81	75	48
	b	29	25	19	16	13	12	12
10	K	300	230	170	111	111	122	60
	b	36	29	23	16	17	23	13
25	K	327	260	230	170	130	155	67
	b	33	32	30	27	17	26	10
50	K	315	350	250	187	187	160	65
	b	28	38	27	24	25	21	8
100	K	367	375	290	220	240	210	77
	b	33	36	31	28	29	26	10

or piles are used to compact, stabilize, and drain compressible material. Such piles sometimes are an economical solution for supporting loads on soil with much smaller bearing capacity than sand. In essence, these are cylindrical piles of sand in the ground of 18 to 20 inches (45.7 to 51 centimeters) in diameter and placed from 6 to 10 feet (1.8 to 3 meters) apart. Essentially, the piles perform as wicks for the water squeezed from the soil. They accelerate settlement of the poor material, thus allowing pore water to drain. Once the holes are filled with sand, a drainage blanket and a surcharge are placed over the area. This expedites consolidation of the soil.

Permanent pumped installations become a more costly solution, considering the additional hydraulic engineering required and the years of maintenance of automatic pumping equipment, including standby equipment.

Although electro-osmosis also is relatively expensive, it sometimes is the optimal solution for certain conditions. In this system, two electrodes are installed in saturated ground. Direct current is applied and the ground water normally moves to the cathode. From this point, the water can be pumped out through a wellpoint. Hydrogen ions (positive) are produced by electrolysis of the water. These ions replace the positive ions in fine-grained soils as they move to the cathode. It is the movement of the ions that induces flow of water in the same direction. This method is particularly effective with silts, normally difficult to drain simply by use of open pumping or with wellpoints.

DRAWBRIDGE. See **Bridge (Structural)**.

DRAWING. One use of this term is in reference to an operation performed on metal. The metal is originally in the form either of sheets, solid blanks, or pierced billets. These are formed in suitable dies into many different shapes, such as hollow cylinders, cup-like parts, or solid parts of various shapes. Pipe, wire, and various structural shapes are often formed by drawing. Drawing reduces the thickness of the metal.

DREDGE. An excavating machine for use in river, harbor, or drainage work is a dredge. A characteristic application of the dredge is in submarine excavation. Dredges are usually floated on watertight hulls. There are several types, which may be classified according to the way they excavate. The dipper dredge, which is the more common type, is very similar to a locomotive crane, except that it is mounted on a floating hull. Its digging equipment consists of a dipper or grab bucket, which is able to dip as deep as 50 feet (15 meters) below the water surface. This type of dredge may be used in dredging channels or in cutting a wide drainage ditch provided the ditch is large enough to float the dredge. This dredge will dig its own waterway through land, and is particularly useful for drainage work. A dredge where the excavating is done by a number of buckets placed on an endless chain is known as an elevator dredge. A bucket chain is able to elevate the spoil considerably higher than other types. It is frequently used to raise sand and gravel from a stream bed.

The hydraulic dredge digs by suction of the spoil material from the bottom. A pipe is lowered to the area to be dredged. A large power-driven rotary cutter is rigged in front of the entrance end of this pipe. Operation of the cutter breaks up the soft material of the bottom so that it may readily be transported by a current of water. A water pump attached to the upper end creates a powerful flow of water through the pipe, which picks up and carries the loose material near the mouth of the pipe. Large, specially designed centrifugal pumps create the flow.

DREIKANTER. Literally a 3-cornered or 3-edged pebble. A term of German origin signifying a pebble that has been sculptured or faceted by natural sandblasting. Such pebbles are usually considered to be proof of the semi-arid or even desert condition under which they have been formed, but they may also be formed in pluvial climates provided that the regolith is composed of porous and shifting sands such as compose glacial sand plains and coastal beaches. They are also called gibbers or glyptoliths.

DREWITE. A term proposed by R.M. Field in 1918 for pure calcium carbonate muds of organic chemical origin. Drewite probably forms the bulk of the fine-grained nonfossiliferous limestone from the pre-Cambrian to the present. It was named after G.H. Drew, a pioneer in the study of marine bacteria.

DRIED-FRUIT INSECTS. Wherever dried fruits are produced, whether in the Mediterranean Basin, South Africa, southern Australia, or California, their chief insect pests are the same species. They have been distributed by commerce, probably for several thousand years. Losses caused by insects in dried fruits are difficult to estimate. The loss of weight from insect feeding is usually trivial. The most serious loss is in appearance and quality, which lowers or destroys market value. The presence of insects or any other foreign material in dried fruit obviously is objectionable to consumers. Other losses from insects in dried fruit include the cost of construction and maintenance of facilities for fumigation, the cost of fumigants, and the expense of applying them. Insects are chiefly responsible for the waste involved in culling out damaged dried fruit, and the costs of screening and washing of fruit, general plant sanitation, and cold storage. Special packages designed to resist and exclude insects add to the expense.

Beetles. The beetles associated with dried fruits develop through 4 stages: egg, larva, pupa, and adult. Most of the eggs hatch within 5 days. The eggshells are thin, and the embryos either hatch within 2 or 3 weeks or die. Larval life proceeds through a varying number of molts and abrupt size changes. Feeding is continuous except when the temperature falls below 45 °F (7.2 °C). Overwintering larvae can feed occasionally on warm days. Beetle pupae develop in cracks in boxes, creases in dried fruits, under bark, or in cells in the soil or ground litter. During the pupal stage, the body structure is completely rearranged, and the resulting adult bears little or no resemblance to the larva from which it developed. The transformation may take only a week or two, or may be prolonged several months by cold weather. As a rule, adult beetles are active feeders. Because some of them live longer in the adult stage than as a larva, they damage dried fruits even more than their larvae do. All of the principal species, except possibly the sawtoothed grain beetle, can fly. They infest commodities by flying or crawling into storage buildings, or by being carried in with dried fruits.

Sawtoothed Grain Beetle (*Oryzaephilus surinamensis*, Linnaeus). This insect is described in the entry on **Grain Storage Insects**. In raisins stored

for a year or more, the insect can become very abundant. It is not numerous in spring; numbers declining markedly during hot weather.

Merchant Grain Beetle (*Oryzaephilus mercator*, Fauvel). Similar in habits and appearance to the sawtoothed grain beetle. See Fig. 1. The insect has been found in waste dates, on the ground in the Coachella valley (California) date gardens, and in cull figs in the Fresno district. It does not endure low temperatures well, nor do the females lay as many eggs as the sawtoothed grain beetle.

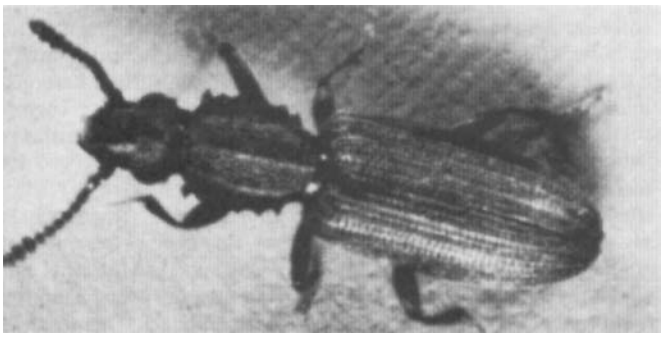

Fig. 1. Merchant grain beetle. (*USDA photo.*)

Small Darkling Beetles (*Blapstinus* species). These are found in orchards. The most common is Blapstinus rufipes (Casey), a dull black, somewhat flattened beetle about $\frac{1}{4}$ inch (6 millimeters) long. These beetles congregate on ripe figs that have fallen to the ground. They may be so numerous as to completely cover a fig. Only fragments of their life history have been recorded. The adults appear in June at about the time the first crop of figs ripen and fall to the ground. The larvae probably develop on plant materials in the soil. As the season advances, they gradually disappear.

These beetles attack tender plants. Young bell pepper plants have been girdled at the soil surface, and as many as 75 adult beetles have been counted around a single seedling. Several species, including *B. rufipes*, have been observed attacking young plants of sugar beet, lima bean, and tomato.

Hairy Fungus Beetle (*Typhaea stercorea*, Linnaeus). A polished, brown, elongate-oval beetle about $\frac{1}{10}$ inch (2.5 millimeters) long. The body is well covered with short, fine hairs. It is a member of the family *Mycetophagidae*, or fungus eaters. It is common in moldy dates lying on moist soil and in moldy raisins. Other foods eaten by this species include stored grain and seeds, tobacco, and cacao. Adults fly in the evening shortly after sunset. On moist, moldy raisins, this beetle develops from egg to adult in 3 weeks. It spends 3 days in the egg, 14 days as a larva, and 4 days as a pupa. See Fig. 2. Newly hatched larvae are unable to develop on clean raisins, but larger larvae can.

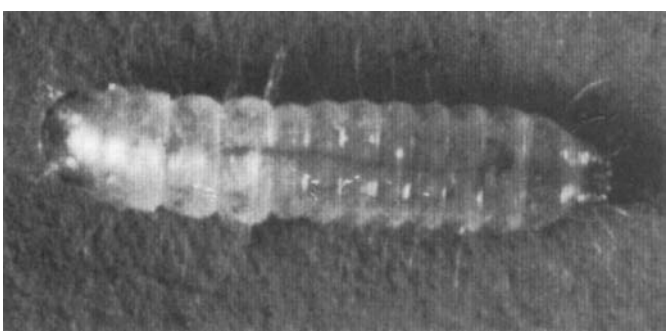

Fig. 2. Larva of hairy fungus beetle. (*USDA photo.*)

Driedfruit Beetle (*Carpophilus hemipterus*, Linnaeus). Adult driedfruit beetles are about $\frac{1}{8}$ inch (3 millimeters) long and black, with 2 amber-brown spots on each wing cover, one near the tip and a smaller one at the outer margin of the base. They are strong fliers, but fly only during daytime when temperature is above 63 °F (17.2 °C). They may travel as far as 4.5 miles (8.3 kilometers) per day.

These beetles, of the family *Nitidulidae*, are among the chief pests of ripening and drying figs. Adults and larvae may be found during the winter and at other times in fruit dumps, rotting melons, stick-tight pomegranates, dropped peaches, plums, citrus fruits, cull figs, and moist raisins. They do not attack sound fruit, but prefer overripe, fermenting, and rotten fruit. This species thrives in fermenting grape pomace, a winery by product. When raisins are being made, damaged grapes, especially those with bunch rot, attract these beetles to the drying trays. Fruit that is very dry or far advanced in decay ceases to attract them. However, larvae that begin growth in overripe figs, for example, may continue their development after the fruit is fairly dry. Much waste fruit falls to the ground under fruit trees and often squashes and cracks open. In date gardens, where frequent irrigation keeps the soil surface moist, dried-fruit beetles abound in fallen waste dates.

Adults feed and larvae develop in a moist, dark environment of yeasty and often moldy pulp. These beetles carry yeasts and mold spores in and on their bodies and inoculate ripening figs with plant diseases. In addition, they carry peach brown rot and bunch rot of grapes. Adults also visit the sap flow of bark wounds in trees that produce a flow of wet and consequently fermentable sap.

Larvae reach a length of $\frac{1}{4}$ inch (6 millimeters) when fully grown. They are white to yellowish. The head and rear end are amber-brown. They are sparsely hairy and have two prominent spine-like projects at the tail end, with two smaller ones in front of them. See Fig. 3. Pupae are about $\frac{1}{8}$ inch (3 millimeters) long, white or pale yellow, and somewhat spiny. No cocoon is formed. The species usually overwinters as pupae in cells in the soil. Larvae and pupae of nitidulids have been found as deep as 2 feet (0.6 meter) in dry soil in a fig orchard, but most are in the upper 8 inches (3 centimeters). Hundreds of fully grown larvae, pupae, and recently transformed adults may be present under each tree in early spring. New adults emerge late in February and early March. By late April, all have left the soil. A combination of light rainfall and a mild winter favors above-average survival of driedfruit beetles, but a cold, wet hibernation period reduces the population. On warm days in winter, a few adults have been captured in rotary net flight traps.

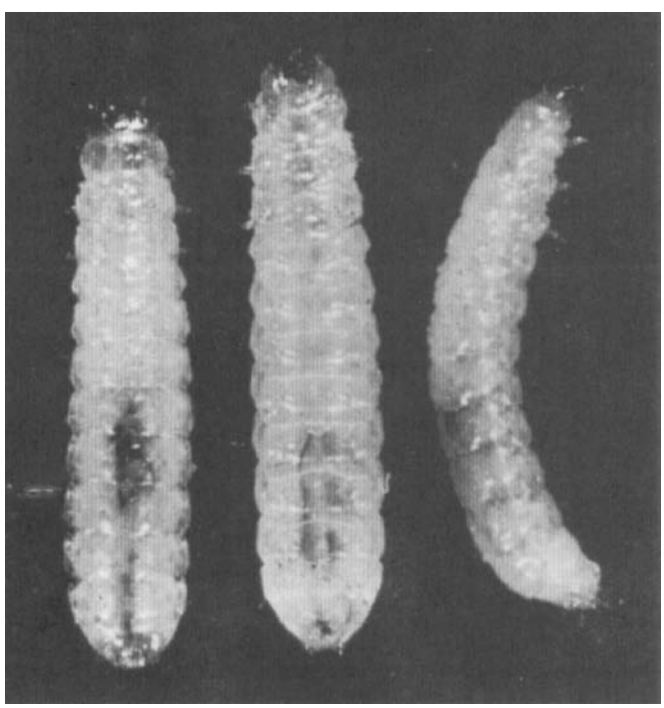

Fig. 3. Larvae of dried-fruit beetle. (*USDA photo.*)

The species have a short developmental period and a long adult life. At 90 °F (32.2 °C), the incubation is 1 day, the larval period is 12.4 days, and the pupal period is 5.8 days. The total from egg to adult is 19.2 days, but may be short as 12 days. Mated females may average 103 days of life and males, 146 days. Total egg production may average more than 1000. The record for one female is 2134 eggs, laid over a period of 79 days.

Corn Sap Beetle (*Carpophilus dimidiatus*, Fabricius). The adult resembles driedfruit beetle, but has no spots and color ranges from brown-yellow through brown-black tinged with red. They are $\frac{1}{16}$ to $\frac{1}{8}$ inch (1.5 to 3 millimeters) long. They fly at any time of day. Food habits are similar to those of driedfruit beetle. They are very common in cull grapefruit and cull dates. Corn sap beetles are particularly fond of developing ears of sweet corn that have been previously damaged by insects or birds. Among their host foods are apple pomace, rotten watermelons, stored groundnuts (peanuts) with split hulls, inferior copra, sago flour, coarse bran, and brazil nuts. Periods from egg to adult is about 2 weeks. Adults live about 60 days. Those that overwinter live up to 200 days. Total egg production of one female is about 200.

Yellow Nitidulid (*Haptoncus luteolus*, Erichson). Very similar to driedfruit and corn sap beetle. They are of a blunt shape and yellow-brown. They do not fly during midday, but are numerous in early morning and late afternoon. Large numbers have been trapped in the San Joaquin and Coachella valleys of California.

Pineapple Beetle (*Urophorus humeralis*, Fabricius). The adults are shiny black, nearly $\frac{3}{16}$ (4.5 millimeters) long. They fly in daytime and are more numerous in date gardens than in fig orchards. Pineapple beetles feed in bunches of dates ripening on the palms. They are the dominant species in Hawaiian pineapple fields, where they feed on fermenting trash left from harvesting. In sugarcane fields, they develop in souring cane trash and damage seed pieces of cane underground. In the Coachella valley, they are abundant in waste grapefruit. From egg to adult requires 16.5 days. Females lay an average of about 880 eggs. Adults reared on pieces of pineapple stump lived an average 89 days.

Leadcable Borer (*Scobicia declivis*, Le Conte). Cylindrical, dark brown or black beetles from $\frac{1}{8}$ to $\frac{1}{4}$ inch (3 to 6 millimeters) long. See Fig. 4. They develop in dead parts of trees. In central California, they fly in the early evening. These insects rarely enter figs. They sometimes bore holes in the laminated paper covers used to enclose raisin stacks for fumigation. They cause losses in wineries by boring into wine barrels and casks. In the past, the adults have caused considerable trouble by boring holes in lead sheaths of telephone cables, thereby allowing dampness to enter the cable. The insects are attracted to products of fermentation and can be baited with ethyl alcohol traps.

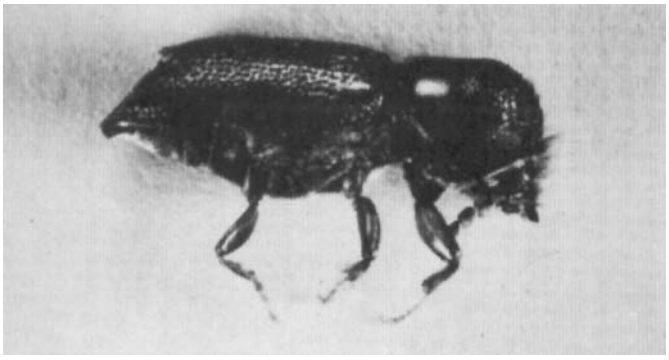

Fig. 4. Adult leadcable borer. (*USDA photo*.)

Date-Stone Beetle (*Coccotrypes dactyliperda*, Fabricius). A minute cylindrical, shiny, dark-brown beetle. It is a close relative of the bark beetles and is common in seeds of waste dates in the Coachella valley. The insect also infests sweet almonds in the Orient and the hard seeds, known as vegetable ivory, produced by several species of palm in Africa. Buttons made from vegetable ivory are also attacked. Thus another name for the insect is *button beetle*. Other hosts are betel nut, nutmeg, and cinnamon bark.

Moths. None of the adult moths can feed, although they do drink liquids, such as plant nectar. The damage is done while they are larvae.

Raisin Moth (*Cadra figulilella*, Gregson). This is a small, gray moth formerly known as *Ephestia figulilella*. Larvae were first noticed in the Fresno, California area in 1928 on muscat raisins. They reached a peak of abundance in 1930. These insects live and develop out-of-doors, although they are often brought into storages with infested commodities. The larvae attack all the usual varieties of drying and dried fruits, fallen figs, and damaged or moldy clusters of grapes and vines. Raisins are attacked until they become unattractively dry. Cottonseed cake, cacao beans, and cashew kernels are among the host foods. Fallen mulberries are important because they are available to the insects early in spring when other food is scarce.

Female raisin moths deposit eggs on all common varieties of drying and dried fruits. From egg to adult requires about 43 days at 83 °F (28.3 °C). Larvae usually molt 6 times. Larval life is greatly extended during winter. In raisin storage, any larvae that escape fumigation continue to feed, and in the spring they pupate and emerge. In vineyards, most of the larvae pass the winter in cocoons in the upper few inches of soil near the vine trunks and along the wires. In fig orchards, many larvae overwinter in a 6-inch (15-centimeter) band of soil around the tree trunks. The overwintering larvae pupate in the spring. Emergence of adult moths begins in April and reaches a peak in May. There are about three overlapping broods per year. In summer, mated females provided with sufficient water average about 350 eggs, with a record noted of 692 eggs. Most eggs are laid in early evening.

Dusky Raisin Moth (*Ephestiodes gilvescentella*, Ragonot). Formerly called *Ephestiodes nigrella* (Hulst), this species resembles the raisin moth in size and appearance. They are found in vineyards and in raisin storage areas. There is a new generation about every 2 months.

Indian Meal Moth (*Plodia interpunctella*, Hübner). This moth also attacks stored grain products and is described in entry on **Grain-Storage Insects**.

Dried-fruit Moth (*Vitula edmandsae serratilineela*, Ragonot). The adult is a mottled gray and about $\frac{3}{4}$ inch (18 millimeters) long. The moth was first reported in California (Santa Clara County) in 1903. The moth is not abundant, but is frequently collected from stored figs, raisins, and prunes in the Santa Clara and San Joaquin valleys. They were much more numerous in early years when large tonnages of raisins were stored in the San Joaquin valley for up to 4 years without insect abatement measures.

Dried-Prune Moth (*Aphomia gularis*, Zeller). The larvae are capable of serious damage. When fully grown, they are more than 1 inch (2.5 centimeters) long and produce considerable webbing and coarse excreta. Before spinning a cocoon for pupation, they frequently excavate a shallow depression in the wood of bins or boxes. The insect is now uncommon in California.

Navel orangeworm (*Paramyelois transitella*, Walker).

Flies. The principal species of fly that attacks dried fruits is *Drosophilia*. See entry on **Drosophila**.

Soldier Fly (*Hermetia illucens*, Linnaeus). Black, two-winged insects that resemble some of the four-winged mud-dauber wasps in size, color, and habit. The larvae or maggots are large, brownish, and flattened and have a tough skin. The larvae feed in accumulations of rotten fruit that are dried out, decayed, and black. In New Zealand, they sometimes damage honeybee colonies by feeding on wax, pollen, and honey. These flies overwinter as larvae.

Wasps and Bees. Large numbers of minute *Bracon hebetor* wasps are sometimes seen flying over dried fruit in storage in the fall. They are parasites of storage moth larvae, including the Indian meal moth and the raisin moth. Larger larvae of the moths are paralyzed by the female wasp. Although this wasp kills many moth larvae, its value in suppressing moth infestations has not been determined.

The wasp *Cephalonomia tarsalis* (Ashmead) is small, black, and a common external parasite of the larvae and pupae of the sawtoothed grain beetle. It is only 0.06-inch (1.5 millimeters) long. Winter is passed in the pupal stage. The cocoons of this parasite are frequently seen where sawtoothed beetles are plentiful. However, it is not considered very effective in controlling the beetle.

Fig Wasp (*Blastophaga psenes*, Linnaeus). This insect is described in entry on **Chalcid Wasp**.

DRIESCH, HANS ADOLF EDUARD (1867–1941). Hans Driesch was a German biologist and philosopher who made contributions to experimental embryology and was one of most prominent proponents of vitalism in twentieth century biology.

Driesch, who was from a rich merchant's family in Hamburg, received his schooling at the famous Joachimsthaler Gymnasium. From 1886 he studied zoology in Freiburg (with August Weismann) and Jena (with Ernst Haeckel and Oscar Hertwig). After a year in Munich, where he studied chemistry and came to know Gustav Wolf who raised his doubts about Darwinism, he returned to Jena, taking his doctorate with Haeckel in 1889 and writing on the developmental history of hydroid polyps. Turning down Haeckel's offer of an assistantship Driesch spent most of the 1890s at the Stazione Zoologica Anton Dohn in Naples which he left for Heidelberg in 1900. In this period he began to develop his critique of Weismann's and Wilhelm Roux' mosaic theory of ontogenesis. In his most famous experiment he succeeded in showing that if sea urchin egg blastomeres were split during cleavage, each part could develop into a whole rather than a half organism. The prospective potency of cells was thus much bigger than their prospective significance, as Driesch put it in 1894. In the 1890s he had adopted a neo-vitalistic style of thinking that supplied organic development with an agent-outside-of-the-machine force. Borrowing from Aristotle he came to call this regulatory force of organic development "entelechy." See also **Haeckel, Ernst Heinrich Philipp August (1834–1919)**; **Hertwig, Wilhelm August Oscar (1849–1922)**; and **Roux, Wilhelm (1850–1924)**.

Driesch got his Habilitation (postdoctoral lecturing qualification) in Heidelberg in 1907 for natural philosophy and subsequently developed his biological ideas into more philosophical dimensions. Starting with "Science and Philosophy of the Organism," first published in English in 1908, he became a philosopher of neo-Kantian direction. Having become a full professor of philosophy in Cologne (1920) and Leipzig (1921), Driesch increasingly included ethical and political issues in his thinking. In the 1930s he began studying parapsychological phenomena. Being a declared pacifist, democrat and outspoken critic of racism and anti-Semitism, he was prematurely sent into retirement by the National Socialists in 1933 and denied the right of public speech. Driesch, whose best-known was the biologist Hans Spemann, died in 1941. See also **Spemann, Hans (1869–1941)**.

DRIFT (Geology). Before Louis Agassiz propounded his theory that extensive deposits of sand, gravel, boulder clays, etc., of Northern Europe and North America were the result of the action of great continental ice sheets, it had been suggested that during some period when the land had stood at a lower level, icebergs were swept from the north over the continents and, melting, dropped their loads of detritus. Thus some of the material that we now know to be of glacial origin was called drift, because it was believed "drifted" to its place through the agency of ice. This was the theory of Sir Charles Lyell as a substitute for the still older theory of the diluvialists who believed that these glacial deposits were positive evidence of the "deluge." Geologists have retained the term drift to designate all unconsolidated sediments which are determined to be of glacial origin, and still further divide drift into stratified drift and unstratified drift or till.

In Great Britain, the term drift is used for all unconsolidated rock debris that may be transported from one location and deposited in another. Drift is distinguished from solid bedrock.

In Africa, the term drift is used to indicate a ford or a sudden dip in a road over which water may flow at times. In South Africa, the term is used for a ford in a river.

DRIFT (Instrument). With reference to industrial and scientific instruments, the Instrument Society of America defines drift as: a change in the output-input relationship over a period of time. Drift (deviation cycle) is defined as the maximum change in output for the same input and operating conditions obtained from a number of test cycles over a specified period of time. The operating conditions may vary between test cycle measurements provided they stay within normal operating conditions of the test device. Typical expression: The maximum drift for any point, at ambient temperature conditions ($75 \pm 2\,^{\circ}$F) ($23.9 \pm 1.1\,^{\circ}$C), and between tests not exceeding ambient temperature limits of 30 to $130\,^{\circ}$F (-1.1 to $54\,^{\circ}$C), was within 0.2% of output span for a period of 30 days.

Point drift is defined as the change in output over a specified period of time for a constant input under specified reference operating conditions. Point drift is frequently determined at more than one input, as for example: at 0%, 50%, and 100% of range. Thus, any drift of zero or span may be calculated. Typical expression: The drift at mid-scale for ambient temperature ($70 \pm 2\,^{\circ}$F) ($21.1 \pm 1.1\,^{\circ}$C) for a period of 48 hours was within 0.1% of output span.

DRIFT (Meteorological). The effect of the velocity of fluid flow upon the velocity (relative to a fixed external point) of an object moving within the fluid; the vector difference between the velocity of the object relative to the fluid and its velocity relative to the fixed reference. In air navigation, drift is often couched in terms of angular difference between heading and course, and thus can be produced only by a crosswind; when the wind velocity is parallel to the heading of the aircraft (direct headwind or tailwind), the drift is considered to be zero. The calculation of the drift (leeway) effects upon an ocean-going vessel is complicated by having to consider the combined effects of two fluids in motion.

DRIFT PIN. A tapered steel pin which is used during the fabrication of a member to hold the individual parts together before the fitting-up bolts (bolts which are necessary to draw the parts together subsequent to riveting) are inserted in the rivet holes. Drift pins are also used together with bolts in steel erection to fasten the members to the gusset plates or other connections before the field rivets are driven.

DRILLING. See **Earth Tectonics and Earthquakes**; **Natural Gas**; **Petroleum**; and **Polar Research**.

DRIZZLE. Very small, numerous, and uniformly distributed water drops that may appear to float while following air currents. Sometimes popularly called *mist*. Unlike fog droplets, drizzle falls to the ground. It usually falls from low stratus clouds and is frequently accompanied by low visibility and fog. In weather observations, drizzle is classified as 1) light, the rate of fall being from a trace to 0.3 mm (0.01 in.) per hour; 2) moderate, the rate of fall being from 0.3 to 0.5 mm (0.01–0.02 in.) per hour, and 3) heavy, the rate of fall being greater than 0.5 mm (0.02 in.) per hour. When precipitation equals or exceeds 1 mm (0.04 in.) per hour, all or part of the precipitation is usually rain. However, true drizzle falling as heavily as 1.3 mm (0.05 in.) per hour has been observed. By convention, drizzle drops are taken to be less than 0.5 mm (0.02 in.) in diameter. Larger drops are considered raindrops. See also **Precipitation and Hydrometeors**.

DROGUE. 1. A device, usually shaped like a funnel or cone, dragged or towed behind something and used, e.g., as a sea anchor.

2. A funnel-shaped part at the end of the hose of a tanker aircraft, used in air refueling to drag the hose out and stabilize it and to receive the probe of the receiving aircraft.

DROGUE RECOVERY. A type of recovery system for space vehicles or space capsules after initial reentry into the atmosphere using deployment of one or more small parachutes to diminish speed, to reduce aerodynamic heating, and to stabilize the vehicle so that larger recovery parachutes can be safely deployed at lower altitudes without too great an opening shock.

DROP. A small volume of liquid, bounded almost completely by free surfaces. The simplest way to form drops is to allow liquid to flow slowly from the open lower end of a vertical tube of small diameter. When the

pendent drop exceeds a certain size it is no longer stable and detaches itself and falls. Drops may also be formed by condensation of a supercooled vapor or by atomization of a larger mass of liquid. The weight of the largest drop that can hang from the end of a tube of radius, a, is nearly

$$mg = 2\pi a\gamma \cos\alpha$$

where γ is the surface tension of the liquid, α is the angle of contact with the tube. This relationship is the basis of a convenient method of measuring surface tension.

DROPLET. A small spherical particle of any liquid; in meteorology, particularly a water droplet. There is no defined size limit separating droplets from drops of water, but it is sometimes convenient to denote two disparate size ranges, such as the oft-used distinction of liquid cloud particles (droplets) from liquid precipitation (drops), thereby implying that a maximum diameter of 0.2 mm (0.008 in.) is the limit for droplets.

DROP-SIZE DISTRIBUTION. The frequency distribution of drop sizes (diameters, volumes) that is characteristic of a given cloud or of a given fall of rain.

Most natural clouds have unimodal (single maximum) distributions, but occasionally bimodal distributions are observed. In convective clouds, the drop-size distribution is found to change with time and to vary systematically with height, the modal size increasing and the number decreasing with height. For many purposes a useful single parameter representing a given distribution is the volume median diameter, that is, that diameter for which the total volume of all drops having greater diameters is just equal to the total volume of all drops having smaller diameters. The drop- size distribution is one of the primary factors involved in determining the radar reflectivity of any fall of precipitation, or of a cloud mass.

See also **Radar Reflectivity**; and **Clouds and Cloud Formation**.

AMS

DROSOMETER. An instrument used to measure the amount of dew formed on a given surface. One type consists of a hemispheric glass vacuum cup exposed to the atmosphere. Dew forming on the glass surface automatically collects in the bottom of the cup and is weighed at the end of the exposure period. Another form of drosometer, the Duvdevani dew gauge, consists of a block of wood with its surface treated in such a manner that dew forms in characteristic patterns. Photographs are supplied with each instrument to enable the observer to match the dew formation with a set of standards corresponding to a dew "fall" of from 0.01 to 0.45 mm (0.0004–0.018 in.).

DROSOPHILA *(Insecta, Diptera).* Also called the vinegar flies, fruit flies, or pomace flies, species of *Drosophila* are common wherever damaged or overripe fruit and vegetable garbage accumulate. They are the principal species of fly that attacks dried fruits. In the mild weather of late summer and early fall, *Drosophila melanogaster* (Meigen) and *D. simulans* (Sturtevant) become abundant in the San Joaquin valley of California, but they do not thrive in the hottest part of summer. In cool weather, *D. pseudobscura* (Frolowa) is more common. More than 50 other species are probably in the area, most of them of minor economic importance. See also entry on **Fruit Fly**.

D. melanogaster, the dominant species in the central valley of California, is a small, clear-winged fly with bright-red eyes and a shining black abdomen, the first 3 segments of which have a yellow band. The body is from $\frac{1}{16}$ to $\frac{3}{32}$ inch (1.5 to 2.5 millimeters) long. These flies are attracted to fermenting fruit waste, melons, piles of peach and apricot pits, damaged grapes, tomatoes, or other fruits. They are common in wineries and in and around tomato and fruit canneries. Cull-fruit dumps on farms and along roadsides swarm with vinegar flies. By leaving rotting fruit and entering figs, the flies inoculate the ripening figs with yeast cells, causing souring. They also contribute to the spread of bunch rot of grapes.

Activity of adult vinegar flies in the field is controlled chiefly by temperature, light intensity, and air movement. They are strong fliers and can fly more than 6 miles per day. They do not move in winds over 5 miles (8 kilometers) per hour. Light intensity of over 150 foot-candles tends to immobilize them. Fly activity may be fairly brisk in a fig tree with heavy foliage. Flies do not congregate in a tree with light foliage because both light and breezes penetrate it. They are active only during the day.

D. melanogaster has the most rapid reproductive rate of any dried-fruit insect. The flies spend only about 24 hours in the egg, 3 days as larva, and 3 days as a pupa, or a total of 7 days. Under some conditions, mature eggs are retained in the body of the female, and such eggs may hatch within 1 hour after they are laid. Adults may lay as many as 2000 eggs, but average about 1000. Females live about 39 days in warm weather, but up to 70 days in cooler weather. Life of the male is about 41 days.

From this fast reproductive cycle and large numbers of offspring produced, it is obvious why the *Drosophila* has been used for innumerable experiments in research and biological laboratories. Much genetic research has centered around these small flies. The general principles followed are well outlined by J. Marx in an article on "Getting a Jump on Gene Transfer in *Drosophila*" (*Science*, **1093**, September 6, 1991).

DROSS. The scum that collects on the surface of melted metal as a result of oxidation and the rising to the surface of impurities.

DROUGHT INDICES. Drought indices assimilate thousands of bits of data on rainfall, snowpack, streamflow, and other water supply indicators into a comprehensible big picture. A drought index value is typically a single number, far more useful than raw data for decision making.

There are several indices that measure how much precipitation for a given period of time has deviated from historically established norms. Although none of the major indices is inherently superior to the rest in all circumstances, some indices are better suited than others for certain uses. For example, the Palmer Drought Severity Index http://www.cpc.ncep.noaa.gov/products/analysis_monitoring/cdus/palmer_drought/, has been widely used by the U.S. Department of Agriculture to determine when to grant emergency drought assistance, but the Palmer is better when working with large areas of uniform topography. Western states, with mountainous terrain and the resulting complex regional microclimates, find it useful to supplement Palmer values with other indices such as the Surface Water Supply Index http://drought.unl.edu/whatis/indices.htm#swsi, which takes snowpack and other unique conditions into account.

The National Drought Mitigation Center http://www.drought.unl.edu/index.htm, is using a newer index, the Standardized Precipitation Index http://lwf.ncdc.noaa.gov/oa/climate/research/prelim/drought/spi.html, to monitor moisture supply conditions. Distinguishing traits of this index are that it identifies emerging droughts months sooner than the Palmer Index and that it is computed on various time scales.

Most water supply planners find it useful to consult one or more indices before making a decision. What follows is an introduction to each of the major drought indices in use in the United States and in Australia.

Percent of Normal

The percent of normal precipitation is one of the simplest measurements of rainfall for a location. Analyses using the percent of normal are very effective when used for a single region or a single season. Percent of normal is also easily misunderstood and gives different indications of conditions, depending on the location and season. It is calculated by dividing actual precipitation by normal precipitation — typically considered to be a 30-year mean — and multiplying by 100%. This can be calculated for a variety of time scales. Usually these time scales range from a single month to a group of months representing a particular season, to an annual or water year. Normal precipitation for a specific location is considered to be 100%.

One of the disadvantages of using the percent of normal precipitation is that the mean, or average, precipitation is often not the same as

the median precipitation, which is the value exceeded by 50% of the precipitation occurrences in a long-term climate record. The reason for this is that precipitation on monthly or seasonal scales does not have a normal distribution. Use of the percent of normal comparison implies a normal distribution where the mean and median are considered to be the same. An example of the confusion this could create can be illustrated by the long-term precipitation record in Melbourne, Australia, for the month of January. The median January precipitation is 36.0 mm (1.4 in.), meaning that in half the years less than 36.0 mm is recorded, and in half the years more than 36.0 mm is recorded. However, a monthly January total of 36.0 mm would be only 75% of normal when compared to the mean, which is often considered to be quite dry. Because of the variety in the precipitation records over time and location, there is no way to determine the frequency of the departures from normal or compare different locations. This makes it difficult to link a value of a departure with a specific impact occurring as a result of the departure, inhibiting attempts to mitigate the risks of drought based on the departures from normal and form a plan of response.

Standardized Precipitation Index (SPI)

The Standardized Precipitation Index (SPI) is a relatively new drought index based only on precipitation. The SPI can be used to monitor conditions on a variety of time scales. This temporal flexibility allows the SPI to be useful in both short-term agricultural and long-term hydrological applications.

The SPI values are given in Table 1.

TABLE 1. SPI VALUES

2.0+	extremely wet
1.5 to 1.99	very wet
1.0 to 1.49	moderately wet
−.99 to .99	near normal
−1.0 to −1.49	moderately dry
−1.5 to −1.99	severely dry
−2 and less	extremely dry

The understanding that a deficit of precipitation has different impacts on groundwater, reservoir storage, soil moisture, snowpack, and streamflow led T. B. McKee, N. J. Doesken, and J. Kleist Colorado State University, to develop the Standardized Precipitation Index (SPI) in 1993. The SPI was designed to quantify the precipitation deficit for multiple time scales. These time scales reflect the impact of drought on the availability of the different water resources. Soil moisture conditions respond to precipitation anomalies on a relatively short scale. Groundwater, streamflow, and reservoir storage reflect the longer-term precipitation anomalies. For these reasons, McKee et al. originally calculated the SPI for 3-, 6-, 12-, 24-, and 48-month time scales.

The SPI calculation for any location is based on the long-term precipitation record for a desired period. This long-term record is fitted to a probability distribution, which is then transformed into a normal distribution so that the mean SPI for the location and desired period is zero. Positive SPI values indicate greater than median precipitation, and negative values indicate less than median precipitation. Because the SPI is normalized, wetter and drier climates can be represented in the same way, and wet periods can also be monitored using the SPI.

McKee et al. used the classification system shown in the SPI values table to define drought intensities resulting from the SPI. McKee et al. also defined the criteria for a drought event for any of the time scales. A drought event occurs any time the SPI is continuously negative and reaches an intensity of -1.0 or less. The event ends when the SPI becomes positive. Each drought event, therefore, has a duration defined by its beginning and end, and an intensity for each month that the event continues. The positive sum of the SPI for all the months within a drought event can be termed the drought's "magnitude".

Based on an analysis of stations across Colorado, McKee determined that the SPI is in mild drought 24% of the time, in moderate drought 9.2% of the time, in severe drought 4.4% of the time, and in extreme drought 2.3% of the time. Because the SPI is standardized, these percentages are expected from a normal distribution of the SPI. The 2.3% of SPI values within the "Extreme Drought" category is a percentage that is typically expected for an "extreme" event (Wilhite 1995). In contrast, the Palmer Index reaches its "extreme" category more than 10% of the time across portions of the central Great Plains. This standardization allows the SPI to determine the rarity of a current drought, as well as the probability of the precipitation necessary to end the current drought.

The SPI has been used operationally to monitor conditions across Colorado since 1994. Monthly maps of the SPI for Colorado can be found on the Colorado State University website http://ccc.atmos.colostate.edu/standardizedprecipitation.php, It is also being monitored at the climate division level for the contiguous United States by the National Drought Mitigation Center and the Western Regional Climate Center (WRCC).

Palmer Drought Severity Index (PDSI)

In 1965, W.C. Palmer developed an index to measure the departure of the moisture supply. See Table 2. The Palmer Drought Index is based on a supply-and-demand model of soil moisture. Supply is comparatively straightforward to calculate, but demand is more complicated as it depends on many factors - not just temperature and the amount of moisture in the soil but hard-to-calibrate factors including evapotranspiration and recharge rates. Palmer tried to overcome these difficulties by developing an algorithm that approximated them based on the most readily available data — precipitation and temperature. See also **Evapotranspiration**.

TABLE 2. PALMER CLASSIFICATIONS

4.0 or more	extremely wet
3.0 to 3.99	very wet
2.0 to 2.99	moderately wet
1.0 to 1.99	slightly wet
0.5 to 0.99	incipient wet spell
0.49 to −0.49	near normal
−0.5 to −0.99	incipient dry spell
−1.0 to −1.99	mild drought
−2.0 to −2.99	moderate drought
−3.0 to −3.99	severe drought
−4.0 or less	extreme drought

The PDSI is a meteorological drought index, and it responds to weather conditions that have been abnormally dry or abnormally wet. When conditions change from dry to normal or wet, for example, the drought measured by the PDSI ends without taking into account streamflow, lake and reservoir levels, and other longer-term hydrologic impacts. The PDSI is calculated based on precipitation and temperature data, as well as the local Available Water Content (AWC) of the soil. From the inputs, all the basic terms of the water balance equation can be determined, including evapotranspiration, soil recharge, runoff, and moisture loss from the surface layer. Human impacts on the water balance, such as irrigation, are not considered. Complete descriptions of the equations can be found in the original study by Palmer and in the more recent analysis by Alley.

Palmer developed the PDSI to include the duration of a drought (or wet spell). His motivation was as follows: an abnormally wet month in the middle of a long-term drought should not have a major impact on the index, or a series of months with near-normal precipitation following a serious drought does not mean that the drought is over. Therefore, Palmer developed criteria for determining when a drought or a wet spell begins and ends, which adjust the PDSI accordingly. Palmer described this effort and gave examples, and it is also described in detail by Alley. In near-real time, Palmer's index is no longer a meteorological index but becomes a hydrological index referred to as the Palmer Hydrological Drought Index (PHDI) because it is based on moisture inflow (precipitation), outflow, and storage, and does not take into account the long-term trend.

In 1989, a modified method to compute the PDSI was begun operationally. This modified PDSI differs from the PDSI during transition periods between dry and wet spells. Because of the similarities between these Palmer indices, the terms *Palmer Index* and *Palmer Drought Index* have been used to describe general characteristics of the indices.

The Palmer Index varies roughly between −6.0 and +6.0. Palmer arbitrarily selected the classification scale of moisture conditions based on his original study areas in central Iowa and western Kansas. Ideally, the Palmer Index is designed so that a −4.0 in South Carolina has the same meaning in terms of the moisture departure from a climatological normal as a −4.0 in Idaho. The Palmer Index has typically been calculated on a

monthly basis, and a long-term archive of the monthly PDSI values for every climate division in the United States exists with the National Climatic Data Center from 1895 through the present. In addition, weekly Palmer Index values (actually modified PDSI values) are calculated for the climate divisions during every growing season and are available in the *Weekly Weather and Crop Bulletin*. These weekly Palmer Index maps are also available on the World Wide Web from the Climate Prediction Center at http://www.cpc.ncep.noaa.gov/products/analysis_monitoring/regional_monitoring/palmer.gif.

The Palmer Index is popular and has been widely used for a variety of applications across the United States. It is most effective measuring impacts sensitive to soil moisture conditions, such as agriculture. It has also been useful as a drought monitoring tool and has been used to trigger actions associated with drought contingency plans. Alley identified three positive characteristics of the Palmer Index that contribute to its popularity: (1) it provides decision makers with a measurement of the abnormality of recent weather for a region; (2) it provides an opportunity to place current conditions in historical perspective; and (3) it provides spatial and temporal representations of historical droughts. Several states, including New York, Colorado, Idaho, and Utah, use the Palmer Index as one part of their drought monitoring systems.

There are considerable limitations when using the Palmer Index, and these are described in detail by Alley and Karl and Knight. Drawbacks of the Palmer Index include:

- The values quantifying the intensity of drought and signaling the beginning and end of a drought or wet spell were arbitrarily selected based on Palmer's study of central Iowa and western Kansas and have little scientific meaning.
- The Palmer Index is sensitive to the AWC of a soil type. Thus, applying the index for a climate division may be too general.
- The two soil layers within the water balance computations are simplified and may not be accurately representative of a location.
- Snowfall, snow cover, and frozen ground are not included in the index. All precipitation is treated as rain, so that the timing of PDSI or PHDI values may be inaccurate in the winter and spring months in regions where snow occurs.
- The natural lag between when precipitation falls and the resulting runoff is not considered. In addition, no runoff is allowed to take place in the model until the water capacity of the surface and subsurface soil layers is full, leading to an underestimation of runoff.
- Potential evapotranspiration is estimated using the Thornthwaite method. This technique has wide acceptance, but it is still only an approximation.

Several other researchers have presented additional limitations of the Palmer Index. McKee et al. suggested that the PDSI is designed for agriculture but does not accurately represent the hydrological impacts resulting from longer droughts. Also, the Palmer Index is applied within the United States but has little acceptance elsewhere. One explanation for this is provided by Smith et al., who suggested that it does not do well in regions where there are extremes in the variability of rainfall or runoff. Examples in Australia and South Africa were given. Another weakness in the Palmer Index is that the "extreme" and "severe" classifications of drought occur with a greater frequency in some parts of the country than in others. "Extreme" droughts in the Great Plains occur with a frequency greater than 10%. This limits the accuracy of comparing the intensity of droughts between two regions and makes planning response actions based on a certain intensity more difficult.

Surface Water Supply Index (SWSI)

The Surface Water Supply Index (SWSI; pronounced "Swazee") was developed by Shafer and Dezman to complement the Palmer Index for moisture conditions across the state of Colorado. The Palmer Index is basically a soil moisture algorithm calibrated for relatively homogeneous regions, but it is not designed for large topographic variations across a region and it does not account for snow accumulation and subsequent runoff. Shafer and Dezman designed the SWSI to be an indicator of surface water conditions and described the index as "mountain water dependent", in which mountain snowpack is a major component.

The objective of the SWSI was to incorporate both hydrological and climatological features into a single index value resembling the Palmer Index for each major river basin in the state of Colorado (Shafer and Dezman 1982). These values would be standardized to allow comparisons between basins. Four inputs are required within the SWSI: snowpack, streamflow, precipitation, and reservoir storage. Because it is dependent on the season, the SWSI is computed with only snowpack, precipitation, and reservoir storage in the winter. During the summer months, streamflow replaces snowpack as a component within the SWSI equation.

The procedure to determine the SWSI for a particular basin is as follows: monthly data are collected and summed for all the precipitation stations, reservoirs, and snowpack/streamflow measuring stations over the basin. Each summed component is normalized using a frequency analysis gathered from a long-term data set. The probability of non-exceedence — the probability that subsequent sums of that component will not be greater than the current sum — is determined for each component based on the frequency analysis. This allows comparisons of the probabilities to be made between the components. Each component has a weight assigned to it depending on its typical contribution to the surface water within that basin, and these weighted components are summed to determine a SWSI value representing the entire basin. Like the Palmer Index, the SWSI is centered on zero and has a range between −4.2 and +4.2.

The SWSI has been used, along with the Palmer Index, to trigger the activation and deactivation of the Colorado Drought Plan. One of its advantages is that it is simple to calculate and gives a representative measurement of surface water supplies across the state. It has been modified and applied in other western states as well. These states include Oregon, Montana, Idaho, and Utah. Monthly SWSI maps for Montana are available from the Montana Natural Resource Information System http://nris.state.mt.us/wis/SWSInteractive/.

Several characteristics of the SWSI limit its application. Because the SWSI calculation is unique to each basin or region, it is difficult to compare SWSI values between basins or regions. Within a particular basin or region, discontinuing any station means that new stations need to be added to the system and new frequency distributions need to be determined for that component. Additional changes in the water management within a basin, such as flow diversions or new reservoirs, mean that the entire SWSI algorithm for that basin needs to be redeveloped to account for changes in the weight of each component. Thus, it is difficult to maintain a homogeneous time series of the index. Extreme events also cause a problem if the events are beyond the historical time series, and the index will need to be reevaluated to include these events within the frequency distribution of a basin component.

Reclamation Drought Index

The Reclamation Drought Index (RDI) (Table 3) was recently developed as a tool for defining drought severity and duration, and for predicting the onset and end of periods of drought. The impetus to devise the RDI came from the Reclamation States Drought Assistance Act of 1988, which allows states to seek assistance from the Bureau of Reclamation to mitigate the effects of drought.

TABLE 3. RDI CLASSIFICATIONS

4.0 or more	extremely wet
1.5 to 4.0	moderately wet
1 to 1.5	normal to mild wetness
0 to −1.5	normal to mild drought
−1.5 to −4.0	moderate drought
−4.0 or less	extreme drought

Like the SWSI, the RDI is calculated at a river basin level, and it incorporates the supply components of precipitation, snowpack, streamflow, and reservoir levels. The RDI differs from the SWSI in that it builds a temperature-based demand component and a duration into the index. The RDI is adaptable to each particular region and its main strength is its ability to account for both climate and water supply factors.

Oklahoma has developed its own version of the RDI and plans to use the index as one tool within the monitoring system designated in the state's drought plan. The RDI values and severity designations are similar to the SPI, PDSI, and SWSI.

Deciles

Arranging monthly precipitation data into deciles is another drought-monitoring technique. It was developed by Gibbs and Maher to avoid

some of the weaknesses within the "percent of normal" approach. The technique they developed divided the distribution of occurrences over a long-term precipitation record into tenths of the distribution. They called each of these categories a *decile*. The first decile is the rainfall amount not exceeded by the lowest 10% of the precipitation occurrences. The second decile is the precipitation amount not exceeded by the lowest 20% of occurrences. See Table 4. These deciles continue until the rainfall amount identified by the tenth decile is the largest precipitation amount within the long-term record. By definition, the fifth decile is the median, and it is the precipitation amount not exceeded by 50% of the occurrences over the period of record. The deciles are grouped into five classifications.

TABLE 4. DECILE CLASSIFICATIONS

Deciles 1–2: lowest 20%	much below normal
Deciles 3–4: next lowest 20%	below normal
deciles 5–6: middle 20%	near normal
deciles 7–8: next highest 20%	above normal
deciles 9–10: highest 20%	much above normal

The decile method was selected as the meteorological measurement of drought within the Australian Drought Watch System because it is relatively simple to calculate and requires less data and fewer assumptions than the Palmer Drought Severity Index. In this system, farmers and ranchers can only request government assistance if the drought is shown to be an event that occurs only once in 20–25 years (deciles 1 and 2 over a 100-year record) and has lasted longer than 12 months. This uniformity in drought classifications, unlike a system based on the percent of normal precipitation, has assisted Australian authorities in determining appropriate drought responses. One disadvantage of the decile system is that a long climatological record is needed to calculate the deciles accurately.

NOTE: This article is a US Government work and, as such, is in the public domain in the United States of America.

DROUGHTS. A drought is a period of time during which weather is in one way or another excessively dry. A drought's severity is determined by the degree of moisture deficiency in the affected area, as measured by various methods. Droughts are a standard, recurring, and normal feature of long-term climate. There are four generally accepted categories of drought: meteorological, socioeconomic, hydrologic, and agricultural.

Meteorological droughts involve a lack of precipitation during a given time period. Their specific definition depends mostly on the region in question; a lack of precipitation for some areas would be excessive precipitation in others. Some regions receive rain year-round, and some receive virtually none. Likewise, some regions receive precipitation consistently throughout the year, and others have seasonal precipitation patterns. A departure from any of these climatological characteristics as abnormally low precipitation can cause a meteorological drought. Meteorological droughts are usually measured in terms of their duration and in contrast to established precipitation averages for specified time periods for a specified area. This type of drought generally precedes the other three types.

Agricultural droughts need not involve a severe lack of precipitation. They are marked by damage to crops and plants due to insufficient water supplies. Because water from rain and snow is more likely to run into creeks and rivers instead of filtering into the soil due to human intervention, agricultural droughts can sometimes occur in spite of noticeable rainfall. Depending on a plant's species and stage of growth, it needs varying amounts of water from the soil; when the majority of crops cannot obtain the amount of water they need, an area is said to be undergoing an agricultural drought. This type of drought is most damaging to farmers and those in poor countries, and it generally comes after the onset of a meteorological drought.

A hydrologic drought involves water shortages in reservoirs, lakes, and streams due to lack of precipitation. These droughts are measured by stream flow and water levels in local reservoirs. Local climate is not the only factor that causes a hydrologic drought; altered land usage, dams, and degraded soil quality can all have effects as well. Reduced precipitation in one area can cause a hydrologic drought in another because various areas are hydrologically connected by their rivers, lakes, and other bodies of water. The primary cause of this type of drought is generally a meteorological drought; hydrologic droughts usually come some time after agricultural droughts.

The final category of drought is socioeconomic. This type of drought, like the other three, involves a lack of precipitation. It occurs when reduced precipitation causes a shortage of water as related to the demands of the local populace. The socioeconomic drought is the only type of drought that has a major effect on the general population, and it is generally the last of the four types to occur.

Aside from lack of rain, the three most important variables to look at during a drought are air temperature, humidity, and circulation patterns in the atmosphere. Atmospheric circulation patterns that produce little or no precipitation are often associated with droughts. Climate abnormalities are another component of a drought. Precipitation levels that would be considered a drought in one area are normal in another that has a different climate. To understand the cause of a drought, scientists study the circulation patterns of the atmosphere across global distances, using computer-generated atmospheric simulator models.

Droughts also have direct effects on communities that experience this phenomenon. Both water quality and cost are negatively affected by droughts. Changes in the taste and odor of drinking water can also occur. Those who draw their water from wells may have to drill more deeply to reach the lowered level of the water table.

During a drought, water conservation is important. Restrictions on watering gardens, washing cars, and using sprinkler systems are applied when a drought emergency or warning is in effect. There are generally three stages of drought preparedness: drought watches, drought warnings, and drought emergencies. During a drought watch, no restrictions are enforced, but citizens are encouraged to curb water usage because the possibility of drought has been established for an area. During a drought warning, restrictions are still not enforced, but citizens are instructed to

reduce water usage further in response to impending drought conditions. The final stage is a drought emergency. This is the most serious stage, often involving mandatory water usage guidelines to ensure that sufficient water is available for critical needs. At this stage, officials try to avoid local shortages by evenly distributing the water available.

Droughts can have a great impact in many ways. There are three main types of impact they can have: economic, social, and environmental. A lack of water in the soil for crops can cause farmers great financial difficulty. The resulting decrease in crop production has a ripple effect on the economy, causing short-term and long-term problems. One of the biggest short-term problems is unemployment. Certain industries can also be affected by long-term problems. For instance, loss of tax revenue can hinder tourism. Brush and trees can become very dry, and an outbreak of destructive fires can result. Drought can harm the logging industry, fisheries, and hydroelectric power generation, all economic effects. It can also cause insect problems in agriculture, as well as erosion and disease. Environmental effects include reduced biodiversity, degraded air quality, and perhaps most importantly, devastating forest fires. Social impacts include induced emigration, rampant famine, and, indirectly, greater poverty. These are merely a few of the multitude of impacts, direct and indirect, that drought can have.

DRUG DISCOVERY (The History). Until the second half of the nineteenth century, the natural world was the principal source of chemical compounds capable of exerting therapeutic activity. Before then, plants, animals and minerals were manipulated by medicine men, shamans, witch doctors and regular physicians alike in what was usually a futile attempt to cure disease. Few of the plants that grow on this planet have yielded medicines of proven value. This is because the metabolites produced in plants are a defense against foraging predators –a somewhat inauspicious role for any potential medicine. Primitive people believed the bitter taste, the irritancy, or the toxic effect of herbs would repel demons from the sick body. Irritant plants were in great demand because they caused the stomach or intestines to expel their contents and thereby rid the body of disease. The vomiting or purging was hailed as a means of expelling demons and later by the Greeks as a means of ejecting excess of one of the four humors thought to be out of balance in the sick. The reality is that plants have not evolved in order to produce pharmaceuticals. See also **Plant Sciences (The History)**.

The Isolation of Active Principles

Attempts by alchemists to transmute metals into gold or find an elixir of life were an exercise in futility. Yet, in the tenth and eleventh centuries their work led to purification of minerals used medicinally. The technology of the alchemists consisted of distillation, sublimation, roasting and exposure to acids or alkalis, ensuring the destruction of compounds capable of exerting a pharmacological effect. Only alcohol and a range of volatile oils survived such processing. Matters improved when liquid extraction techniques were exploited by pharmacists seeking to devise methods for detecting active principles in plant products in order to establish their authenticity. In Sweden in the latter part of the eighteenth century, Karl Scheele treated gum benzoes with milk of lime, thereby forming a solution of calcium benzoate. When he added hydrochloric acid to neutralize this, benzoic acid precipitated. He went on to isolate tartaric, malic, citric and other acids. None of these possessed pharmacological activity. See also **Biochemistry (The History)**.

The credit for isolating the first active principle went to a German apothecary, Friedrich Wilhelm Sertürner. Inspired by the need to know if opium supplied to him was adulterated, he succeeded in isolating meconic acid. This had no activity when given to dogs. But a second product precipitated when ammonia was added to the mother liquors. Sertürner crystallized this from alcohol and obtained crude crystals which put a dog to sleep. In 1816 he obtained pure crystals of morphine and his work came to the attention of Joseph Gay-Lussac who published it, ensuring that it gained wide prominence. Emetine was then isolated from ipecacuanha by Joseph Pelletier at the Ecole Supérieure de Pharmacie in Paris, working in association with the eminent physiologist and physician François Magendie. In 1818 Wilhelm Meisner proposed the term "alkaloid" to describe these nitrogenous bases. Pelletier and his student Joseph Caventou went on to isolate quinine from cinchona bark, in 1820, although this had previously been isolated in Jena by Friedlieb Runge. See also **Alkaloids**; **Magendie, François (1783–1855)**; and **Sertürner, Friedrich Wilhelm (1783–1841)**.

The Therapeutic Use of Alkaloids. The isolation of alkaloids was driven by the need to identify adulterated medicinal products. However, Pelletier and Caventou made the novel suggestion that physicians should examine the therapeutic potential of alkaloids. This was acted upon by Magendie, who in 1821 published a formulary of pure chemicals, mostly alkaloids. It was reprinted in many languages and led to the rapid acceptance of alkaloids into medicine.

By the time Magendie had published his formulary, about twenty alkaloids had already been isolated. Thousands have been extracted since. Of those introduced into the clinic in the nineteenth century, the following are still prescribed: colchicine (1820), caffeine (1821), atropine (1833), quinidine (1833), papaverine (1848), cocaine (1860), physostigmine (1864), pilocarpine (1875), hyoscine (1881) and theophylline (1888). In addition, a variety of non-alkaloidal products were isolated from plants during the nineteenth century, including salicin (1829), impure digitoxin (1841), guaiacol (1843), methyl salicylate (1843), digitalin (1874), khellin (1879) and podophyllotoxin (1880).

It was not only plant extraction that advanced in the nineteenth century. Synthetic chemistry developed rapidly in the second half of the century and opened up a treasure trove of novel compounds which set the pharmaceutical researcher free of the confines of natural product chemistry. The full extent of the treasure trove is only just beginning to be realized today with the introduction of combinatorial chemistry techniques which enable major pharmaceutical companies to synthesize a million compounds each year and submit these to high throughput screening for biological activity.

Inhalational Anesthetics. Unexpected events have often triggered major developments in drug discovery. The term "serendipity" is used to describe this, having been introduced by Horace Walpole (1717–1797) after he read about three princes of Serendip who kept stumbling upon objects they were not seeking. Walpole emphasized there were two components to serendipity. The first was making the chance discovery and the second was having the sagacity to exploit it.

Nitrous oxide was synthesized by Joseph Priestley in 1772. A quarter of a century later, Humphry Davy inhaled the gas to ascertain that it was harmless, only to find that it caused him to be initially euphoric and then highly excitable. His report led to others experimenting with it. One was Quincy Colton, an itinerant showman who invited his audience in Hartford, Connecticut, to inhale the gas on stage. Horace Wells, a dentist, astutely observed that one of the participants obviously felt no pain upon gashing his leg as he staggered around. Wells persuaded Colton to administer the gas to him the following morning so that he could have a painful tooth extracted. The resulting painless extraction was followed by Wells giving a disastrously flawed demonstration in the Massachusetts General Hospital. Fortunately, his former partner William Morton learned from the experience and substituted ether for the less potent nitrous oxide in a successful demonstration in the same hospital almost two years later in 1846. See also **Priestley, Joseph (1733–1804)**.

Ether was an immediate success, but it had a variety of shortcomings. Particular concern about its inflammability and irritant effect on the respiratory tract encouraged James Young Simpson to inhale, with his friends, a variety of organic solvents. Of these, chloroform proved to have obvious advantages and it soon rivaled ether in operating theatres around the world. Nitrous oxide later came into anesthetic practice in the hands of Colton, who administered it at high concentration mixed with adequate oxygen to thousands of dental patients. The three synthetic chemicals revolutionized surgery.

Chloroform had been synthesized from chloral hydrate. Aware of this, Oscar Liebreich administered chloral hydrate to rabbits, in 1868, in the

mistaken belief that the alkalinity of the blood would cause it to liberate chloroform gradually and produce a sustained hypnotic effect. The rabbits did fall asleep, but this was due to the liver metabolizing it to form trichloroethanol. Although the theory had been wrong, the synthetic drug chloral hydrate turned out to be safer and far more effective than any natural hypnotic such as opium. The foul taste of chloral hydrate (and even more so of trichloroethanol) was addressed by chemists who introduced a variety of analogues. See also **Anesthesia (The History)**.

Alkaloid Analogues. The development of analogues of chloral hydrate in the 1870s and 1880s set a pattern, namely a lead compound representing a major advance but problems with it resulting in the development of analogues devoid of one or other of these drawbacks. Chemistry had advanced sufficiently for this to be done, but not only for synthetic drugs. Alkaloids and other plant products had their chemical structure manipulated. When Alder Wright converted morphine to its diacetate in 1874, this was not believed to have any clinical advantage over morphine, but 24 years later it was marketed by F. Bayer & Co. as Heroin in the erroneous belief that it was free from the potentially lethal respiratory depressant action of morphine.

More analogues of morphine were prepared in the twentieth century, the initial ones being simple chemical derivatives prepared by esterification, etherification, oxidation and reduction. Nothing superior to the natural product emerged from this effort. Further compounds were prepared once the chemical structure of morphine was elucidated in 1923, particularly ones in which the ring system was modified. This has led to alternatives of limited value, such as buprenorphine and nalbuphine.

After discovering that tropine and tropic acid, the two products obtained upon chemical hydrolysis of atropine, could recombine on being heated together in dilute acid, Alfred Ladenburg in 1880 found that tropic acid could be substituted by the related mandelic acid. The resulting analogue, homatropine, acted more quickly on the eye to paralyze the ciliary muscles during ophthalmological examinations. The effect wore off rapidly, enabling patients to read again in minutes rather than days. In this case, the molecular manipulation of atropine was minuscule yet the clinical consequences were significant. In the 1920s, the tropine ring was shown to be replaceable and a wide variety of atropine analogues were introduced thereafter, including the pain killer pethidine and the tranquillizer haloperidol. Both of these spawned many more drugs.

Chemists in the late nineteenth century had limited horizons. They concerned themselves with making analogues or substitutes for morphine and quinine, both being drugs that produced troublesome side effects. The first two quinine substitutes, Kairin and thalline, were simple tetrahydroquinolines that had been developed following the discovery that quinine contained a quinoline ring system. Both were too toxic to remain on the market for long. Next came phenazone in 1884, synthesized by Ludwig Knorr in the belief that it would be another tetrahydroquinoline, but his intention was thwarted when the product underwent an internal rearrangement to form a compound that proved to be a valuable anti-inflammatory, antipyretic drug. Phenazone spawned a host of analogues, including amidopyrine, phenylbutazone, oxphenbutazone, azapropazone and sulfinpyrazone.

Although cocaine had been isolated from coca leaf in 1860, it was not until 1884 that any therapeutic application for it was identified. That year Carl Koller found it to be a highly effective local anesthetic for eye surgery. Before long, it was being injected in close proximity to nerves. In 1892, Albert Einhorn, a researcher at the University of Munich, realized the chemical structure of cocaine resembled that of atropine. He then attempted to find out whether or not both of the ring systems were essential for anesthetic activity. This led him to synthesize the eucaines as cocaine substitutes. Einhorn went on to develop procaine in 1910. This remained the local anesthetic of choice until the middle of the century, being free from the addictive properties and expense of cocaine.

Synthetic Drugs. The industrial production of coal gas became widespread in the early nineteenth century. Coal tar was initially an unwelcome waste product, but Friedlieb Runge in 1833 distilled from it an acid oil now known as phenol. As it could prevent the development of the odors associated with putrefaction, it was introduced as an antiseptic. See also **Biotechnology (The History)**.

The use of phenol by Joseph Lister resulted in the advent of antiseptic surgery in 1865. Attempts to avoid its damaging effects on the skin and internal tissues led to synthesis of analogues, one of which, salicylic acid, was introduced in the belief that it would slowly decompose to liberate phenol. It proved less successful as an antiseptic than in alleviating rheumatoid arthritis, a disease then incorrectly believed to be due to bacterial infection. It was superseded by aspirin, in which the irritant phenolic group was masked by acetylation. This was introduced by F. Bayer & Co. in 1899. See also **Lister, Joseph (1827–1912)**.

Twentieth Century Developments

Pharmaceutical companies soon realized that plant products could not be patented, whereas their analogues could. The same applied to the animal derived hormones, the first to be obtained in pure form being adrenaline (epinephrine). It was isolated by Jokichi Takamine in 1901 and synthesized four years later. Marketed as a vasoconstrictor, it also proved of value in relief of bronchospasm if inhaled by asthmatics. There was little interest in developing analogues of it until the introduction in 1926 of ephedrine, an alkaloid with a somewhat similar chemical structure and pharmacological action. Ephedrine had two obvious advantages, namely it was active when given by mouth and the effects lasted several hours, but it was less effective in acute asthma attacks. This led pharmaceutical companies to ring the changes between the structures of the two compounds to produce a variety of drugs used mainly as decongestants in cough and cold remedies. In 1939, C. H. Boehringer of Ingelheim prepared one with only the desirable features of adrenaline (epinephrine) and ephedrine. This was isoprenaline, which acted on only one subtype of receptors for adrenaline, namely the beta-adrenoreceptors. It remained the bronchodilator of choice for asthmatics until salbutamol, the first of several superior analogues, was introduced in 1970. In this and similar drugs, the introduction of bulky groups in the side-chain inhibited fit to receptors in the heart, thereby producing a bronchodilator relatively free of cardiac side effects. See also **Adrenaline and Noradrenaline**; and **Asthma**.

When the dichloro-analogue of isoprenaline was reported to antagonize some of the effects of adrenaline on the heart, Black and his colleagues at ICI Pharmaceuticals (now AstraZeneca) exploited this observation by developing analogues of it which did not retain adrenaline-like activity. This led to the first beta-adrenoceptor antagonists ("beta-blockers"), which proved to be immensely valuable in the treatment of cardiovascular disease.

The next pure hormone was isolated in 1917 by Edward Kendall at the Mayo Clinic in Rochester, Minnesota. It was marketed soon after for the treatment of thyroid deficiency and remains widely prescribed. See also **Kendall, Edward Calvin (1886–1972)**; and **Thyroid Gland**.

Insulin. The introduction in 1922 of the hormone insulin saved the lives of millions of diabetics. This was extracted from pancreatic glands by Friedrich Banting and Charles Best. Their work at the University of Toronto succeeded because they initially treated the glands with alcohol to denature protein-digesting enzymes. Utilizing recently developed procedures for assaying sugar levels in submilliliter samples of blood, they monitored extraction procedures until high yields were achieved. See also **Banting, Frederick (1891–1941)**; and **Insulin**.

Sex Hormones. In 1913 the Swiss company CIBA marketed a crude ovarian extract with a low level of activity. Further development was hampered by lack of an effective means of assaying activity of extracts. This problem was overcome in 1923 when Edgar Allen and Edward Doisy of Washington University, St Louis, Missouri, assayed extracts by microscopic examination of changes in vaginal smears taken from laboratory mice. After it was discovered that the amount of hormone in urine was greatly increased during pregnancy, Doisy successfully used fat solvents to isolate oestrone from large volumes of pregnant mares' urine. It was used to alleviate menopausal symptoms until superseded by the more potent oestradiol, which was also extracted by Doisy. In 1938, Schering chemists in Germany found that the ethyl derivative, ethinyloestradiol, was not degraded by liver enzymes and could be given by mouth. It remains in use as the oestrogenic component of oral contraceptives. See also **Doisy, Edward Adelbert (1893–1986)**.

Progesterone, the active principle in the corpus luteum, was isolated in 1934. When an ethinyl group was introduced in an attempt to overcome degradation by liver enzymes, the resulting ethisterone was found to possess virilizing effects on females due to chemical similarity to testosterone (testosterone had been isolated using an assay in which androgenic activity was measured by growth of a cockscomb). The problem of virilization with ethisterone was overcome in the 1950s with the development of norethisterone and similar norsteroids. These met the

requirements of Gregory Pincus and John Rock, who were seeking an oral progestogen to exploit the discovery that increased production of progesterone in pregnancy inhibited ovulation. This led to the introduction of oral contraception.

Similar extraction techniques were used by biochemists in the 1930s to isolate a variety of hormones from the cortex of the adrenal glands. Quantities obtained were minuscule, hence therapeutic applications were not considered. In 1948, Edward Kendal working with Louis Sarett of Merck & Company in New Jersey synthesized a few grams of cortisone. It was distributed to physicians, resulting in Philip Hensch of the Mayo Clinic discovering its powerful antiarthritic properties, as well as problems associated with long-term usage. These arose from the drug also having an effect on the mineral balance in the body. When analogues were found that had a variance between the intensity of these actions, chemists deduced what structural changes were needed to prepare corticosteroids with a low level of mineralocorticoid activity. So effective has this structure–activity work been that asthmatics now inhale corticosteroids to suppress bronchial congestion.

Following upon investigations by Thomas Lewis in 1927 and Henry Dale two years later, it was acknowledged that histamine played some role in the body. This led Daniel Bovet at the Pasteur Institute in Paris to seek a compound which could interfere with that role and reveal its nature. On screening compounds previously synthesized at the Institute, he found that piperoxan had weak activity. He and Anne-Marie Staub then examined analogues of this and developed potent antihistamines for biochemical studies. In 1942, researchers at the Rhône-Poulenc Laboratories, also in Paris, developed phenbenzamine, the first antihistamine safe enough for therapeutic application. It relieved allergies, dried up nasal secretions, and became popular as a remedy for colds. Other companies modeled a variety of antihistamines on the structure of phenbenzamine. These caused drowsiness, a problem not overcome until novel antihistamines were introduced in the 1980s. See also **Bovet, Daniel (1907–1992)**; **Dale, Henry Hallett (1875–1968)**; and **Lewis, Thomas (1881–1945)**.

Administration of the antihistamine known as promethazine was found by Henri Laborit, a French naval surgeon, to be superior to other drugs for minimizing the consequences of surgical shock. Researchers at Rhône-Poulenc then supplied Laborit with the related drug chlorpromazine. He found it to be quite effective as an anti-shock agent but observed that his patients seemed abnormally detached from their surroundings. Laborit informed psychiatrists and they administered the drug to a highly agitated manic patient who then became quite calm. Clinical trials ensued in 1952 and chlorpromazine became established as the first synthetic tranquillizer. During the next few decades, a wide variety of tranquillizers, antidepressants and antianxiety drugs were introduced, many modeled on the phenothiazine tricyclic ring of chlorpromazine.

The failure of antihistamines to block the action of histamine in the stomach whereby gastric acid was released was investigated by James Black and Robin Ganellin at the Smith Kline Laboratories in England. All analogues of histamine that they tested retained some ability to stimulate acid release. Progress was made only after it was realized that this would not occur if a charge could not form on the side-chain. Taking into account the distribution of electrons in the molecules and the nature of chemical tautomerism, the investigators were able to introduce cimetidine as a potent H_2-blocker in 1976. A rival compound was made by Glaxo researchers in which the cimetidine type of side-chain was retained and the histamine ring was replaced. These two drugs competed for first and second place in world sales. See also **Black, James Whyte**.

Chemotherapy. The first drugs to treat protozoal infections were developed by Paul Ehrlich in Frankfurt in the opening years of the twentieth century. His previous work, in which he treated patients with methylene blue since it stained the plasmodia that caused malaria, came to nothing because of the lack of an animal model for testing analogues. When Ehrlich learned that animals could be infected with the trypanosomes that caused another protozoal disease, sleeping sickness, he decided to screen dyes in infected animals. This led to the introduction of trypan red, but as it could cause blindness, it was restricted to treating trypanosomiasis in cattle. See also **Ehrlich, Paul (1854–1915)**.

The failure of his venture into chemotherapy because of the toxic properties of an otherwise effective drug taught Ehrlich an important lesson. His next project was with analogues of an arsenic-containing drug, atoxyl. It had been announced in 1905 that it could eliminate trypanosomes in experimental animals and was being evaluated in Africa where sleeping sickness was endemic. Since injections had to continue for 6 months and some patients were blinded, Ehrlich recruited chemists to prepare safer analogues. Taking the highly original step of testing for toxicity as thoroughly as for efficacy, he established a therapeutic index for every compound, i.e. the ratio of the toxic dose to the effective dose. Although he never found an arsenical effective against trypanosomiasis, the 606th compound prepared in his laboratory proved to be capable of curing syphilis. This was arsphenamine, marketed as Salvarsan in 1910. As it was a polymer, a single intravenous injection cured patients by releasing active monomers over a prolonged period. Hundreds of thousands of patients were cured and arsphenamine and its analogues became the drugs of choice for syphilis until the introduction of penicillin. See also **Trypanosomiasis**; **African Trypanosomiasis**; and **Chaga's Disease (South American Trypanosomiasis)**.

The work of Ehrlich was responsible for further successes. Development of his experiments with dyes led the Bayer Company to introduce the antitrypanosomal Bayer 205 during World War I. Refusal to divulge the structure resulted in Ernst Fourneau of the Pasteur Institute introducing an identical compound under the name of suramin in 1924. He had examined Bayer patents, drawn the necessary conclusions and begun to synthesize 25 possible compounds! Since then, pharmaceutical companies always divulge chemical structures in their patents.

Further examination of dyes at the laboratories where suramin was developed led to the discovery of synthetic antimalarials in 1926, and then the potent antibacterial properties of the first man-made systemic antibacterial, the sulfonamide Protosil Rubrum, i.e. sulfamidochrysoidine. The antimalarials were developed after it was discovered that canaries could be infected with malaria, while the successful development of sulfamidochrysoidine was due to Gerhard Domagk seeking the most virulent strain of hemolytic streptococcus against which to test compounds. This and sulfonamides developed by other companies dominated medical treatment of bacterial infections until superseded by the penicillin's. See also and **Domagk, Gerhard Johannes Paul (1895–1964)**; **Sulfonamides (The History)**.

Penicillins. The details of the serendipitous discovery of penicillin in 1928 are well known, namely Alexander Fleming returning to St Mary's Hospital in London from holiday and observing that where a culture plate had been contaminated accidentally by a *Penicillium* fungal mould there was no growth of the bacteria with which the plate had previously been smeared. Fleming realized that the mould was producing a substance that was killing off the bacteria in its vicinity. He investigated the nature of the substance, but once he found it lacked sufficient stability to permit topical use as an antiseptic, he abandoned the study. In 1939 Ernst Chain at Oxford was examining the ability of penicillin to prevent bacterial cell wall formation when his superior, Howard Florey, realized that it was capable of killing pathogenic organisms and so suggested that it was worthy of examination as a systemic antibacterial. His broader perspective on the possible uses of penicillin was due to the success of the newly introduced sulfonamides. Small amounts of penicillin were isolated by the Oxford investigators and shown to be clinically effective, but wartime conditions denied British companies an opportunity to take on production. The pharmaceutical industry in the United States was able to accept this responsibility and a massive collaborative venture resulted in supplies of the antibiotic being available to treat the casualties following the D-day landings. See also **Chain, Ernst, Boris (1906–1979)**; **Fleming, Sir Alexander (1881–1955)**; and **Florey, Howard Walter (1898–1968)**.

The first penicillin, benzylpenicillin, was feebly active by mouth unless large doses were given. The development in 1957 of an orally active penicillin with a different side-chain, phenoxymethylpenicillin, stimulated pharmaceutical development of techniques for producing penicillin's with a variety of side-chains. These altered the range of bacteria against which the drugs were effective, and provided analogues that were unaffected by bacterial enzymes that decomposed penicillin's. The range of antibiotics widened after similar molecules known as cephalosporins were isolated from *Cephalosporium* moulds in the 1960s.

The commercial imperative to isolate antibiotics stimulated worldwide screening of soil samples. This resulted in the rapid isolation and large-scale production of a wide range of antibiotics from fungi and especially from bacteria known as streptomycetes. Though thousands of antibiotics were isolated, the majority were too toxic to be considered for therapeutic

use. About fifty have remained in the product lists of pharmaceutical companies and their impact has been immense, but increasing resistance to antibiotics is of deep concern. See also **Antibiotics**.

Cancer Chemotherapy. The development of the first cancer chemotherapeutic agents took place at the same time as that of penicillin. The initial steps followed the entry of the United States into the war following the bombing of Pearl Harbor. In January 1942 the U.S. Office of Scientific Research and Development awarded a grant to Yale researchers Louis Goodman and Alfred Gilman to investigate the toxicological properties of vesicant chemical warfare agents containing nitrogen mustard that had recently been developed in Germany. Within weeks, it was found that after absorption into the circulation of laboratory animals, these attacked a variety of rapidly dividing cells including those of the blood-forming precursors in bone marrow, the gastrointestinal tract, the lymphatic system and the hair follicles. Speculation that the mustards might also attack rapidly dividing tumors led to injection of a mustard into a laboratory mouse bearing a huge experimental tumor. The complete disappearance of this after a few injections led to a month long remission, but the tumor reappeared. Repeated treatment at first seemed successful, but remission was brief. A third course of injections failed. On administering the mustard to a patient with an inoperable tumor in the neck, a rerun of the mouse scenario occurred. More patients received the treatment with favorable results, hence clinical trials were initiated. These were done in total secrecy during the war due to the source of funding being the Chemical Warfare Service (!), but results made public in 1946 ensured the place of the nitrogen mustards in medicine. Since then, nonvesicant analogues have been made by lowering the chemical reactivity of the reactive amine centre in the molecules through the attachment of an aromatic ring. Even mustards with this lowered reactivity are capable of reacting with intracellular DNA and crosslinking its strands to prevent cell division.

The next cancer chemotherapeutic agents to be developed were the antimetabolites. The first of these was discovered during a follow-up of a report in 1944 claiming that a recently isolated vitamin, folic acid, inhibited growth of breast cancer in mice. At the Children's Medical Center in Boston, Sidney Farber carried out preliminary studies on around 100 patients. To his initial horror, he found that the vitamin accelerated the growth of malignant blood and marrow cells in those with leukemia. After considering matters further, Farber approached Lederle Laboratories who had supplied the vitamin and asked if they could develop an antimetabolite. This term had recently been introduced following the discovery that sulfonamide antibacterials act by blocking the action of a key bacterial metabolite, 4-aminobenzoic acid. In 1947, Lederle supplied Farber with an analogue of folic acid that had weak antimetabolite activity. This was pteroylaspartic acid, in which an amino acid, aspartic acid, replaced the glutamic acid residue in folic acid. When injected, it slowed down the growth rate of leukemic cells, but did not save any lives. Its successors, aminopterin and the still more potent methotrexate, were able to produce remission in about 30% of the children who received them. When cortisone and the related prednisolone became available shortly after, their known ability to suppress replication of white blood cells was successfully exploited when combinations of one of them with methotrexate produced remission in almost 60% of children with leukemia. This success stimulated research into antimetabolites in which chemists made close structural analogues of what were considered key metabolites in cells. Soon, mercaptopurine became available (a hypoxanthine analogue) and it, too, was effective in leukemia. When combined with methotrexate and a corticosteroid, remission rates in children with leukemia rose to 90%. The remissions were temporary and treatment had to be administered in repeated cycles. However, by the late 1970s treatment protocols based on these three drugs in combination with others were beginning to achieve a high proportion of cures of the commonest type of childhood leukemia. Today, cure rates in excess of 70% in acute lymphocytic leukemia are routinely being attained. A variety of other antimetabolites have been developed and are effective against other malignancies. Many are capable of inhibiting specific enzymes and, in theory, should provide cures for a wide range of diseases both malignant and nonmalignant. In practice, it has proved difficult to find antimetabolites that are both effective and safe, despite many thousands, perhaps hundreds of thousands, of molecules having been synthesized for this purpose. See also **Cancer and Oncology**; **Folic Acid**; and **Leukemias**.

A common experience in chemotherapy has been the discovery that a drug developed specifically to treat one disease has proved effective against another. Ehrlich developed arsphenamine to destroy trypanosomes, but it was more efficient at killing the spirochaetes that caused syphilis. Domagk screened sulfamidochrysoidine against virulent hemolytic streptococci, but clinicians found it also killed staphylococci and other bacteria. The same situation has arisen with antimetabolites, the most celebrated case being the discovery of the first effective drug against the *Human immunodeficiency virus* (HIV) that causes acquired immune deficiency syndrome (AIDS), namely zidovudine. In 1964, Jerome Horwitz at the Michigan Cancer Foundation synthesized his Compound S as an analogue of the DNA nucleotide building-block thymine. His hope that it would act as an antimetabolite for use in leukemia was dashed when the compound was shown to be highly toxic. Twenty years later it was discovered that the HIV virus was the probable cause of AIDS and pharmaceutical companies raced ahead to screen both old and new antimetabolites for activity against the virus. The first to show promise was compound S, now known as zidovudine (then known as AZT). So encouraging were the initial results that the clinical trial was cut short as it was believed that it would be unethical to deny the drug to those who were receiving dummy placebo treatment. See also **Acquired Immune Deficiency Syndrome (AIDS)**; and **Human Immunodeficiency Viruses (HIV)**.

Antimetabolites effective against other viruses, particularly herpes, have also generally been developed initially as anticancer agents. Aciclovir, widely used for cold sores caused by herpes simplex, is one such drug, having being designed as an analogue of the antileukemia drug cytarabine. By removal of part of a sugar ring, an acylic analogue was prepared which was totally devoid of the high toxicity associated with cytarabine itself. See also **Antiviral Drugs**.

DRUMLIN. A drumlin is a hill composed of glacial material of unstratified and heterogeneous character usually about 100 feet (30.5 meters) in height and $\frac{1}{4}-\frac{1}{2}$ mile (0.4–0.8 kilometer) in length, oval in shape, and with its long axis parallel with the general direction of ice movement. Sometimes a mass of bed rock seems to have been the anchor about which the glacial till was deposited. Drumlins are known, however, which contain no bed rock core. Drumloid-shaped hills similar to the smaller glaciated rock features called roches moutonnée are sometimes called rock drumlins.

DRUMSKIN ACTION. The vibration of a wall as a whole under the action of an incident sound wave.

DRUSE. A cavity, usually in a sedimentary rock, the walls of which are encrusted with minerals which have been derived, through underground solutions, from the rocks in which the cavities were formed, by solution.

DRY ADIABAT. A line of constant potential temperature on a thermodynamic diagram. In terms of pressure p, and specific volume v, the equation for a dry adiabat may be written

$$pv^c p^{/c} v = \text{Constant}$$

where c_p and c_v are the specific heats of dry air at constant pressure and volume, respectively. Meteorologically, the dry adiabat is intended to represent the lifting of dry air in a dry-adiabatic process. Since this is also an isentropic process, a dry adiabat is an isentrope.

DRY CELL. See **Battery**.

DRY EYE. This condition is due to a deficiency in the production and/or composition of tears by the eye's lacrimal glands. Symptoms are redness, swelling and irritation, often accompanied by excessive watering of the affected eye. The condition is more common as the eye ages and may be worsened by a dry climate, exposure to wind, smoke, smog, air conditioners and ceiling fans. Most dry eye can be corrected by the use of artificial tear drops prescribed by an eye doctor. See also **Lacrimal System**.

Vision Rx, Inc., Elmsford, NY

DRYING OILS. Among the oldest binders for paints and printing inks are drying oils, which are liquid vegetable or fish oils that react with oxygen to form solid films. They have been used since prehistoric times; in the nineteenth and early twentieth centuries, binders of most paints and printing inks were drying oils. Their use has decreased; however, they still have applications. Most importantly, they are raw materials for other binders such as alkyd resins, epoxy esters, and uralkyds. See also **Alkyd Resins**. These resins can be considered to be synthetic drying oils.

Natural Oils

Most drying oils are derived from plant seeds. The largest volume drying oil, linseed oil, is obtained from flaxseed, *Linum usitatissimum*. In the United States flax is grown in North Dakota, Minnesota, and South Dakota. Flax for oil is also raised in Canada, Argentina, India, and parts of the former USSR. Soybean oil, the second most important oil, is obtained from soybeans, the seed of *Glycine max* (L) Merrill. It is produced in the United States, Brazil, Argentina, and China. Without modification, it is semidrying oil, not a drying oil. Perilla, safflower, sunflower, and walnut oils have limited uses as drying oils. Tung oil, also called wood oil or chinawood oil, is obtained from the seed kernels of the tung tree, *Aleurites fordii*. The principal source of the oil is China. Limited quantities of another conjugated oil, oiticica oil from the oiticica tree, *Licania rigida*, also are used. The only animal oils used as drying oils on a significant scale are marine fish oils, primarily from anchovy, menhaden, pilchard, and sardines. Fish oil is isolated by steam treatment of the fish.

Castor oil, derived from the beans of *Ricinus communis*, is converted to a drying oil by heating with catalysts to yield dehydrated castor oil.

Trees, especially conifers, contain tall oils. Tall oil is not isolated directly; tall oil fatty acids are isolated from the soaps generated as by-products of the sulfate pulping process for making paper.

A wide variety of other oils have been investigated and, in many cases, used commercially over the years. More complete listings are available.

Naturally occurring drying oils are triglycerides. The reactivity of the oils results from the presence of esters of fatty acids with two or more nonconjugated double bonds separated by single methylene groups, $-CH{=}CHCH_2CH{=}CH$ hose with two or more conjugated double bonds.

Oils are classified as drying oils, which form solid films on exposure to air; semidrying oils, which form tacky, sticky films; and nondrying oils, which do not undergo marked increase in viscosity on exposure to air. Drying oils are further classified as nonconjugated and conjugated oils, depending on whether the double bonds in the predominant fatty acids are separated by one methylene group or are conjugated.

A general statement, useful in considering synthetic drying oils as well as natural oils, is that if the average number of methylene groups between two double bonds per molecule is greater than 2.2, the oil is a drying oil; if less than 2.2, the oil is a drying oil. There is no sharp dividing line between semidrying and nondrying oils.

The reactivity of nonconjugated drying oils is related to the average number of methylene groups between double bonds per molecule. Such methylene groups are allylic to two double bonds, and show much greater reactivity than methylene groups allylic to only one double bond.

The reactions taking place during drying are complex, with many side reactions. Films form from a drying oil, such as linseed oil, in the following steps: an induction period during which naturally present antioxidants, mainly tocopherols, are consumed; a period of rapid oxygen uptake with a weight gain of about 10% (ftir shows an increase in hydroperoxides and appearance of conjugated dienes during this stage); a complex sequence of autocatalytic reactions in which hydroperoxides are consumed and the cross-linked film is formed; and cleavage reactions to form low mol wt by-products.

The rates at which nonconjugated drying oils dry are slow. Metal salts (driers) are known to catalyze the drying rate. The most widely used are the oil-soluble cobalt, manganese, lead, zirconium, and calcium salts of 2-ethylhexanoic acid or naphthenic acids. See also **Paints and Coatings**.

Combinations of metal salts are almost always used. Although mixtures of lead with cobalt and/or manganese are particularly effective, toxicity regulations ban the use of lead driers in consumer paints sold in interstate commerce in the United States. Combinations of cobalt and/or manganese with zirconium, and frequently also with calcium, are commonly used. The amounts of driers needed are very system specific. Their use should be kept to the minimum possible level since they not only catalyze drying but also catalyze the post-drying embrittlement and discoloration reactions.

Oils containing conjugated double bonds, such as tung oil, dry more rapidly than nonconjugated drying oils. Free-radical polymerization of the conjugated diene systems can lead to chain-growth polymerization rather than just combination of free radicals to form cross-links. In general, the water and alkali resistance of films formed using conjugated oils are superior, presumably because more of the cross-links are stable carbon-to-carbon bonds. However, because α-eleostearic acid in tung oil has three double bonds, discoloration on baking or aging is severe.

Both nonconjugated and conjugated drying oils can be polymerized by heating under an inert atmosphere to form so-called bodied oils. Bodied oils have higher viscosities and are often used in oil paints to improve application and performance characteristics.

Synthetic and Modified Drying Oils

The drying rate of drying oils can be increased by dissolving a solid resin in the oil and diluting with a hydrocarbon solvent. Such a solution is called a varnish. The solid resin serves to increase the glass-transition temperature, T_g, of the solvent-free film so that film hardness is achieved more rapidly.

In varnish manufacture, the drying oil, i.e., linseed oil, tung oil, or mixtures of the two, and the resin are cooked together to high temperatures to yield a homogeneous solution for the proper viscosity. The varnish is then thinned with hydrocarbon solvents to application viscosity. Varnishes were widely used in the nineteenth and early twentieth centuries. They have been replace almost completely by a wide variety of other products, especially alkyds, epoxy esters, and urethane oils.

Tung oil dries rapidly, but is expensive, and its films discolor rapidly owing to the presence of three double bonds. These defects led to efforts to synthesize conjugated oils, especially those containing esters of fatty acids with two conjugated double bonds.

When oil-derived fatty acids react with polyols having more than three hydroxyl groups per molecule, the average number of cross-linking sites per molecule increases proportionally to the functionality of the polyol. Because the number of reactive sites in soybean oil with the composition listed is 2.07, soybean oil is a semidrying oil. However, the pentaerythritol (2,2-bis(hydroxymethyl)-1,3-propanediol) ester of soybean fatty acids with 2.76 reactive sites per molecule is a drying oil.

Oxidizing alkyds can be considered as still-higher functionality drying oils. Their drying speed is faster owing to both the higher functionality and the higher T_g of the rigid aromatic rings in the phthalate esters.

Oils, with either conjugated or nonconjugated double bonds, react with maleic anhydride (2,5-furandione) to form adducts. The products of these reactions with maleic anhydride, termed maleated oils, react with polyols to give moderate mol wt derivatives that dry faster than the unmodified oils. Such products have not found significant commercial use, but similar reactions with alkyds and epoxy esters are used on a large scale to make water-dilutable derivatives.

Both conjugated and nonconjugated drying oils react in the presence of free-radical initiators with such vinyl monomers as styrene, vinyltoluene, acrylic esters, and cyclopentadiene. High degrees of chain transfer cause the formation of wide varieties of products, including low mol wt homopolymers of the vinyl monomer, short-chain graft copolymers, and dimerized drying oil molecules. The reaction products with drying oils, except cyclopentadiene, are not commercially important, but the same principle is widely used in making modified alkyds.

Uses

Although some drying oils continue to be used as drying oils, the largest use of drying and semidrying oils is as raw materials, either directly or as the fatty acids obtained by saponification, in the manufacture of oxidizing

alkyds, epoxy esters, urethane oils, and synthetic drying oils. Tall oil fatty acids also are used to manufacture dimer acids.

Although most drying oils have been replaced as paint vehicles by latexes and other synthetic resins, oils are still being used to a degree in paint and allied products. In exterior house paints, linseed oil or oxidizing alkyds are used when paint must be applied at temperatures as low as 4 to 5 °C, i.e., temperatures at which latexes do not coalesce satisfactorily. They also are used in primers over chalky surfaces where latex paints do not provide adequate adhesion.

Most stains used for finishing shingles and other natural wood exterior products are made with pigmented linseed oil, diluted with hydrocarbon solvents for penetration.

Red lead-in-oil primers have been used for many years for corrosion protection of steel where it is not practical to remove oily rust particles from the surface of the steel; concern about lead content has resulted in use reduction.

The use of drying oils in printing inks has decreased. Some inks based on drying oils are still used for sheet-fed letterpress printing. The principal remaining use is in lithographic printing, particularly sheet-fed lithographic printing.

DRYING (Process). Frequently in the process industries, materials must be dried, i.e., liquid must be removed from a solid or gaseous phase. In most instances, the liquid to be removed is water, although in solvent recovery systems, for example, the liquid may be an organic solvent. See **Dehumidification** for a discussion of the drying of gases. Some materials which must be dried include: (1) solutions, colloidal suspensions, and emulsions, such as extracts, milk, blood, waste liquors, rubber latex, and inorganic salt solutions; (2) slurries, which are pumpable suspensions, as found in calcium carbonate, bentonite, clay slip, and lead concentrates; (3) sludges and pastes, such as centrifuged solids, starch, filter-press cakes, and sedimentation sludges; (4) powders that may be relatively free-flowing when wet, but very dusty when dry, including pigments, cement, clay, and centrifuged precipitates; (5) fibrous solids and granular and crystalline solids, such as sand, ores, rayons staple, salt crystals, and synthetic rubber; (6) formed and shapes solids, such as pottery, rayon cakes, shotgun shells, brick, rayon skeins, lumber, and objects that have been painted or otherwise coated; (7) sheeted materials, such as impregnated fabrics, paper, plastic, and fiber-board — in the continuous form; or veneers, wallboards, foam-rubber sheets, and photographic prints — in the individual-piece configuration. Because of this very wide variety of drying requirements, it is obvious that there does not exist what might be termed a universal dryer. Further, universal dryer design criteria are difficult to develop and summarize. See Table 1.

Basic Concepts of Drying. Two criteria hold for a large number of drying situations, and they break the drying process down into two main periods: (1) the constant-rate period, the rate of removal of liquid per unit of drying surface is essentially steady, but to qualify the surface of the material must remain fully wet (saturated) during this period; and (2) the falling-off period, during which time the rate of drying decreases as it becomes increasingly difficult to move moisture from the capillaries and interstices of the material to the surface where the moisture can be taken up and moved away. With temperature and air flow (if air is the absorbing and moisture conveying medium to be used) well established, the constant-rate period is relatively easy to forecast and to design because this situation is somewhat analogous to that of drying a shallow container of water. Knowing the foregoing conditions as well as the wetted area involved, drying time periods can be predicted. But, in the case of the falling-off period, the dryer designer must be intimately familiar with the mechanism whereby moisture is held to the material and the mechanics involved in moving the moisture to the surface where it can be picked up.

Thus, the falling-off period has been broken down into two phases: (1) the unsaturated-surface drying period; and (2) the internal-moisture movement period. This first period does not impose unusually difficult analysis because essentially the condition is analogous to a partially-filled shallow vessel whose surface is decreasing as drying proceeds. Essentially, this is an extension of the analysis of the constant-rate period, still leaving the internal-movement situation to be predicted. Formulas are available to assist the designer, based upon past experience with specific drying situations and materials. This is a process that is difficult to assess theoretically, and almost always requires experimental runs or comparisons with other at least somewhat similar materials that have been

TABLE 1. MAJOR TYPES OF PROCESS DRYERS

Continuous Dryers	
Direct Heating	**Indirect Heating**
Tunnel Dryers. Material to be dried is placed on trucks or carts which are moved through a tunnel in which there is a flow of hot gases. Temperature of the tunnel may be zone controlled.	*Drum Dryers*. For materials in liquid and slurry form. One or several drums dip into the liquid or slurry and thus coat the heated drums. The drum temperature is controlled to effect drying during a part of the rotation of the drum from which the dried material is removed by knife prior to dipping one again into the liquid material.
Through-circulation Dryers. Material is supported on a conveying screen that moves continuously. Hot gases from below or above conveyor pass through the material and pick up moisture.	*Cylinder Dryers*. Material in the form of a continuous sheet passes over and around cylinders which rotate and which are heated, usually by steam or hot water.
Rotary Dryers. Material (liquid) is pumped to and showered within a rotating cylinder through which hot gases flow.	*Screw-conveyor Dryers*. A conveyor is housed within a closed, heated housing. This operation may proceed at atmospheric pressure or under vacuum.
Tray Dryers. Material is placed on vibrating trays over or under which hot gases flow.	*Vibrating-tray Dryers*. Similar to the directly heated tray dryer except that the heat is conducted to the trays indirectly (as by electrical heating) rather than by hot gases.
Sheeting Dryers. Material in sheet form passes continuously through a hot chamber. Depending upon product, sheet may be taut (as pinned to a frame). or it may pass through dryer in festoon manner	*Steam-tube Rotary Dryers*. Material is passed through a long rotating cylinder. A shell around the cylinder contains steam, hot water, or other heating medium.
Pneumatic Conveyor Dryers. Material is moved in a stream of gas at high-velocity and high temperature and finally collected by a cyclone separator.	
Batch Dryers	
Through-circulation Dryers. Material is placed on trays with screen bottoms. Hot gases are blown from below through material.	*Agitated-pan Dryers*. Material is placed in covered shallow pans. Pans are jacketed for heating. An agitator stirs the material constantly. This design may be operated at atmospheric pressure or under vacuum.
Vacuum Rotary Dryers. Material is subjected to agitation within a stationary, horizontal shell under vacuum. The agitation may be heated to increase drying effectiveness.	*Vacuum Tray Dryers*. Trays in which material is placed are heated by conduction from supporting shelves. The whole compartment may be under a relatively high vacuum. The material is not agitated.
Tray and Compartment Dryers. Material is placed on trays which then may be placed on trucks or on permanent shelves within dryer. Hot gases are blown across the trays.	

dried successfully. One can generally state that where materials are to be dried to a low-moisture content, the internal-moisture movement period will require the largest portion of the total drying time.

Classification of Dryers. In reviewing the wide variety of drying equipment available, there are a few major classifications that are helpful. There is the distinction between continuous and batch operations. If a continuous drying operation is desired because it will fit into the overall manufacturing operations best, then this decision will rule out those drying concepts that can be applied only in a batch manner. In some instances, it may turn out that in an otherwise fully continuous manufacturing process, the drying portion will have to be handled by batches simply because, for the particular product, batch drying offers the greatest efficiency. There is also the distinction between direct heating and indirect heating methods used in dryers. In direct heating, the heat needed is applied by way of immediate contact between the wet material and hot gases. In indirect heating, the heat needed is transferred to the wet material through an intervening medium, commonly pipes or a retaining wall. There are numerous instances, for example, where a product may be too sensitive to withstand exposure to a moving hot gas.

Since a large majority of drying equipment involves the use of hot gases (usually air), other means of heating can be overlooked. Dielectric heating and freeze-drying, for example, are other means where practical.

Drying equipment also can be made available with means to accelerate the drying process if these means are acceptable to product quality. For example, agitation, stirring, and otherwise keeping the material to be dried in constant motion naturally assists the amount of exposure of surfaces to the drying medium. Numbers of materials, however, cannot be handled in this fashion and require relatively conservative, still conditions.

Principal design configurations of drum-type dryers are illustrated and described in Figs. 1, 2, 3, and 4; conveyor-type dryers in Figs. 5, 6, and 7.

Dehydration. This operation is sometimes described as the removal of 95% or more of the water from a substance, by exposure to thermal energy by various means. Frequently used in food processing, the aims of dehydration are reduction in volume of the product, increase in shelf life, and lower transportation costs, among other factors. There is no clearly defined line of demarcation between drying and dehydrating, the latter sometimes being considered as a subelement of drying. Usually, the direct use of solar energy, as in the drying of raisins, hay, etc., is not lumped in with dehydrating. The term dehydration also is not generally applied to situations where there is loss of water as the result of evaporation. Rehydration or reconstitution of a dehydrated product is the act of restoring a product to essentially its original condition by the simple addition of water, usually just prior to use (as consumption of a food product). The distinction between the terms drying and dehydrating may be somewhat clarified by the fact that most substances can be dried beyond their capability of restoration.

In the case of drying foodstuffs, this is a complex combination of coupled heat and mass transfer through natural tissues. The need to take into account the structure of the food, as opposed to considering it as an homogenous solid, is important. In general, the main source of water in a tissue is the cell. Thus, the transport of water to the outside involves migration through the cell and its enveloping structure, through the porous structure of the tissue, and then through the outside boundary layer. To be able to predict drying behavior, it is necessary to establish the extent to which the foregoing transport steps are controlling. There is no general answer because both the cellular structure and the characteristics of the porous-like tissue structure are involved and the roles they play in the transport process may differ widely — simply because tissue properties change from one foodstuff to the next.

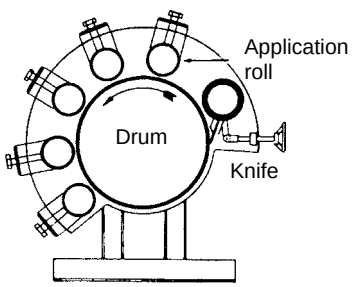

Fig. 1. Single-drum dryer (atmospheric). Dryers of this type may be dip or splash fed (not shown), or, as shown, equipped with applicator rolls. The latter is particularly effective for drying high-viscosity liquids or pasty materials, such as mashed potatoes, applesauce, fruit-starch mixtures, gelatin, dextrine-type adhesives, and various starches. The applicator rolls eliminate void areas, permit drying between successive layers of fresh material and form the product sheet gradually. While single applications may dry to a lacy sheet or flakes, the multiple layers generally result in a product of uniform thickness and density with minimum dusting tendencies. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc.*)

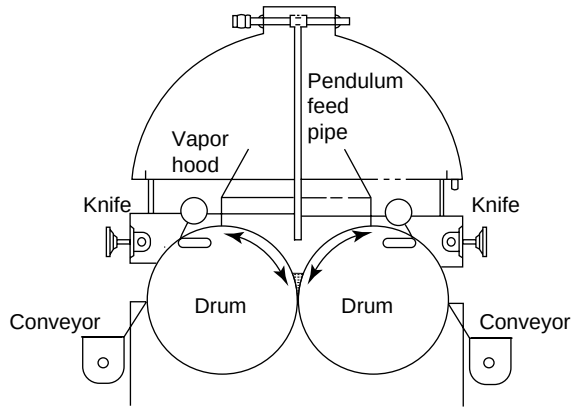

Fig. 2. Double-drum dryer (atmospheric). Dryers of this type handle a variety of food products of widely varying densities and viscosities — dilute solutions, heavy liquids, or pasty materials. A number of products can be dried successfully with this kind of configuration, inasmuch as exposure to temperature above the boiling point is restricted to just a few seconds. The movable drum permits effective control over product film thickness. Feed may be by perforated tube trough, pendulum, or various special configurations. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc.*)

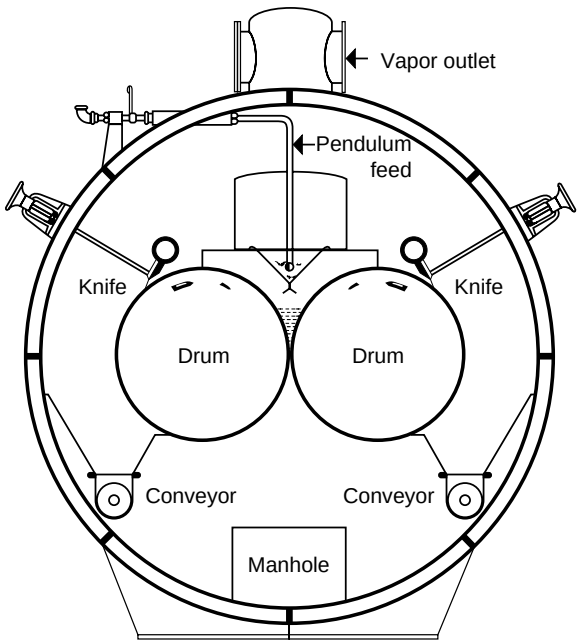

Fig. 3. Single- and double-drum dryer (vacuum). Design configurations like this are applicable whenever products must be dried without exposure to high temperatures or reactive atmospheres. Vacuum operation is particularly suited for vitamin extracts, protein hydrolyzates, soluble coffee, and malt products. Continuous drying without breaking vacuum is achieved by a special conveyance system that utilizes two receivers and air locks. Single-drum feed is usually the pan type with pump and spreading device, or a spray film for materials that are repelled by contact with heated surfaces. Double-drum utilize pendulum or perforated tube feed. Specially designed dispersion devices for feed also can be used. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc.*)

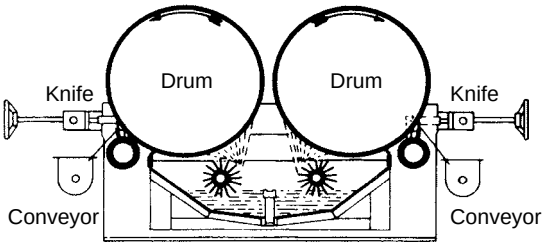

Fig. 4. Twin-drum dryers are designed for handling slurries, corrosive solutions, crystal-bearing or crystal-forming liquids and delicate, heat-sensitive products which may be exposed to high temperatures only for a very limited time. These drums may utilize pendulum or perforated tube for top feed, or splash or spray for bottom feed. Heat-sensitive materials are not in direct contact with the drums. The temperature remains fairly constant and preconcentration is minimized. Cooling and agitation of the material in the pan may also be provided when necessary. (*Buflovak Division, Blaw-Knox Food & Chemical Equipment, Inc.*)

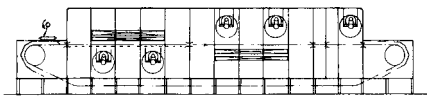

Fig. 5. Single-stage, single-pass conveyor dryer of convection type commonly used to dry, cool, toast, roast, bake, and heat materials. Such units can be zoned for various product drying temperatures, cooling, humidifying, and conditioning requirements. The air flow through the product can be upward or downward and the heat source can be steam, gas, oil, electric, or waste heat. Dryers with this design configuration are applicable to the processing of breakfast cereals, pet foods, fresh vegetables, fruits, and nuts, among numerous other food substances. (*The National Drying Machinery Company*.)

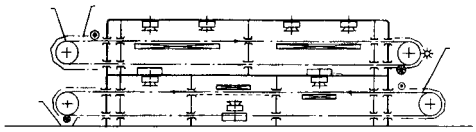

Fig. 6. A multi-tier, multi-pass conveyor dryer. Due to space limitations it is sometimes necessary to tier dryers and use gravity or transfer conveyors to carry the product from one tier to the other. The location of the discharge end will vary with the number of tiers. (*The National Drying Machinery Company*.)

The energy requirements for drying have been studied rather intensively in recent years because the cost of a product can be markedly affected by this energy intense operation. Some researchers have observed that drying costs are much lower for air drying and drum drying than for freeze-drying.

A simplified flow diagram for the preparation of dehydrated fruits and vegetables is given in Fig. 8.

Combination Drying Operations. For some products, it is sometimes advantageous to combine drying with other associated operations. For example, in a fluidized-bed spray granulation process (FBSG), drying, cooling, granulating, and coating of final products, such as various organic and inorganic salts, minerals, dyestuffs, herbicides, pharmaceuticals, and pulping waste liquors, among others, can be accomplished with a reduction of materials-handling and energy costs. FBSG may be defined as a particle-forming process by which a solid containing liquid and possibly a particulate solid is converted into a granular solid state through interaction between the sprayed liquid and a fluidized layer of granules already formed by the process. The liquid feed can be a solution, suspension, or melt. As observed by Mortensen and Hovmand, the most characteristic and essential part of the FBSG process is the formation of new particles and their growth in the fluidized bed, determining the size distribution and bulk density of the product. New particles are produced in two ways within the fluidized bed: (1) from attrition between the fluidized granules; (2) by spray drying the droplets sufficiently prior to contact with particles in the fluidized layer. The process involves a number of variables, most of which are subject to control: (1) feed concentration, (2) ambient air temperature, (3) dryer inlet gas temperature, (4) dryer outlet gas temperature, (5) heating surface temperature, and (6) fluidizing gas velocity.

Spiral Drying Technique. Also sometimes referred to as the DRT (*Drallrohr Trocknung*) technique, this is a relatively recent, innovative process targeted at reducing energy costs. As pointed out by Hess and Rossi, the dryer is designed for continuous moisture removal from wetwater products via fresh ambient air or of solvents via recirculated inert gas. The product's residence time is a matter of seconds, thus precluding thermal degradation of the product. A jacketed outer cylinder is designed for pressurized heat transfer media. The cylinder rests on a base which also incorporates the product inlet. Dry powder is discharged at the top of the cylinder after the product film has moved spirally up the inner wall. Placed within the cylinder is a steam-heated concentric displacement body, which rotates slowly via an external geared motor. The body's outer surface has numerous segmented air-guide plates that are arranged at an appropriate angle. The distance between these plates and the inner wall is greater than the product film thickness. A blower moves the conveying gas tangentially into the tube base, entering opposite a wet-feed metering screw. Thus, the gas disperses the wet feed via intense mixing. This mixture is prevented from bypassing up the column by the displacer's segmented guide plates and is forced into a corkscrew-shaped path along the jacketed surface inner face. Inertial force creates a product film that threads its way upward at constant speed, but in a spiral path until it reaches the top of the dryer. Claims for energy conservation, protection of product, and corrosion resistance, among other factors, are well detailed in the Hess/Rossi reference.

Molecular Sieve Dehydration. This is also a relatively new technology that extends the use of molecular sieve adsorptive dehydration to the removal of over 20% water from organic admixtures.

Numerous other improvements in drying technology are described in the references given. See also **Spray Drying**.

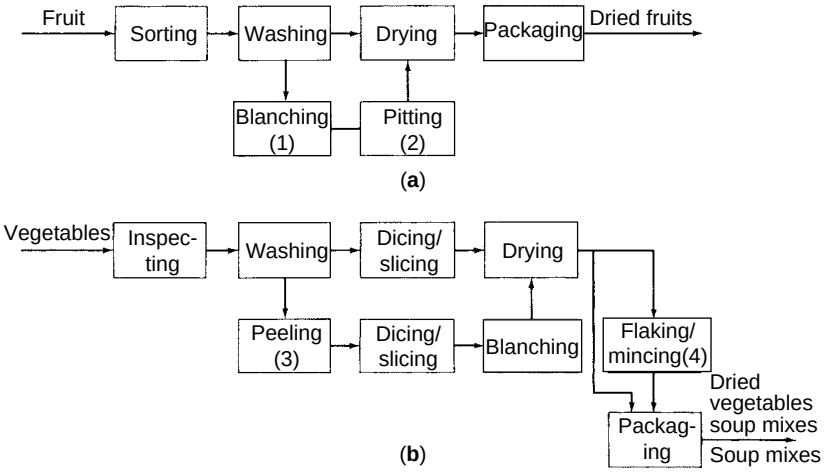

Fig. 8. Simplified flowsheets of operations required in preparation of (**a**) dried fruit and (**b**) dried vegetable products. Operations (1) and (2) are required only for certain fruits, such as prunes. Operation (3) is required only for certain vegetables, such as potatoes. Operation (4) is required only for certain end products.

DRY-REED RELAY. An electromechanical, magnetically actuated, hermetically sealed switch used mainly for analog multiplexing and for controlling low-power loads (3 to 5 VA). The relay capsule is comprised of overlapped cantilevered contacts housed in a hermetically sealed glass capsule. An inert or reducing atmosphere under moderate pressure is contained in the capsule. See Fig. 1. The length of the capsule ranges from less than an inch (2.5 cm) to several inches (8–10 cm), depending upon the power level and application for which the switch is designed. Diameters range from 0.25 to 0.1 in. (0.6–0.25 cm). Nickel-iron alloy contacts, with relatively high permeability and low retentivity, usually are used. Frequently, the contact portion of the reed is electroplated with another metal for the reduction of contact resistance and to increase reliability.

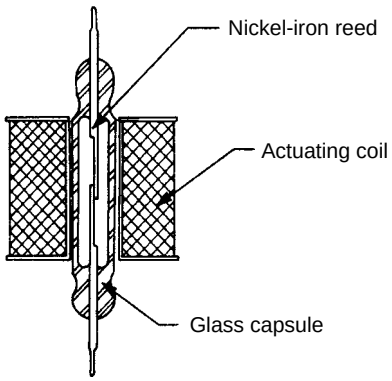

Fig. 1. Dry-reed relay.

The switch usually is actuated by a magnetic field that is produced by a coil wrapped around the capsule, or by a magnet located near the capsule. Opening of the switch is accomplished by the restoring spring force of the reeds proper. Through the use of permanent magnets, the reeds can be biased to achieve normally closed, latching, and other contact actions.

DU BOIS-REYMOND, EMIL HEINRICH (1818–1896). Emil Du Bois-Reymond was a Prussian-German physiologist who developed physical methods for research in electrophysiology.

Du Bois' father was an artisan from the formerly Prussian Swiss Neufch Â;tel; his mother came from a Berlin Huguenot family. He was born and schooled in Berlin and from 1837 studied medicine, first in Bonn and later at Berlin University, where he joined the circle of the students of the physiologist Johannes Müller. The title of his 1843 dissertation, *Quae apud veteres de piscibus electricis exstant argumenta*, indicatesnot only the beginning of a lifelong obsession with electric fishes, but also an interestin the field of electrophysiology to which he was to make important contributions. In the 1840s he propagated together with his friends Ernst Brücke, Hermann Helmholtz and Carl Ludwig a research program of "organic physics" which aimed at establishing physiology as an independent discipline that could explain all physiological processes in line with physico-chemical laws of nature. Du Bois' own contributions to this enterprise lay almost exclusively in the field of electrophysiology to which he supplied important results, fundamental methods of research and numerous technical devices. He succeeded in proving the presence and nature of electric currents in muscles, an enterprise that included the construction of a novel amplifier designed to measure weak currents. The promotion of experimental physiology by the organic physicists included sometimes ferocious antivitalist rhetoric and a demand for physiology to be "fully resolved into the realm of the theoretical sciences." However, with vitalistic models being virtually outdated in physiology at the time, these attacks served other purposes: namely to distinguish the work of the organic physicists who aimed at an independent discipline and who concentrated on sensory physiology from that of other physiologists who favored closer links with microscopic anatomy. See also **Ludwig, Carl Wilhelm Friedrich (1816–1895)** .

Du Bois took his Habilitation (a German postdoctoral university qualification) in 1846, became extraordinary professor in 1855 and finally Johannes Müller's successor as Professor of Physiology at Berlin University after the latter's untimely death in 1858. From 1851 he was a member of the Prussian Academy of Sciences, and from 1867 its secretary, and was twice elected rector of Berlin University. Whereas Brücke, Helmholtz and Ludwig extended their research into other fields after mid-century, Du Bois' contributions remained restricted to electrophysiology. He seems to have been in an intellectualcrisis in the mid 1850s, and had to wait substantially longer than his fellow physicists before being appointed a full professor. Even the grand independent institute for physiology that he was finally given in 1877 was modeled on the blueprint of Ludwig's famous institute in Leipzig. Du Bois, however, in the later stages of his career, became somethingof a spokesman for the natural sciences in Germany, and engaged in debates on the cultural values and philosophical problems of scientific knowledge. These included high-level considerations of the limits of scientific knowledge and brought Du Bois to coin his famous "ignoramus –ignorabimus" (*we do not know and will not know*) to counter Ernst Haeckel's monism. However, Du Bois also at times expressed the modern scientist's arrogance towards classical scholars, for example labeling Goethe's theory of colors as 'amateurish'. Du Bois himself remained rooted in the world of classical heroes that he sometimes mocked. In his 1877 lecture on *Culturgeschichte und Naturwissenschaft* his enthusiasm for science and technology stood side by side with a critique of the utilitarianism and the "Americanization" of science and society in the newly founded German Kaiserreich. Du Bois' scientistic world views, which had been so optimistic earlier on, showed signs of cultural pessimism in his later days.

CHRISTOPH GRANDMANN, University of Heidelberg, Heidelberg, Germany

D^2-STATISTIC. In multivariate analysis, a statistic which measures the "distance" between two populations with identical dispersions. If (α_{ij}) is the dispersion matrix of a p-variate complex, (α^{ij}) is its inverse and δ_i is the difference of means of the ith variate, the distance Δ is defined by

$$\Delta^2 = \sum_{ij=1}^{p} \alpha^{ij}\delta_i\delta_j$$

and for a sample, the definition of the squared distance is similar with estimated means and dispersions on the right. General concept is sometimes referred to as the Mahalanobis' generalized distance.

DUCK. See **Poultry**; and **Waterfowl**.

DUCTED-FAN ENGINE. An aircraft engine incorporating a fan or propeller enclosed in a duct; especially, a jet engine in which an enclosed fan or propellant is used to ingest ambient air to augment the gases of combustion in the jetstream. The air may be taken in at the front of the engine and passed around the combustion section, or it may be taken in aft of the combustion chamber. In the former case the ducted fan may be considered a type of bypass engine.

DUCTILE FRACTURE. Fracture that occurs with a considerable expenditure of energy and is normally associated with and preceded by extensive plastic deformation.

DUCTILITY. A measure of the ability of a metal to deform plastically, without fracturing. Ductility is generally associated with tensile properties or the ability to be cold drawn, as in wire drawing or sheet stamping operations. Percent elongation and reduction of area in the tension test are the usual measure of ductility.

DUFF. The vegetative matter, such as leaves, twigs, dead logs, etc., that covers the ground in the forest; unconsolidated decomposing and partially decomposed organic material immediately under a layer of leaf litter. Duff forms a layer about 5 cm (2 in.) thick that overlies the soil of a forest floor. Its thermal insulation is an important factor in the formation of permafrost, and the quality and moisture content of duff is significant in considerations of forest fire hazard (fire weather). See also **Permanent Frost**.

DUGONG. See **Sea Cows**.

DUJARDIN, FÉLIX (1891–1860). Dujardin was a French zoologist who made important preliminary studies of animal protoplasm and expanded the study of Parasitology and protozoology.

Dujardin, a watchmaker's son from Tours, France, showed an early interest in art and chemistry. After working as a hydraulic engineer in Sedan, where he married Clémentine Grégoire (1823), Dujardin returned to Tours as a librarian and teacher (mathematics, chemistry, geometry). He also botanized in the surrounding area. After a fewyearsin Paris (1833–1839) without a formal position, he accepted the chair in geology at Toulouse. A year later (1840), he became professor of zoology and botany at Rennes, where he remained until his death.

Dujardin's work is characterized by careful observation of organisms in their natural state, and fine drawings of his results. He developed a system of lenses beneath the stage of his microscope similar to a condenser.

He differentiated a new family, the Rhizopods among the disparate microscopic Foraminifera. In addition to refining the taxonomy, he made a more fundamental discovery. A contemporary of Dujardin's, Christian Ehrenberg, claimed that the microscopic aquatic organisms known as *Infusoria* contained a miniature form of the organ systems of more complex animals. In opposition to this, Dujardin coined the term "sarcode" (from the Greek, sarca=flesh) to describe the apparently undifferentiated nature of the protoplasm that formed these creatures. He subjected this 'living jelly' (gelée vivante) to a range of chemical tests, but did not think in cellular terms or link animal sarcode with the similar material in plants.

Other studies on a range of parasites of invertebrates (1841) and intestinal parasites (1845), which were the results of numerous dissections, provided excellent descriptions of known and new species. Dujardin also appreciated, but failed to publish, his ideasabout the role of intermediate hosts in the life cycles of *Trematodes* and *Cestodes*.

DULBECCO, RENATO (1914–). Renato Dulbecco is an Italian-born American virologist who showed how tumor virusescan transform normal cells into cancer-like cells.

Though Renato Dulbecco demonstrated a talent and a disposition for laboratory science as a medical student at the University of Turin, after earning his degree in 1936 he left the laboratory to practice medicine. He served in the military, worked in the Italian Resistance during World War II, practiced dentistry, and even tried his hand in politics, before finally returning to laboratory science. He took an assistantship at the Institute of Pathological Anatomy in Turin in 1945, and studied physics, as this would reinforce his new line of research, the effect of radiation on cellular development. Salvador Luria, also interested in this field, invited Dulbecco to work at his laboratory in Bloomington, Indiana. Dulbecco and his family moved to the United States in 1947. Dulbecco's successes in Indiana caught the attention of Max Delbrück, who enticed him to join the phage group at the California Institute of Technology, and to study animal virology. See also **Delbruck, Max Ludwig Henning (1906–1981)**; and **Virology (The History)**.

Research in animal virology was hindered at the time by the fact that it was impossible to obtain stable animal cell cultures. In 1950 Dulbecco set himself to the task of developing a technique for growing animal cell cultures, and in 1952 achieved success. With his cultures he was able to indicate the action of viruses by inoculating the cell culture with very dilute viral solution. Translucent plaques formed where the virus had killed the cells. This basic technique, indispensable for quantifying viral action, had been used for decades in bacteriophage research (viruses infecting bacterial cells), but this was the first time it could be employed in animal virology.

After this success, Dulbecco began to research the polio virus, and later, tumor viruses. His research demonstrated how a tumor virus can transform normal cells into cancer-like cells that reproduce without restraint. In 1972 he joined the Imperial Cancer Research Fund Laboratories in London to work in the field of human cancers. In his Nobel Prize address in 1975, he commented on the research problems posed by cancer, and condemned the way that society plays loosely with known carcinogens, particularly tobacco. He retired in 1992, but remains active, participating in conferences and demonstrations and commenting publicly on the important biological issues of our time.

SUZANNE BOARD, Toronto, Ontario, Canada

DULONG AND PETIT LAW OF SPECIFIC HEATS. It has long been known that the atomic heats of the great majority of elements have nearly the same value at room temperature; in fact, the thermal capacity of a gram-atom of most elements is not far from 6 calories per degree. Dulong and Petit expressed this by stating that the specific heats of elements are in inverse proportion to their atomic weights.

That this should be the case for gases, easily follows from the kinetic theory and the principle of equipartition of energy. For example, if the same mean energy per molecule is necessary to raise the temperature of oxygen and of hydrogen 1°, the same is true per atom, and weights of these gases having the same number of atoms will have equal thermal capacities.

For solids the matter is not quite so simple, and the more exacting theories of Einstein, Debye, and others show that the atomic heat should be expected to vary with the temperature. According to Debye, there is a certain characteristic temperature for each crystalline solid at which its atomic heat should equal 5.67 calories per degree. Einstein's theory expresses this temperature as $h\nu_m/k$, in which h is Planck's constant, k is Boltzmann's constant, and ν_m is a frequency characteristic of the atom in question vibrating in the crystal lattice.

DUMAS METHOD FOR VAPOR PRESSURE. A small quantity of the liquid the density of whose vapor is required is inserted into a weighed glass bulb which has a neck drawn to a point. The bulb is heated to about 30 °C above the boiling point until the liquid disappears, the vapor being

rapidly expelled and carrying the air in the bulb with it. After measuring barometric pressure and temperature of the bath, the bulb is sealed off, cooled, and reweighed. The end of the neck is then broken off under water, when the water completely fills the bulb. The weight of the bulb is again found, full of water, giving its internal volume. From the readings the weight of a known volume of vapor is found, and hence its density. The method is frequently used when a more accurate method than the Victor Meyer method is required. Modifications have been made at lower pressures and higher temperatures.

DUMMY. 1. In computer operations, an artificial and intrinsically useless unit of information inserted solely to fulfill certain prescribed conditions such as word length or block length.

2. In rocketry, an inert stage, i.e., no propellant.

DUMMY ANTENNA. A device that has the necessary impedance characteristics of an antenna and the necessary powerhandling capabilities, but which does not radiate or receive radio waves. Also called *artificial antenna*. In receiver practice, that portion of the impedance not included in the signal generator is often called *dummy antenna*.

DUMORTIERITE. This mineral found within schists and gneisses is valuable for use in the manufacture of high-grade porcelain. It is a borosilicate of aluminum $Al_7(BO)_3(SiO_4)O_3$, crystallizing in the orthorhombic system. Crystals are rare; commonly occurs as fibrous aggregates of blue to pink color, with vitreous luster. Transparent to translucent with hardness of 8.5, and specific gravity of 3.41.

World occurrences include France, Madagascar, Brazil, and Mexico, with California and Nevada the principal United States localities.

DUNE. An elliptical or crescent-shaped mound of sand which may reach a height of a hundred or more feet. The windward slopes of dunes are gentle, the lee sides are steep. If the dune is crescent-shaped, the convex side will face the direction from which the wind is blowing. Crescent-shaped dunes are called *barchans*. Sand blown up the windward side drops down the lee slope, causing the dunes to migrate slowly. This action can be quite destructive, unless prevented by some form of vegetation to hold the dunes in place. Small dunes may progress in their forward movement from 10 to 20 feet (3 to 6 meters) per year, although progress of over 1000 feet (30 meters) per year has been reported in some areas of the world, as at the Bay of Bicay in France. In terms of gradually, but steadily destroying woods, forests, agricultural land, and villages at their periphery, the sand and wind working together, in essence, create the effects of a slowly moving flood with sand as the inundating medium instead of water. The progress of dune movement and hence possible destruction depends largely on the presence of winds of long duration and of reasonable intensity.

As wind conditions change, so do the dunes. Consequently, there are dunes which reflect conditions of prior geologic and climatic periods, as in the case of the lacustrine dunes found along the southern and southeastern shore of Lake Michigan. Often dunes will be found in areas where former lakes existed. There is also some dune formation along riverbanks, as for example, the dunes along the eastern banks of the Mississippi, the Missouri, and Rio Grande Rivers in the United States. But generally the inland dunes are found mainly in the large desert areas — the Sahara, Arabian, Gobi deserts and regions of Iran, Turkey, Mongolia, and the United States that are essentially arid. Comparatively few inland dunes are found in the United States, some in California and a few in the sand hill region of western Nebraska.

Oceanic coastal dunes are found in several parts of the world — Brittany, Cornwall, the eastern shoreline of the United States from Cape Cod southward, and the western shoreline, notably along California coasts.

DUODENUM. See **Digestive System (Human)**.

DUPLEXER. Also known as transmit-receive circuit, a duplexer makes possible the use of the same antenna for both transmission and reception by preventing the flow of damaging amounts of power to the receiver during transmission, without at the same time reducing excessively the input to the receiver during reception.

DURBIN-WATSON STATISTIC. The usual mode in linear regression, for example

$$y = \sum_{i=1}^{p} \beta_i x_j + \in$$

requires that the residual term ε is a random variable and, in particular, that the values from one observation to another are independent. If a set of values of y's and x's is available in temporal order, one problem is to decide whether this assumption is acceptable. The Durbin-Watson statistic, which is dependent on the observed residuals, is designed to test the hypothesis of independence in the true (unknown) residuals.

DURICRUST. A general term for a hard crust on the surface of, or layer in the upper horizons of, a soil of a semiarid climate. It is formed by the accumulation of soluble minerals deposited by mineral-bearing waters that move upward by capillary action and evaporate during the dry season. It may consist of concentrations of aluminous and ferruginous material (*ferricrete*) upon feldspathic rocks, of siliceous material (*silicrete*) upon argillaceous and arenaceous rocks, or of calcareous material (*caliche* or *calcrete*) upon carbonate rocks. The term sometimes excludes calcareous crusts.

DUST. Solid materials suspended in the atmosphere in the form of small irregular particles, many of which are microscopic in size.

It imparts a tannish or grayish hue to distant objects. The sun's disk is pale or colorless or has a yellowish tinge at all periods of the day. Dust cannot be a stable component of the atmosphere because it must eventually fall back to the earth's surface when winds and turbulence become too weak to bear it aloft. Dust is due to many natural and artificial sources, for example, volcanic eruptions, salt spray from the seas, blowing solid particles, plant pollen, bacteria, and smoke and ashes from forest fires and industrial combustion processes. It was once thought that dust particles were a main source of condensation nuclei; this is no longer regarded as probable as most dusts are not sufficiently hygroscopic.

See also **Dust Devil**; **Duststorm**; and **Dust Whirl**.

AMS

DUST BOWL. A name given, early in 1935, to the region in the south-central United States affected by drought and duststorms at that time.

It included parts of five states: Colorado, Kansas, New Mexico, Texas, and Oklahoma. It resulted from a long period of deficient rainfall combined with loosening of the soil by destruction of the natural vegetation. The name has since been extended to similar regions in other parts of the world. See also **Soil**.

AMS

DUST DEVIL. A well-developed dust whirl; a small but vigorous whirlwind, usually of short duration, rendered visible by dust, sand, and debris picked up from the ground. Dust devils occasionally are strong enough to cause minor damage (up to F1 on the Fujita scale). Diameters range from about 3 meters (10 feet) to greater than 30 meters (98 feet); their average height is about 200 meters (656 feet), but a few have been observed as high as 1 kilometer (0.6 mile) or more. They have been observed to rotate anticyclonically as well as cyclonically. Although the vertical velocity is predominantly upward, the flow along the axis of large dust devils may be downward. Large dust devils may also contain secondary vortices. Dust devils are best developed on a hot, calm afternoon with clear skies, in a dry region when intense surface heating causes a very steep lapse rate of temperature in the lowest 100 meter (328 feet) of the atmosphere. See also **Fronts and Storms**; and **Tornado**.

DUSTSTORM. An unusual, frequently severe weather condition characterized by strong winds and dust-filled air over an extensive area. Prerequisite to a duststorm is a period of drought over an area of normally arable land, thus providing the very fine particles of dust that distinguish it from

the more common sandstorm of desert regions. A duststorm usually arises suddenly in the form of an advancing dust wall that may be many kilometers long and and a kilometer or so deep, ahead of which there may be some dust whirls, either detached or merging with the main mass. Ahead of the dust wall the air is very hot and the wind is light. In U.S. weather observing practice, if blowing dust reduces visibility to between 5/8 and 5/16 statute mile, a "duststorm" is reported; if the visibility is reduced to below 5/16 statute mile, it is reported as a "severe duststorm." Duststorm winds can also be associated with thunderstorm outflows and gust fronts. While these are often shorter-lived than synoptically forced duststorms, they can be quite intense, with an impressive leading edge of the dusty gust front, sometimes called a dust wall. See also **Soil**; and **Winds and Air Movement**.

DUST WHIRL. (Also called dancing dervish, dancing devil, devil, satan, shaitan; and, over desert areas, desert devil, sand auger, sand devil.) A rapidly rotating column of air (whirlwind) over a dry and dusty or shady area, carrying dust, leaves, and other light material picked up from the ground. When well developed it is known as a dust devil. Dust whirls typically form as the result of strong convection during sunny, hot, calm summer afternoons. This type is generally several meters in diameter at the base, narrowing for a short distance upward and then expanding again, like two cones apex to apex. Their height varies; normally it is only 30–100 meters (98–328 feet), but in hot desert country it may be as high as 1 kilometer (0.6 mile). Rotation may be either clockwise or counterclockwise. Dust whirls move erratically, from one patch of heated air to another, and generally slowly. In desert country it is not unusual for three or more desert devils to be visible at the same time. Another type of vigorous dust whirl occurs under the bases of cumulonimbus or cumulus clouds, almost always on or near a wind-shift line. These vortices often inflict little or no damage and are short-lived, but occasionally represent the first visible sign of a developing tornado. Another form of dust whirl, often seen at street corners, is merely an eddy caused by the meeting of winds blowing along two intersecting streets. Such whirls are small and very short-lived.

DUTY CYCLE. A term, applied to instruments and devices, to denote the following characteristics: (1) the time interval occupied by a device on intermittent duty in starting, running, stopping, or idling (an example would be the maximum time that a device can operate continuously), and (2) the ratio of the "on time" interval occupied in operating a device to the total time of one operating cycle (the ratio of the pulse-duration time to the pulse-reception time). An illustration of duty cycle is given in Fig. 1.

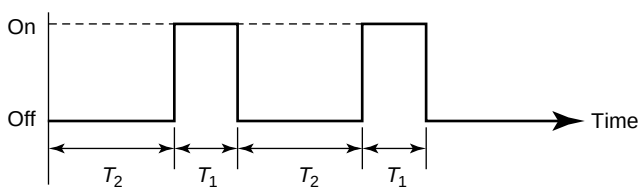

Fig. 1. Examples of duty cycle. During period T_1, the device is on. During T_2, the device is off. The duty cycle in percent is $(T_1T_2) \times 100$.

DU VIGNEAUD, VINCENT (1901–1978). An American biochemist who won the Nobel Prize for chemistry in 1955. His work involved the study of the metabolism of biologically significant sulfur compounds, which led to the finding of transmethylation in mammalian metabolism. He isolated and proved the structure of the vitamin biotin, and synthesized penicillin, oxytocin, and the vasopressin hormone of the posterior pituitary. His education was at Rochester, Yale, St. Louis, and George Washington Universities.

DYADIC. In ordinary vector analysis no meaning is attached to a symbol such as **AB**, where neither dot nor cross stands between two vectors. Such a quantity is called a dyad and the symbolic sum of two or more dyads is a dyadic polynomial or, more briefly, a dyadic. It is useful in the study of linear vector functions and has applications to theories of rotation and strain, electromagnetism, and optical phenomena in nonisotropic solids.

Consider the vector function

$$\mathbf{r}' = \mathbf{i}(c_1\mathbf{i}\cdot\mathbf{r}) + \mathbf{j}(c_2\mathbf{j}\cdot\mathbf{r}) + \mathbf{k}(c_3\mathbf{k}\cdot\mathbf{r}),$$

which is readily interpreted since the quantities in parentheses are scalars. The same equation, however, can be more simply written as $\mathbf{r}' = (\mathbf{i}c_1\mathbf{i} + \mathbf{j}c_2\mathbf{j} + \mathbf{k}c_3\mathbf{k})\cdot\mathbf{r}$ or, generally, if $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3, \ldots, \mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3, \ldots$ are two sets of vectors, as $\mathbf{r}' = (\mathbf{a}_1\mathbf{b}_1 + \mathbf{a}_2\mathbf{b}_2 + \mathbf{a}_3\mathbf{b}_3 + \cdots)\cdot\mathbf{r} = \Phi\cdot\mathbf{r}$. In the last equation, the direct or scalar product of the dyadic Φ and the vector $\mathbf{r}$ yields a new vector $\mathbf{r}'$. The scalar product is not always commutative, for it does not follow that $\Phi\cdot\mathbf{r} = \mathbf{r}\cdot\Phi$. A special dyadic is the idemfactor, $\mathbf{I} = \mathbf{ii} + \mathbf{jj} + \mathbf{kk}$, which has the property that $\mathbf{I}\cdot\mathbf{r} = \mathbf{r}\cdot\mathbf{I} = \mathbf{r}$.

Nine fundamental dyads can be formed from unit vectors, $\mathbf{i}, \mathbf{j}, \mathbf{k}$. The nonian form of any dyadic can be written in terms of them and scalar quantities a_{mn} as

$$\Phi = a_{11}\mathbf{ii} + a_{12}\mathbf{ij} + a_{13}\mathbf{ik} + a_{21}\mathbf{ji} + a_{22}\mathbf{jj} + a_{23}\mathbf{jk} + a_{31}\mathbf{ki} + a_{32}\mathbf{kj} + a_{33}\mathbf{kk}$$

One can continue the algebra of dyadics, defining several kinds of products, reciprocals, conjugates, and other properties. A sophisticated approach to the dyadic regards it as a special kind of tensor with nine components. Each of them is a function of three coordinates and they transform from one coordinate system to another according to rules that can be derived. A dyadic can also be written in matrix form and can be generalized to the concept of triad, tetrad, polyad, and polyadic. See also **Tetradic**.

DYE AND DYE INTERMEDIATES. The first synthetic dye, Mauveine, was discovered by Perkin in 1856. Hence the dyestuffs industry can rightly be described as mature. The early dyes industry saw the discovery of the principal dye chromogens (the basic arrangement of atoms responsible for the color of a dye). Indeed apart from one or two notable exceptions, all the dye types used today were discovered in the nineteenth century. The introduction of the synthetic fibers, nylon, polyester, and polyacrylonitrile during the period 1930–1950, produced the next significant challenge. The discovery of reactive dyes in 1956 heralded a big breakthrough in the dyeing of cotton; intensive research into reactive dyes followed over the next two decades and, indeed, is still continuing today. See also **Dyes: Reactive**.

The scale and growth of the dyes industry is inextricably linked to that of the textile industry. The two most important textile fibers are cotton, the largest, and polyester. Consequently, dye manufacturers tend to concentrate their efforts on producing dyes for these two fibers.

Perkin, an Englishman, working under a German professor, Hoffman, discovered the first synthetic dye, and even today the geographical focus of dye production lies in Germany (BASF, Bayer, Hoechst), England (Zeneca), and Switzerland (CIBA-GEIGY and Sandoz). Far Eastern countries, such as Japan, Korea, and Taiwan, and Third World countries, such as India, Brazil, and Mexico, also produce dyes.

Dyes may be classified according to chemical structure or by their usage or application method. The former approach is adopted by practicing dye chemists who use terms such as azo dyes, anthraquinone dyes, and phthalocyanine dyes. The latter approach is used predominantly by the dye user, the dye technologist, who speaks of reactive dyes for cotton and disperse dyes for polyester. Very often, both terminologies are used, for example, an azo disperse dye for polyester and a phthalocyanine reactive dye for cotton.

The most appropriate system for the classification of dyes is by chemical structure, which has many advantages. First, it readily identifies dyes as belonging to a group that has characteristic properties, for example, azo dyes (strong and cost-effective) and anthraquinone dyes (weak and expensive). Secondly, there are a manageable number of chemical groups (about a dozen). Most importantly, it is the classification used most widely by both the synthetic dye chemist and the dye technologist. Thus, both chemists and technologists can readily identify with phrases such as an azo yellow, an anthraquinone red, and a phthalocyanine blue.

It is advantageous to consider the classification of dyes by use or method of application before considering chemical structures in detail because of dye nomenclature and jargon that arises from this system. Classification by usage or application is the principal system adopted by the *Colour Index* (CI).

Dyes can also be classified according to their usage.

Dyes are named either by their commercial trade name or by their *Colour Index* name. In the *Colour Index* these are cross-referenced.

The commercial names of dyes are usually made up of three parts. The first is a trademark used by the particular manufacturer to designate both

the manufacturer and the class of dye, the second is the color, and the third is a series of letters and numbers used as a code by the manufacturer to define more precisely the hue, and also to indicate important properties the dye possesses.

Classification of Dyes by Chemical Structure

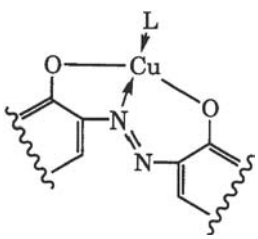
The two overriding trends in dyestuffs research for many years have been improved cost-effectiveness and increased technical excellence. Improved cost-effectiveness usually means replacing tinctorially weak dyes such as anthraquinone, the second largest class after the azo dyes, with tinctorially stronger dyes such as heterocyclic azos, triphendioxazines, and benzodifuranones. This theme will be pursued throughout this section discussing dyes by chemical structure.

Azo Dyes. These dyes are by far the most important class, accounting for over 50 % of all commercial dyes, and having been studied more than any other class. Azo dyes contain at least one azo group (−N=N−) but can contain two (disazo), three (trisazo), or, more rarely, four or more (polyazo) azo groups. The azo group is attached to two radicals of which at least one, but, more usually, both are aromatic.

In monoazo dyes, the most important type, the A radical often contains electron-accepting groups, and the E radical contains electron-donating groups, particularly hydroxy and amino groups. If the dyes contain only aromatic radicals such as benzene and naphthalene, they are known as carbocyclic azo dyes. If they contain one or more heterocyclic radicals, the dyes are known as heterocyclic azo dyes.

Almost without exception, azo dyes are made by diazotization of a primary aromatic amine followed by coupling of the resultant diazonium salt with an electron-rich nucleophile.

The three metals of importance in azo dyes are copper, chromium, and cobalt. The most important copper dyes are the 1:1 copper(II): azo dye complexes of formula; they have a planar structure.



In contrast, chromium(III) and cobalt(III) form 2:1 dye:metal complexes that have nonplanar structures. Geometrical isomerism exists.

Premetallized dyes are now used widely in various outlets to improve the properties of the dye, particularly lightfastness. However, this is at the expense of brightness, because metallized azo dyes are duller than nonmetallized dyes.

Carbocyclic azo dyes are the backbone of most commercial dye ranges. Based totally on benzene and naphthalene derivatives, they provide yellow, red, blue, and green colors for all the major substrates such as polyester, cellulose, nylon, polyacrylonitrile, and leather.

The carbocyclic azo dye class provides dyes having high cost-effectiveness combined with good all-around fastness properties. However, they lack brightness, and consequently, they cannot compete with anthraquinone dyes for brightness. This shortcoming of carbocyclic azo dyes is overcome by heterocyclic azo dyes.

One long-term aim of dyestuffs research has been to combine the brightness and high fastness properties of anthraquinone dyes with the strength and economy of azo dyes. This aim is now being realized with heterocyclic azo dyes, which fall into two main groups: those derived from heterocyclic coupling components, and those derived from heterocyclic diazo components.

All the heterocyclic coupling components that provide commercially important azo dyes contain only nitrogen as the hetero atom. They are indoles, pyrazolones, and especially pyridones; they provide yellow to orange dyes for various substrates.

In contrast to the heterocyclic coupling components, virtually all the heterocyclic diazo components that provide commercially important azo dyes contain sulfur, either alone or in combination with nitrogen (the one notable exception is the triazole system). These S or S/N heterocyclic azo dyes provide bright, strong shades that range from red through blue to green, and therefore complement the yellow-orange colors of the nitrogen heterocyclic azo dyes in providing a complete coverage of the entire shade gamut.

Anthraquinone Dyes. This second most important class of dyes also includes some of the oldest dyes; they have been found in the wrappings of mummies dating back over 4000 years. In contrast to the azo dyes, which have no natural counterparts, all the important natural red dyes were anthraquinones. See also **Dyes: Natural**. However, the importance of anthraquinone dyes is declining due to their low cost-effectiveness.

Anthraquinone dyes are based on 9,10-anthraquinone [CAS: 84-65-1], which is essentially colorless. To produce commercially useful dyes, powerful electron-donor groups such as amino or hydroxy are introduced into one or more of the four alpha positions (1,4,5, and 8). The most common substitution patterns are 1,4-, 1,2,4-, and 1,4,5,8-. To maximize the properties, primary and secondary amino groups (not tertiary) and hydroxy groups are employed.

Anthraquinone dyes are prepared by the stepwise introduction of substituents on to the performed anthraquinone skeleton or ring closure of appropriately substituted precursors.

The principal advantages of anthraquinone dyes are brightness and good fastness properties, but they are both expensive and tinctorially weak. However, they are still used extensively, particularly in the red and blue shade areas, because other dyes cannot provide the combination of properties offered by anthraquinone dyes, albeit at a price. See also **Dyes: Anthraquinone**.

Benzodifuranone Dyes. These (BDF) dyes are challenging anthra quinone dyes. The BDF chromogen is one of the very few novel chromogens to have been discovered in this century. As with many other discoveries the BDF chromogen was detected by accident.

BDFs are unusual in that they span the whole color spectrum from yellow through red to blue, depending on the electron-donating power of the R group on the phenyl ring of the aryl acetic acid.

Polycyclic Aromatic Carbonyl Dyes. Structurally, these dyes contain one or more carbonyl groups linked by a quinonoid system. They tend to be relatively large molecules built up from smaller units, typically anthraquinones. Since they are applied to the substrate (usually cellulose) by a vatting process, the polycyclic aromatic carbonyl dyes are often called the anthraquinonoid vat dyes.

Although the colors of the polycyclic aromatic carbonyl dyes cover the entire shade gamut, only the blue dyes and the tertiary shade dyes, namely, browns, greens, and blacks, are important commercially. As a class, the polycyclic aromatic carbonyl dyes exhibit the highest order of lightfastness and wetfastness.

Indigoid Dyes. Like the anthraquinone, benzodifuranone, and polycyclic aromatic carbonyl dyes, the indigoid dyes also contain carbonyl groups. They are also vat dyes.

Indigoid dyes represent one of the oldest known classes of dyes. Although many indigoid dyes have been synthesized, only indigo [CAS: 482-89-3] itself is of any importance today. Indigo is the blue used almost exclusively for dyeing denim jeans and jackets and is held in high esteem because it fades in tone to give progressively paler blue shades.

Polymethine and Related Dyes. Cyanine dyes are the best known polymethine dyes. Nowadays, their commercial use is limited to sensitizing dyes for silver halide photography. However, derivatives of cyanine dyes provide important dyes for polyacrylonitrile. They include azacarbocyanines, hemicyanines, and diazahemicyanines.

Styryl Dyes. The styryl dyes are uncharged molecules containing a styryl group $C_6H_5-CH=C$ usually in conjugation with an *N,N*-dialkylaminoaryl group. Styryl dyes were once a fairly important group of yellow dyes for a variety of substrates. They are synthesized by condensation of an active methylene compound, especially malononitrile [CAS: 109-77-3] with a carbonyl group, especially an aldehyde. As such, styryl dyes have small molecular structures and are ideal for dyeing densely packed hydrophobic substrates such as polyester.

Yellow styryl dyes have now been largely superseded by superior dyes such as azopyridones, but there has been a resurgence of interest in red and blue styryl dyes.

Blue styryl dyes are produced when an even more powerful electron-with-drawing group than tricyanovinyl is used. Thus, Sandoz discovered that the condensation of the sulfone [CAS: 74228-25-4] with an aldehyde

gives the bright blue dye for polyester. In addition to exceptional brightness, this dye also possesses high tinctorial strength. However, its lightfastness is only moderate.

Di- and Triaryl Carbonium and Related Dyes. As a class, these dyes are bright and strong, but are generally deficient in lightfastness. Consequently, they are used in outlets where brightness and cost-effectiveness, rather than permanence, are paramount, for example, the coloration of paper. Many dyes of this class, especially derivatives of pyronines (xanthenes), are among the most fluorescent dyes known.

Resurgence of interest in triphendioxazine dyes arose through successful modification of the intrinsically strong and bright triphendioxazine chromogen to produce blue reactive dyes for cotton. These blue reactive dyes combine the advantages of azo dyes and anthraquinone dyes. Thus they are bright, strong dyes with good fastness properties.

Phthalocyanines. Apart from the recent discoveries of benzodifuranone dyes and diketopyrrolopyrrole pigments, phthalocyanine [CAS: 574-93-6] is the only novel chromogen of commercial importance discovered since the nineteenth century. It was discovered accidently in 1928, when during the routine manufacture of phthalimide from phthalic anhydride and ammonia it was found that the product contained a blue contaminant. Chemists of Scottish Dyes Ltd, now part of Zeneca, carried out an independent synthesis of the blue material by passing ammonia gas into molten phthalic anhydride containing iron filings.

Phthalocyanines are analogues of the natural pigments chlorophyll and heme. However, unlike these natural pigments, which have extremely poor stability, phthalocyanines are probably the most stable of all the colorants in use today. Substituents can extend the absorption to longer wavelengths, into the near infrared, but not to shorter wavelengths, and so their hues are restricted to blue and green.

Of all the metal complexes evaluated, copper phthalocyanines give the best combination of color and properties and consequently the majority of phthalocyanine dyes are based on copper phthalocyanine.

Besides being extremely stable, phthalocyanines are bright and tinctorially strong (ε_{max} ~100, 000); this renders them cost-effective. Consequently, phthalocyanines are used extensively in printing inks and paints.

Quinophthalones. Like the hydroxy azo dyes, quinophthalone dyes can, in theory, exhibit tautomerism. The dyes are synthesized by the condensation of quinaldine derivatives with phthalic anhydride. Quinophthalones provide important yellow dyes for the coloration of plastics and for the coloration of polyester.

Sulfur Dyes. These dyes are synthesized by heating aromatic amines, phenols, or nitro compounds with sulfur or, more usually, alkali polysulfides. Sulfur dyes are used for dyeing cellulosic fibers. They are insoluble in water and are reduced to the water-soluble leuco form for application to the substrate by using sodium sulfide solution. The sulfur dye proper is then formed within the fiber pores by atmospheric oxidation. Sulfur dyes constitute an important class of dye for producing cost-effective tertiary shades, especially black, on cellulosic fibers.

Dye Intermediates

The precursors of dyes are called dye intermediates. They are obtained from simple raw materials, such as benzene and naphthalene, by a variety of chemical reactions. Usually, the raw materials are cyclic aromatic compounds, but acyclic precursors are used to synthesize heterocyclic intermediates. The intermediates are derived from two principal sources, coal tar and petroleum.

Intermediates Classification. Intermediates may be conveniently divided into primary intermediates (primaries) and dye intermediates. Large amounts of inorganic materials are consumed in both intermediates and dyes manufacture.

Inorganic materials include acids (sulfuric, nitric, hydrochloric, and phosphoric), bases (caustic soda, caustic potash, soda ash, sodium carbonate, ammonia, and lime), salts (sodium chloride, sodium nitrite, and sodium sulfide) and other substances such as chloride, bromine, phosphorus chlorides, and sulfur chlorides. The important point is that there is a significant usage of at least one inorganic material in all processes, and the overall tonnage used by, and therefore the cost to, the dye industry is high.

Dye intermediates are defined as those precursors to colorants that are manufactured within the dyes industry, and they are nearly always colorless. Colored precursors are conveniently termed color bases. As distinct from primaries they are only rarely manufactured in single-product units because of the comparatively low tonnages required. Fluorescent brightening agents (FBAs) are neither intermediates nor true colorants.

There are at least 3000 different intermediates in current manufacture (over half that number are specifically mentioned in the *Colour Index*), and in addition there is a comparatively small number of products manufactured by individual companies for their own specialties.

The Chemistry of Dye Intermediates

The chemistry of dye intermediates may be conveniently divided into the chemistry of carbocycles, such as benzene and naphthalene, and the chemistry of heterocycles, such as pyridenes and thiophenes.

Equipment and Manufacture

The basic types of dye (and intermediate) manufacture are shown in Figure 1. There are usually several reaction steps or unit processes.

Health and Safety Aspects

The toxic nature of some dyes and intermediates has long been recognized. Acute, or short-term, effects are generally well known. They are controlled by keeping the concentration of the chemicals in the workplace atmosphere below prescribed limits and avoiding physical contact with the material. Chronic effects, on the other hand, frequently do not become apparent until after many years of exposure.

The positive links between benzidine derivatives and 2-naphthylamine with bladder cancer prompted the introduction of stringent government regulations to minimize such occurrences in the future. Currently, the three principal regulatory agencies worldwide are European Core Inventory (ECOIN) and European Inventory of Existing Commercial Substances (EINECS) in Europe, Toxic Substances Control Act (TOSCA) in the United States, and Ministry of Technology and Industry (MITI) in Japan. Each of these has its own set of data and testing protocols for registration of a new chemical substance.

Dyes, because they are intensely colored, present special problems in effluent discharge; even a very small amount is noticeable. However, the effect is more aesthetically displeasing rather than hazardous. Of greater concern is the discharge of toxic heavy metals such as mercury and chromium.

Effluents from both dye works and dyehouses are treated both before leaving the plant, e.g., neutralization of acidic and alkaline liquors and heavy metal removal, and in municipal sewage works. Various treatments are used.

Biological treatment is the most common and most widespread technique used in effluent treatment, having been employed for over 140 years. There are two types of treatment, aerobic and anaerobic.

Removal of color by adsorption using activated carbon is also employed. Activated carbon is very good at removing low levels of soluble chemicals, including dyes. Its main drawback is its limited capacity. Consequently, activated carbon is best for removing color from dilute effluent.

Chemical treatment of the effluent with a flocculating agent is the most robust and generally most efficient way to remove color.

Chemical oxidation is a more recent method of effluent treatment, especially chemical effluent. This procedure uses strong oxidizing agents like ozone, hydrogen peroxide, chlorine, and potassium permanganate in order to force degradation of even some of the more resilient organic molecules.

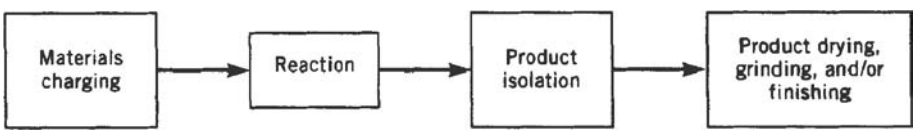


Fig. 1. Operation Sequence in dye and intermediate manufacture

Additional strategies being implemented to minimize dye and related chemical effluent include designing more environmentally friendly chemicals, more efficient (higher yielding) manufacturing processes, and more effective dyes, e.g., reactive dyes having higher fixation.

DYE CARRIERS. Dye carriers are needed for complete dye penetration of polyester fibers. Carriers cause the glass-transition temperature, T_g, of the polyester polymer to become lower and allow the penetration of water-insoluble dyes into the fiber.

Dye carriers, occasionally called dyeing accelerants, are used on cellulose triacetate fibers, but have found their greatest use in the dyeing of polyester.

Carrier Properties

Most carriers are aromatic compounds, and have similar solubility parameters to the poly(ethylene terephthalate) fibers and to some disperse dyes.

The four main groups of compounds most commonly used as dye carriers are phenolics, chlorinated aromatics, aromatic esters, and phthalates. In order for these compounds to act effectively as carriers, they must be homogeneously dispersed in the dyebath. Because the carrier-active compounds have little or no solubility in water, emulsifiers are needed to disperse these compounds in the dyebath. See also **Emulsions**.

Proper emulsification is essential to the satisfactory performance of a carrier. A well-formulated carrier readily disperses when poured into water, and forms a milky emulsion upon agitation or steaming. It should not cause oil separation upon heating or crystallization and sedimentation upon cooling.

Many proprietary carries are available as solids (flakes or pellets) or in preemulsified form. These present some difficulties in the dyehouse. The former require dispersion in water through steam injection and addition to a preheated dyebath. The latter suffer from short storage life owing to separation of the emultion. Currently the industry prefers clear products easily emulsified by premixing with water at the time of use.

Manufacturing of the flake and pellet forms requires melting of the various components. The mass solidifies upon cooling and can be flaked or pelletized according to need.

The preemulsified carriers contain water. These products usually require homogenization through colloidal mills or similar equipment to reduce the particle size and ultimately stabilize the product. The preemulsified as well as the clear self-emulsifying products require the use of a solvent when the carrier-active material is a solid.

The formulation of a carrier depends on four considerations: *(1)* the carrier-active chemical compound; *(2)* the emulsifier; *(3)* special additives; and *(4)* environmental concerns. Additional parameters to be considered in the formulation of a carrier product with satisfactory and repeatable performance arise from the equipment in which the dyeing operation is to be carried out. The choice of equipment is usually dictated by the form in which the fiber substrate is to be processed, e.g., loose fiber, staple, continuous or texturized filament, woven or knot fabric, yarn on packages or in skeins.

A carrier is selected by the dyer according to various criteria. The type of equipment and conditions under which it is to be used have already been mentioned. Other considerations include color yield, dye migration, and product and emulsion stability.

The amount of dye successfully removed from the dyebath by the fiber results in a specific depth of shade or intensity of coloration. This is commonly called color yield. The color-building properties of a carrier are influenced by other factors, such as the fiber to liquor ratio (its concentration in the dyebath), the maximum temperature that can be reached on the chosen machine, and other dyebath additives.

Dye carriers promote dye migration and transfer, thus producing level and satisfactory dyeings.

The dyestuff is exhausted out of the dyebath and into the fiber with the assistance of carriers and heat. This process can be reversed by the use of an excessive amount of carrier, the depth of shade can be greatly reduced, and the dyestuff returned to the dyebath (stripping effect). This phenomenon is utilized to level an unevenly dyed fabric. Some carriers are more effective than others in promoting dye migration and equalizing the dye distribution through the fiber substrate.

These properties are not necessarily related, but are both highly prized in the selection of a carrier. The first refers to the storage or shelf stability of the product. Many carrier preparations are not properly balanced, or unsuitable emulsifiers have been used. Upon storing, these products separate in layers, particularly when exposed to temperature changes.

Emulsion stability refers to the stability of the emulsion in water. It must withstand various dyebath conditions.

Most carrier-active compounds are based on aromatic chemicals with characteristic odor. An exception is the phthalate esters, which are often preferred when ambient odor is objectionable or residual odor on the fabric cannot be tolerated. The toxicity of carrier-active compounds and of their ultimate compositions varies with the chemical or chemicals involved. The environment surrounding the dyeing equipment where carriers are used should always be well-ventilated, and operators should wear protective clothing (e.g., rubber gloves, aprons, and safety glasses or face shields, and possibly an appropriate respirator). Specific handling information can be obtained from the supplier or manufacturer.

The increasingly stringent government regulations and the introduction of carrierless–dyeable polyester have not substantially affected the use of carriers. The factor with the greatest impact on their use has been provided by the spectacular technological advances in dyeing equipment that have taken place since the early 1980s. High temperature dyeing has greatly reduced the time element (dyeing cycle) and the need for carriers.

DYES: ANTHRAQUINONE. Anthraquinone chemistry began in 1868 with the elucidation of the structure of the naturally occurring compound alizarin (1,2-dihydroxyanthraquinone) [CAS: 72-48-0] by C. Graebe and C. Liebermann.

Subsequently, H. Caro and W. H. Perkin independently developed the commercial manufacturing process of alizarin from anthraquinone through anthraquinone-2-sulfonic acid. Taking advantage of these inventions, many manufacturers came to produce various kinds of hydroxyanthraquinones, which were used as mordant dyes for dyeing cotton and wool. See also **Anthraquinone**.

Mordant dyes have excellent lightfastness. However, their colors are not so brilliant, and they need treatment of fibers with metal salts such as those of Cr, Al, Fe, or Ni before dyeing, which makes the dyeing process complicated and leveling properties unsatisfactory.

In 1894 the first two anthraquinone acid dyes, CI Acid Violet 43 [CAS: 4430-18-6] (CI 60730) and CI Acid Green 25 [CAS: 4403-90-1] (CI 61570) were invented. This encouraged the subsequent development of various kinds of anthraquinone acid dyes, which were used to dye wool in fast, brilliant shades without need for pretreatment.

In 1901, mercury catalyzed α-sulfonation of anthraquinone was discovered, and this led to the development of the chemistry of α-substituted anthraquinone derivatives (α-amino, α-chloro, α-hydroxy, and α, α'-dihydroxyanthraquinones). In the same year R. Bohn discovered indanthrone. Afterward flavanthrone, pyranthrone, and benzanthrone, etc, were synthesized, and anthraquinone vat dyes such as benzoylaminoanthraquinone, anthrimides, and anthrimidocarbazoles were also invented. These anthraquinone derivatives were widely used to dye cotton with excellent fastness, and formed the basis of the anthraquinone vat dye industry.

The appearance of synthetic fibers in the 1920s accelerated the further development of anthraquinone dyes. Soon after British Celanese succeeded in commercializing cellulose acetate fiber in 1921, anthraquinone disperse

dyes for this fiber were invented by Stepherdson (British Dyestuffs Corp.) and Celatenes (Scottish Dyes) independently. Anthraquinone disperse dyes for polyester fiber were developed after the introduction of this fiber by ICI and Du Pont in 1952. These dyes were improved products of the disperse dyes that had been developed for cellulose acetate fiber 30 years before.

In the 1950s acid dyes were successively developed to dye nylon carpet with excellent fastness and uniform leveling. Development of polyacrylonitrile fiber stimulated the invention of anthraquinone basic dyes, modified disperse dyes in which quaternary ammonium groups are introduced.

Production of anthraquinone reactive dyes based on derivatives of bromamine acid was first commercialized in 1956. Some improvements have been made and now they are predominantly used among the reactive blue dyes. CI Reactive Blue 19 [CAS: 2580-78-1] (CI 61200) (developed by Hoechst in 1957) has the greatest share among them including dye chromophores other than anthraquinones.

Manufacturing Overview

The synthesis of an anthraquinone dye generally involves a large number of steps. For example, CI Disperse Red 60 [CAS: 17418-58-5] (CI 60756) (a typical disperse red dye) requires five steps starting from anthraquinone, and CI Disperse Blue 56 [CAS: 31810-89-6] (CI 63285) requires six steps. The manufacturing process of anthraquinone vat dyes is more complicated, and, in the extreme case of CI Vat Blue 64 [CAS: 15935-52-1] (CI 66730), requires 11 steps starting from phthalic anhydride. Highly toxic metals such as mercury or chromium(VI) are sometimes required. Some processes need to employ a large amount of organic solvent, and others involve a great quantity of waste acids. With the increasing demand for environmental protection, the regulation of pollutant effluents has become more stringent year after year, which has caused a sharp increase in the costs for wastewater treatment. This situation has led to intensive improvement of conventional methods and the development of new synthetic routes as well.

Efforts have also been made to overcome complicated processes. Methods to reduce the number of steps or to use new starting materials have been studied extensively.

Because of their small extinction coefficients anthraquinone dyes have less tinctorial strength than azo dyes; that is the intrinsic disadvantage of anthraquinones. This fact and the complexity of preparation have made their production costs higher than those of azo dyes. However, the anthraquinone dyes have excellent properties that are not attainable by azo dyes, such as brilliancy of color, fastness, and excellent dyeing properties (leveling and dye bath stability). Thus the anthraquinone dyes have been widely used in the areas where these properties are required. Cotton or polyester–cotton blend fibers for military wear and working wear that require extreme fastness are dyed mainly with anthraquinone vat dyes. Most polyester fabrics for automobile seats are dyed with anthraquinone disperse dyes, since the requirement for lightfastness is extremely high and, simultaneously, bright shades are needed.

World dye manufacturers have already begun to develop new types of dyes that can replace the anthraquinones technically and economically. Some successful examples can be found in azo disperse red and blue dyes. Examples are brilliant red [CAS: 68353-96-6] and CI Disperse Blue 165 [CAS: 41642-51-7] (CI 11077). They have come close to the level of anthraquinone reds and blues, respectively, in terms of brightness. In the reactive dye area intensive studies have continued to develop triphenodioxazine compounds to replace anthraquinone blues.

Method of Synthesis

Anthraquinone dyes are derived from several key compounds called dye intermediates, and the methods for preparing these key intermediates can be divided into two types: *(1)* introduction of substituent(s) onto the anthraquinone nucleus, and *(2)* synthesis of an anthraquinone nucleus having the desired substituents, starting from benzene or naphthalene derivatives (nucleus synthesis). The principal reactions are nitration and sulfonation, which are very important in preparing α-substituted anthraquinones by electrophilic substitution. Nucleus synthesis is important for the production of β-substituted anthraquinones such as 2-methylanthraquinone and 2-chloroanthraquinone. Friedel-Crafts acylation using aluminum chloride is applied for this purpose. Synthesis of quinizarin (1,4-dihydroxyanthraquinone) is also important.

1-Aminoanthraquinone [CAS: 82-45-1] is the most important intermediate for manufacturing acid, reactive, disperse, and vat dyes.

1-Amino-4-bromoanthraquinone-2-sulfonic acid (bromamine acid) [CAS: 116-81-4] is the most important intermediate for manufacturing reactive and acid dyes.

1-Amino-2-bromo-4-hydroxyanthraquinone (bromo pink) [CAS: 116-82-5] is one of the most important intermediates for manufacturing red disperse dyes.

1-Amino-2-chloro-4-hydroxyanthraquinone (chloro pink) [CAS: 2478-67-3] is another important intermediate in red disperse dye manufacture.

1,4-Dihydroxyanthraquinone, also known as quinizarin [CAS: 81-64-1], is of great importance in manufacturing disperse, acid, and vat dyes.

Leuco-1,4-diaminoanthraquinone [CAS: 81-63-0] (leucamine) is an important precursor for 1,4-diaminoanthraquinone [CAS: 128-95-0].

1,4-Diamino-2,3-dichloroanthraquinone [CAS: 81-42-5] (CI Disperse Violet 28) is an important compound as an intermediate for CI Disperse Blue 60 and CI Disperse Violet 26.

1,4-Diamino-2,3-dicyanoanthraquinone [CAS: 81-41-4] is the key intermediate for manufacturing CI Disperse Blue 60.

1,4,-Diaminoanthraquinone-2,3-dicarboxyimide [CAS: 128-81-4] is the intermediate for CI Disperse Blue 60.

Anthraquinone-1-sulfonic acid [CAS: 82-48-5] has become less competitive than 1-nitroanthraquinone as the intermediate for 1-aminoanthraquinone. However, it still has a great importance as an intermediate for manufacturing vat dyes via 1-chloroanthraquinone.

1-Chloroanthraquinone [CAS: 82-44-0] is an intermediate for manufacturing vat dyes such as CI Vat Brown 1.

1-Methylaminoanthraquinone [CAS: 82-38-2] is an important intermediate for manufacturing solvent dyes and acid dyes.

Anthraquinone-α, α'-disulfonic acids and their derivatives are important intermediates for manufacturing disperse blue dyes (via 1,5- or 1,8-dihydroxyanthraquinone, or 1,5-dichloroanthraquinone) and vat dyes (via 1,5-dichloroanthraquinone).

1,5-Dichloroanthraquinone [CAS: 82-46-2] is an important intermediate for vat dyes and disperse blue dyes.

1,5-Dihydroxyanthraquinone (anthrarufin) [CAS: 117-12-4] is an important intermediate for manufacturing disperse blue dyes.

1,5- and 1,8-Dinitroanthraquinone are the key intermediates for manufacturing disperse blue dyes via dinitrodihydroxyanthraquinone and vat dyes via diaminoanthraquinones.

1,5-Dihydroxy-4, 8-dinitroanthraquinone [CAS: 128-91-6] is an important dye precursor for CI Disperse Blue 56, hydrolysis with aqueous alkali. 1,5-Dinitro-4,8-dihydroxyanthraquinone is also prepared from dimethoxyanthraquinone. High purity of 1,5-dimethoxyanthraquinone is required for manufacturing disperse blue dyes.

2-Methylanthraquinone and its derivatives are important as intermediates for manufacturing various kinds of vat dyes and brilliant blue (turquoise blue) disperse dyes. Aminoanthraquinone-2-carboxylic acid [CAS: 82-24-6] is also an important intermediate for vat dyes and disperse dyes.

2-Chloroanthraquinone and its derivatives are the most important intermediates for vat dyes and high performance organic pigments. 2-Amino-3-hydroxyanthraquinone [CAS: 117-79-3] is an intermediate for CI Vat Red 10.

Benzanthrone [CAS: 82-05-3] is reducing agent such as iron. Benzanthrone is an important intermediate for manufacturing vat dyes.

N-Methylanthrapyridone and Its Derivatives. 6-Bromo-3-methyl anthrapyridone [CAS: 81-85-6] is an important intermediate for manufacturing dyes soluble in organic solvents.

Reactive Dyes

Most of the anthraquinone reactive dyes are derived from bromamine acid. These dyes give a bright blue shade and excellent lightfastness. A great number of reactive groups have been proposed; typical examples include sulfatoethylsulfone, dichlorotriazine, monochlorotriazine, monofluorotriazine, and other heterocyclic groups. See also **Dyes: Reactive**.

CI Reactive Blue 19 [CAS: 2580-78-1] (CI 61200) is most widely used for dyeing cellulose fibers in exhaustion dyeing, and it gives a brilliant reddish blue shade and excellent lightfastness.

Disperse Dyes

Disperse dyes are water-insoluble, aqueous dispersed materials that are used for dyeing hydrophobic synthetic fibers, including polyester, acetate, and polyamide.

In 1923, the first disperse dye was developed for dyeing cellulose acetate fibers. However, in recent years the most important application of disperse dyes has been to dye polyester fibers. Accompanied by the rapid growth of polyester fibers after World War II, disperse dyes have currently achieved the largest production among all dye classes in terms of quantity.

By introducing amino, hydroxy, or methyl groups onto the anthraquinone moiety as the principal auxochromes, dyes that have yellow through greenish blue shades are obtained. Among these dyes many that have brilliant red, violet, blue, and greenish blue shades have great industrial importance in view of their affinity for polyester or cellulose acetate fibers and lightfastness and sublimation resistance. On the contrary, yellow or orange dyes are not satisfactory because of the rather simple molecular structure. Therefore these shades are obtained from other chromophores.

On the basis of the kind and the position of their substituents and their color range, the anthraquinoid disperse dyes may be classified as follows:

Color range	Chemical description
red	1-amino-4-hydroxyanthraquinones
blue, greenish blue	1,1,4,5,8-substituted anthraquinones
greenish blue	1,4-diaminoanthraquinone-2,3-dicarboxyimides
violet, blue	1,4-diaminoanthraquinone derivatives
violet, blue	*N*-substituted 1-amino-4-hydroxyanthraquinones

Acid Dyes

Acid dyes are used for dyeing wool, synthetic polyamides, and silk in aqueous media. Anthraquinone acid dyes give brilliant reds, violets, blues, and greens and exhibit excellent lightfastness. Because of their relatively high cost, they are used to dye high grade textiles in pale and moderate shades. Various kinds of anthraquinone acid dyes have been developed so far mainly by IG-Farbenindustrie in Germany applying chemical reactions that were studied in developing vat dyes. However, the number of commercial products has declined because of poor properties or unavailable raw materials. Anthraquinone acid dyes may be classified into two groups: bromamine acid derivatives and quinizarin derivatives.

Acid dyes derived from bromamine acid are important because they give bright blue shades with excellent lightfastness that are not obtainable with azo dyes. Among the bromamine acid derivatives CI Acid Blue 25 [CAS: 786-71-2] (CI 62055) and CI Acid Blue 40 [CAS: 6424-85-7] (CI 62125) are the first acid dyes, invented in 1913. T hese dyes are obtained from bromamine acid by reaction with aniline and p-aminoacetoanilide respectively. They show good leveling properties in acidic media. However, the wetfastness is not so good.

Dyes with better wetfastness and better affinity in neutral or weakly acid bath have been developed by introducing more hydrophobic amines. Examples are CI Acid Blue 129 [CAS: 6397-02-0] (CI 62058), CI Acid Blue 126 [CAS: 72152-61-5], and CI Acid Blue 230 [CAS: 12269-82-8] (CI 62073). However, uniform leveling cannot be obtained with these dyes.

Vat Dyes

Anthraquinone vat dyes have been used to dye cotton and other cellulose fibers for many decades. Despite their high cost, relatively muted colors, and difficulty in application, anthraquinone vat dyes still form one of the most important dye classes of synthetic dyes because of their all-around superior fastness.

Anthraquinone vat dyes are water-insoluble dyes. They are converted to leuco compounds (anthrahydroquinones) by reducing agents such as sodium hydrosulfite in alkaline conditions. These water-soluble leuco compounds have an affinity to cellulose fibers and penetrate them. After reoxidation by means of air or other oxidizing agents, the dye becomes water-insoluble again and fixes firmly on the fiber.

The anthraquinone vat dyes can be classified into several groups on the basis of their chemical structures: *(1)* benzanthrone dyes, *(2)* indanthrones, *(3)* anthrimides, *(4)* anthrimidocarbazoles, *(5)* acylaminoanthraquinones, *(6)* anthraquinoneazoles, *(7)* anthraquinone acridones, *(8)* anthrapyrimidines, and *(9)* highly condensed ring systems. Recently, research and development efforts have focused on improved manufacturing of traditional vat dyes.

Mordant Dyes

Mordant dyes have hydroxy groups in their molecular structure that are capable of forming complexes with metals. Although a variety of metals such as iron, copper, aluminum, and cobalt have been used, chromium is most preferable as a mordant. Alizarin or CI Mordant Red 11 [CAS: 72-48-0] (CI 58000), the principal component of the natural dye obtained from madder root, is the most typical mordant dye. Many mordant dyes have given way to the vat or the azoic dyes, which are applied by much simpler dyeing procedures.

Acid–mordant dyes have characteristics similar to those of acid dyes which have a relatively low molecular weight, anionic substituents, and an affinity to polyamide fibers and mordant dyes. In general, brilliant shades cannot be obtained by acid–mordant dyes because they are used as their chromium mordant by treatment with dichromate in the course of the dyeing procedure. However, because of their excellent fastness for light and wet treatment, they are predominantly used to dye wool in heavy shades (navy blue, brown, and black).

Functional Dyes

The investigation of new dyes has always been focused on the development of fast, brilliant, inexpensive, and easy applicable dyes. Because a great emphasis has been placed especially on fastness, the dyes with poorer fastness have been ignored in the past. However, in recent years new needs for dyes that change color in response to low energy stimuli including light, electricity, or heat have arisen in the electronics industry.

In order to develop the dyes for these fields, characteristics of known dyes have been re-examined, and some anthraquinone dyes have been found usable. One example of use is in thermal-transfer recording where the sublimation properties of disperse dyes are applied. Anthraquinone compounds have also been found to be useful dichroic dyes for guest-host liquid crystal displays when the substituents are properly selected to have high order parameters. These dichroic dyes can be used for polarizer films of LCD systems as well. Anthraquinone derivatives that absorb in the near-infrared region have also been discovered, which may be applicable in semiconductor laser recording.

Consumption

Anthraquinone dyes are the most important dye class after azo dyes. The consumption of each dye class or set of classes is approximately parallel to the consumption of fibers to which they are applied.

Among these dye classes, anthraquinone dyes are in an important position in reactive dyes and vat dyes for cellulose fibers, disperse dyes for polyester, and acid dyes for polyamide. Applications for high performance organic pigments for plastics and paints are also important areas.

Health and Safety Information

In general, anthraquinone dyes and their intermediates have not been reported as strongly toxic substances, but for many compounds safety data have not been evaluated. 1-Nitroanthraquinone, 1-chloroanthraquinone, and benzanthrone are reported to cause mild skin irritation in a test with rabbits, 500 mg/24 h. Some eye irritation data have been reported.

There are some tumorigenic data for anthraquinone dyes and intermediates which have been evaluated thoroughly. Data for 2-aminoanthraquinone and 2-methyl-1-nitroanthraquinone are available. 2-Aminoanthraquinone has been assessed by the United Nations International Agency for Research on Cancer (IARC) from studies in animals, and is judged to fall into the *Animal: Limited Evidence* group. 2-Aminoanthraquinone has been evaluated by EPA (Genetic Toxicology program) and a positive carcinogenic effect for rat and mouse is designated. 2-Methyl-1-nitroanthraquinone has been assessed by IARC and judged as belonging in the *Animal: Sufficient Evidence* group. 2-Methyl-1-nitroanthraquinone has been evaluated by the National Cancer Institute (NCI) and clear evidence of carcinogenicity for rat and mouse is demonstrated.

Most anthraquinone dyes and their intermediates are handled in a powder form. Their dust poses the threat of contact to eyes and skin or contamination of surroundings. Attention must be paid to avoid these hazards. Special attention should be paid to avoid contact with compounds that are recognized to have probable carcinogenicity.

In the case of handling in relatively small quantities, i.e., for laboratory use, normal personal equipment, i.e., dust masks, safety glasses, and gloves, and hoods with local exhaust ventilation should be used. In plant

operations, special technical handling measures should be taken because the possibility of contact is extremely high, especially when charging the raw materials or isolating or packaging the intermediates or final products.

DYES: NATURAL. From the earliest of times humans admired the beautiful natural colors of plants and minerals, and sought to enhance human appearance through color. To do so, they painted their bodies with various natural dyes. The ancient Celtic people used the blue dye from the woad plant; the Aztecs in South America used the red dye from the cochineal bug. As time went on, natural dyes were used more and more as cosmetics: hair was dyed, lips were painted, and cheeks were rouged. Some dyes found questionable use in the treatment of illness. Natural dyes were used to make foods and wines more attractive, although many times they were used to disguise an inferior or spoiled product. But the greatest use for natural dyes occurred when the art of weaving developed. A few synthetic dyes were developed before 1856, but without impact. Then, in 1856, Perkin laid the foundation for the synthetic dyestuff industry by his synthesis and manufacture of the dye Mauve. In quick succession, a number of other synthetic dyes appeared on the market, and the natural dyestuff industry was doomed. Natural dyes were replaced by synthetic dyes, although lately there has been a revival of the use of natural dyes for coloring foods, and some textile manufacturers are using natural dyes for dyeing their products.

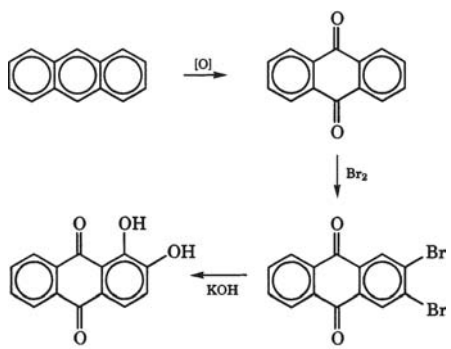
Anthraquinones

The anthraquinone structure occurs in both the plant and animal kingdom. Those natural dyes having this structure surpass all other natural dyes in fastness properties. See also **Dyes: Anthraquinones**.

Alizarin. There is only one significant plant anthraquinone dye, alizarin [CAS: 72-48-0] (CI Natural Red 6, 8, 9, 10, 11, and 12; CI 75330). In ancient times, alizarin was the preferred red dye. Cloth dyed with it has been found in Egyptian tombs dating 6000 years ago. The dye is found in the madder plant, a member of the Rubiaceae family. In 1944 about 35 species of this plant were known, but the use of more sophisticated analytical methods led to the detection of many more species; by 1984 the number had increased to 50.

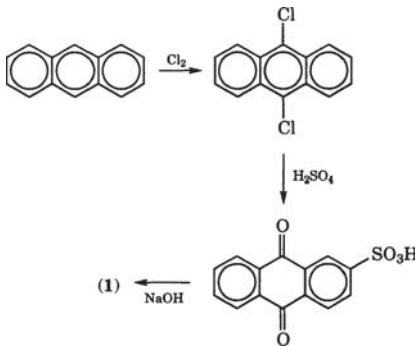
Alizarin is a mordant dye forming various colored coordination complexes with different metallic salts. Based on analytical results, a structural formula has been proposed for the alizarin complex.

Anthracene was oxidized to anthraquinone, dibrominated, and the dibromo derivative subjected to a caustic fusion. Alizarin was obtained in an impure form and in low yield. This represented the first synthesis of a natural dye.



(1)

Later, at BASF, a process was developed for the manufacture of alizarin by the caustic fusion of anthraquinone-2-sulfonic acid (so-called silver salt) which was patented in England on the 25th of June, 1869. One day later, W. Perkin applied for a patent for the manufacture of alizarin by a process almost identical to the German process except that the "silver salt" was prepared as follows:



Later, improvements were made in the process: use of oleum for sulfonating anthraquinone and the addition of an oxidizing agent to the caustic melt.

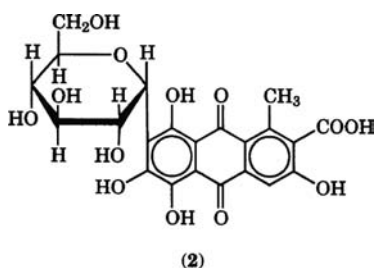
For years this was the process used to manufacture alizarin, although it was claimed that a more economical process would result if 2-chloroanthraquinone were to be used instead of silver salt.

Just as synthetic alizarin forced natural alizarin out of the market, synthetic alizarin has been replaced by azoic dyes because they are easier to apply.

Animal Anthraquinone Dyes. Many accounts claim that kermisic acid [CAS: 476-35-7] (CI Natural Red 3; CI 75460) is the oldest dyestuff ever recorded. The name *kermes* is derived from an Armenian word meaning little worm for which the later Latin equivalent was *vermiculus*, the basis of the English word vermillion. The dye was obtained from an oriental shield louse, *K. ilicis*, which infest the holm oak *Quercus ilex* and the shrub oak *Q. coccifera*. The dye produces a brilliant scarlet color with an alum mordant. Although expensive, it was cheaper than its rival Tyrian Purple. It was in great demand until the sixteenth century, when it was displaced by carminic acid.

The structure of kermisic acid is 1,3,4,6-tetrahydroxy-7-carboxy-8-methylanthraquinone.

[CAS: 1260-17-9] (CI Natural Red 4; CI 75470), is a red dye occurring as a glycoside in the body of the cochineal insect *Dactylopius coccus* of the order Homoptera, family Coccidae. This insect is native to Central and South America. The Aztecs had extracted the dye from the insect centuries before the coming of the Spaniards. For breeding purposes, the insects were collected in the autumn and carefully protected during the winter months. Cochineal was harvested after three months, and then the bugs were killed by immersion in hot water, by placing in hot ovens, or by exposure to the hot sun. The latter method produced the highest quality dye. At present, Peru and the Canary Islands are the main source of the dye. Until the advent of synthetic dyes, the principal use for carminic acid was for dyeing tin-mordanted wool or silk. Its aluminum lake, carmine, finds use in the coloring of foods. The structural formula of carminic acid is (2). See also **Colorants (Foods)**.



(2)

This acid has been designated [CAS: 6219-66-5] (CI Natural Red 25; CI 75450). Lac dye ranks as the most ancient of animal dyes. It is found in lac, the resinous secretion of a very small insect, *Coccus laccae*, found growing in India and Southeast Asia. The word lac is derived from the Hindu word *lakh* meaning one hundred thousand or a great number, having

reference to the fact that a great number of these or a great number, having reference to the fact that a great number of these insects had to be gathered in order to produce any quantity of dye. The resinous secretion of the insect is found deposited on branches of trees and is called stick-lac. Water extraction of stick-lac produces the lac dye. The remaining water insoluble material contains several other anthraquinone pigments of minor importance. The lac dye was first investigated in 1887 and named laccaic acid. Structures were proposed for this material, but around 1965 it was discovered, chromographically, that lac dye is actually a mixture of acids derived from 2-phenylanthraquinone [CAS: 6485-97-8].

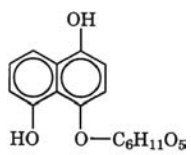
Naphthoquinone Dyes

Although naphthoquinones represent the largest group of naturally occurring quinones, only a small number of these achieved importance as dyestuffs.

Lawsone [CAS: 83-72-7] (CI Natural Orange 6; CI 75420), also known as henna and isojuglone, occurs in the shrub henna (*Lawsone alba*). In England, the plant is known as Egyptian privet. The dye was extracted from the leaves of the plant, using sodium bicarbonate, and the extracts used to dye protein fibers an orange shade. Henna is probably the oldest cosmetic known. The ancient Egyptians used it as a hair dye and for staining fingernails. It is said that Mohammed dyed his beard with henna. Lawsone has been identified as 2-hydroxy-1,4-naphthoquinone. It has been synthesized by the Thiele acetylation of 1,4-naphthoquinone followed by hydrolysis and oxidation.

Lapacol [CAS: 84-79-7] (CI Natural Yellow 16; CI 75490) (lapachic acid, taiguie acid, tecomin) is a yellow pigment occurring in the wood of trees of the genus *Tecoma*, native to the West Indies and tropical South America. The shavings of the wood, treated with lime water, give an extract that dyes cotton yellow.

Juglone [CAS: 481-39-0] (CI Natural Brown 7; CI 75500) was isolated from the husks of walnuts in 1856. Juglone occurs in walnuts as a glycoside of its reduced form, 1,4,5-trihydroxynaphthalene. Its structure is (3)



(3)

Juglone is most readily synthesized by Bernthsen's method. Although it no longer has any commercial value as dye, it is a fungicide and as such finds use in the treatment of skin diseases. Its toxic properties have been made use of in catching fish. Juglone has been used to detect very small amount of nickel salts since it gives a deep violet color with such salts.

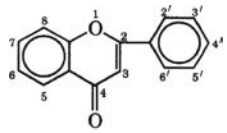
Alkannin, shikonin, and shikalkin are grouped together because the first two are enantiomers and the last one is their racemate. Alkannin [CAS: 577-88-4] (CI Natural Red 20; CI 75530) (*Anchusa tinctoria* or *alkanna tinctoria*) is a member of the Boraginaceae family. It is found in the roots of alkanet, a perennial shrub native to Southern Europe. This reddish dye was used not only for dyeing cloth but also for coloring olive oil, and as a rouge and lip stain. The generic name Anchuss is derived from the Greek word meaning face paint.

Alkannin occurs in the roots of the plant as the alkali-sensitive ester of angelic acid. It may be extracted from the roots by using boiling light petroleum ether. Treatment of this extract with dilute sodium hydroxide gives a blue solution from which the dye is precipitated by the addition of acid. The crude product is purified by vacuum sublimation. Its structure is a hydroxylated naphthoquinone with a long, unsaturated side chain; it has the (*S*)-configuration.

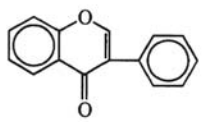
Shikonin [CAS: 517-89-5] (CI 75535) occurs as an acetyl derivative in the Japanese shikone, *Lithospermum erythrorhizon*, another member of the Boraginaceae family. It is the (*R*)-optical isomer of alkannin. Tissue cultures of *L. erythrorhizon* are used in Japan to manufacture shikonin mainly for cosmetic use. Both alkannin and shikonin are mordant dyes producing violet to gray colors on fabrics. In Japan, shikonin was used to dye fabrics a color known as Tokyo Violet. Shikalkin [CAS: 54952-43-1] the racemate, has been synthesized.

Flavones. These compounds are the most widely distributed natural coloring matter formerly used as dyestuffs. Flavone-type dyes occur in all the higher plants: in the leaves, roots, bark, fruits, pollen, and flower petals. The most widespread flavone dye are quercetin [CAS: 117-39-5] and kaempferol [CAS: 520-18-3]. In general, the dyes occur as glycosides, the most common sugar being glucose.

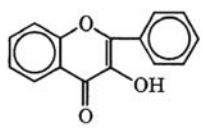
The basic unit of the flavone-type dyes is 2-phenylbenzopyrone (4) which unsubstituted is flavone [CAS: 525-82-6] (4) isoflavone [CAS: 574-12-9] is (5) and flavonol [CAS: 577-85-5] is (6).



(4)



(5)



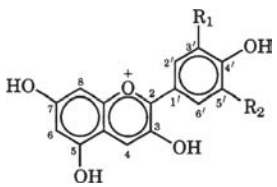
(6)

Flavone dyes having these structures are hydroxylated and methoxylated derivatives. Those dyes containing not more than three hydroxyls are generally termed flavones, whereas those containing up to and including six are flavonols.

The flavone, isoflavone, and flavonol-type dyes owe their importance to the presence of an *o*-hydroxy carbonyl structure within the molecule. Positions 4 and 5 can chelate with different metallic salts to give colored insoluble complexes. In other words, these dyes require a mordant in order to fix them onto the fiber.

Anthocyanins. Like the flavones, the anthocyanins are found throughout nature. This class of polyphenolic compounds is responsible for the pink, red, violet, and blue colors found in plants. The term anthocyan is derived from the Greek words *antho* for flower and kyanos for blue. It was proposed first to denote the blue color of the cornflower. Later, as knowledge about plant pigments increased, the term was extended to include all such pigments and the ending "in" was added. Like many other natural phenolic substances, anthocyanins occur in plants as glycosides; the sugar-free anthocyanins are known as anthocyanidins.

All anthocyanidins have the 2-phenylbenzopyrylium or flavylium cation structure, a resonance hybrid of oxonium forms and carbenium forms [CAS: 14051-53-7]. There are three fundamental groups of anthocyanidins to which all the other anthocyanidins could be referred. In the following structure R=R′ =H designates pelargonidin R=OH, R′ =H is cyanidin; and R=R′=OH is delphinidin.



The anthocyanins are pH sensitive. Their color, in part, is determined by the pH of the sap.

A convenient method for synthesizing anthocyanidins involves the condensation of an *o*-hydroxybenzaldehyde with an acetophenone.

Indigoid Dyes

Tyrian Purple. The ancient kingdom of Tyre owed its fame and fortune to the purple dye produced from the lowly mollusks found on its shores.

From early Egyptian and pre-Roman times, about 1600 BC, it was known that these shellfish produced a secretion which, on exposure to light and air, produced a beautiful and fast purple dye. The dye became known as Tyrian Purple [CAS: 19201-58-7] (CI 75800) reflecting its place of origin. These mollusks belong to the Muricidae family and the genera *Murex* and *Purpura* which include *M. brandaris* and *M. trunculus*, the principal sources of the dye. The dye is 6,6'-bromoindigotin [CAS: 19201-53-7].

Indigotin. The blue dye of the ancient world was derived from indigo and woad. Which plant is the oldest is a matter of conjecture. That indigo was known at least four thousand years ago is evident from ancient Sanskrit writings. Cloth dyed with indigotin [CAS: 482-89-3] (CI Natural Blue; CI 75780) has been found in Egyptian tombs and in the graves of the Incas in South America. Indigo belongs to the legume family. The two most important species are *Indigo tinctoria* and *I. suffruticosa*, found in India and the Americas, respectively. The leaves of the indigo plant do not contain the dye as such, but in the form of its precursor, a glycoside known as indican.

Woad, *Isatis tinctoris*, belongs to a genus that comprises some thirty species.

In 1890, it was observed that treatment of ω-bromoacetanilide with alkali produced oxindole. Based on this observation, K. Heumann treated *N*-phenylglycine with alkali and obtained indoxyl (keto form), which on aerial oxidation converted to indigotin. Later, a variation of the original Heumann process was made: aniline, formaldehyde, and hydrogen cyanide react to form phenylglycinonitrile, which is hydrolyzed to phenylglycine. This is the most widely used process for manufacturing indigotin.

The greatest improvement in the manufacture of indigotin came when sodamide was used with alkali in the conversion of phenylglycine to indoxyl.

Although there is still demand for indigotin for dyeing blue jeans, it has lost a good part of the market to other blue dyes with better dyeing properties. At present, practically all the indigotin consumed in the United States comes from abroad.

Natural Food Colors

In the 1970s, decertification of the important food colors FD&C Reds 2 and 4 caused much concern among manufacturers of food dyes. With the possibility that other synthetic dyes would be banned present, attention was turned to the use of natural dyes as food colorants. Many such dyes had been in use for hundreds of years until they were replaced by synthetic dyes.

The yellow dye curcumin [CAS: 458-37-7] (CI Natural Yellow 3; CI 75300), also known as tumeric, occurs in the roots of the plant *Curcuma tinctoria*, found growing wild in Asia. The dye is an oil-soluble bright yellow material, and is the only natural yellow dye that requires no mordant. It finds use as a colorant for baked goods such as cakes. Carmine [CAS: 1390-65-4] is the trade name for the aluminum lake of the red anthraquinone dye carminic acid obtained from the cochineal bug. The dye is obtained from the powdery form of cochineal by extraction with hot water, the extracts treated with aluminum salts, and the dye precipitated from the solution by the addition of ethanol. This water-soluble bright red dye is used for coloring shrimp, pork sausages, pharmaceuticals, and cosmetics. It is the only animal-derived dye approved as a colorant for foods and other products.

Carotenoids. The carotenoids are a group of widely distributed, highly colored, fat-insoluble, naturally occurring organic compounds. They owe their color to the four repeating isopyrene units found in the molecule and may, therefore, be classified as tetraterpenoids. The carotenoids may be divided into two principal groups, the carotenes, which are strictly hydrocarbons, and the xanthophylls, which contain oxygen. Carotenoids are found in almost all fruits and vegetables, egg yolk, dairy products, and sea foods. The chemistry of the carotenoids has been described in a number of reviews.

Although the carotenoids can be obtained from natural sources, it is far more economical to manufacture them for commercial use. Three have been manufactured for many years: β-carotene [CAS: 7235-40-7], canthaxanthin [CAS: 514-78-3]and β-apo-8'-carotenal [CAS: 1107-26-2].

In general, the low solubility of the carotenoids creates a problem when they are applied as food dyes. To overcome this, a microcrystalline powder form has been prepared. This is then mixed into an edible fat. In this form it finds use for coloring margarine, butter, cake mixtures, and other fact-containing foods. β-Carotene is available also as an emulsion, in a water-dispersed form, and as a liquid suspension. Canthaxanthin is commercially available as a 10 % water-dispersable beadlet or spray-dried powder. Because of its exceptionally good tomato color-enhancing properties, it finds use in tomato-based products such as pizza and spaghetti sauce. It is useful in water-based foods such as peach ice cream and pink grapefruit beverages. β-Apo-8'-carotenal has high tinctorial strength; because of this, it is marketed in several different strengths, usually as a dispersion in vegetable oils. Its main use is for coloring process cheese and French dressing.

Carotenoids have two general characteristics of importance to the food industry: they are not pH sensitive in the normal 2–7 range found in foods, and they are not affected by vitamin C, making them especially important for beverages.

Bixin [CAS: 6983-79-5] (CI Natural Orange 4; CI 75120) is found in the seed of the plant *Bixa orellana*, native to India. Later it was found growing in South America, where the Indians used the red dye from the seeds as a body paint. An extract of the seeds appears on the market as annatto. This extract is used in coloring butter, margarine, and cheese such as Leicester cheese. In Mexican and South American cuisine, it finds special use as a flavor and coloring matter. Annato is available as an aqueous solution, as an oleaginous dispersion, and a spray-dried powder.

Crocetin [CAS: 27876-94-4](CI Natural Yellow 6; CI 75100) occurs in saffron as crocin [CAS: 42553-65-1], the digentiobiose ester of crocetin. Saffron is found in the pistils of the plant *Crocus sativus*. Saffron is often confused with safflower, sometimes known as bastard saffron. The name of the plant, *Crocus sativus*, comes from the Arabic word *za faran*, meaning yellow. The Romans and the Greeks used saffron not only as a dye but also as a spice. In the early days of Greece, yellow was the official color, and Grecian women were especially fond of clothes dyed with saffron. Because of its scarcity, saffron ranked among the most expensive dyes of the ancient world.

Betalaines. In 1968, the term betalaines was used to describe collectively two groups of plant pigments: the red betacyanins and the yellow betaxanthins. The red and yellow dyes found in beets, *Beta vulgaris*, fall into this category.

The color of betalaines is barely affected by the pH range normally found in foods. However, the dyes are heat-sensitive, which places some limitations on their use as food dyes.

Beet juice contains about 80 % of fermentable carbohydrates and nitrogenous compounds. To remove these compounds, a yeast fermentation utilizing *Candida utillis* has been suggested. By so doing, a more concentrated form of the dye becomes available. The red dye from beets is sold as beet juice concentrate, as dehydrated beet root, and as a dried powder.

Chlorophyll. The determination of the structure of chlorophyll involved the efforts of many famous chemists, notably R. Willstätter (Nobel Prize 1915) who, during the period 1906–1914, laid the foundation for the future investigation of chlorophyll. He not only prepared relatively pure chlorophyll for the first time, but also isolated two different modifications of the molecule. These he designated as a- and b-chlorophyll. H. Fischer (Nobel Prize 1930) suggested the structural formula for chlorophyll based on his work with hemin. In 1960, R. B. Woodward (Nobel Prize 1965) and his co-workers synthesized chlorophyll and hemin Chemically pure chlorophyll is difficult to prepare, since it occurs mixed with other colored substances such as carotenoids. Commercially it is solvent extracted from the dried leaves of various plants such as broccoli or spinach. Chlorophyll is water-insoluble. It has none of the characteristics of a dye in that it has no affinity for the usual fibers such as cotton or wool. Chlorophyll is properly classified as a pigment [CAS: 8049-84-1] (CI Natural Green 3; CI 75810). As such, it finds use for coloring soaps, waxes, inks, fats, or oils. Chlorophyll is an ester composed of an acidic part, chlorophyllin, esterified by an aliphatic alcohol known as phytol. Hydrolysis of chlorophyll using sodium hydroxide produces the moderately water-soluble sodium salts of chlorophyllin, phytol, and methanol. The magnesium in chlorophyllin may be replaced by copper. The sodium copper chlorophyllin salt is heat-stable, and is ideal for coloring foods where heat is involved, such as in canning. See also **Chlorophylls**.

Health, Safety, and Environmental Factors of Natural Dyes

Natural dyes comprise those colors derived from plant or animal matter without chemical processing. They have been known and used for

thousands of years without any reports showing that they are harmful. Modern tests have verified the safety of natural dyes as food colorants; many of these dyes are on the FDA's list of approved food dyes.

Natural dyes processed for the market do not undergo any chemical operations. Those operations involved are purely physical, such as grinding, spray or vacuum drying, and water or solvent extractions. None of these operations create any great environmental problems.

The use of natural dyes as food colorants evolved over a period spanning thousands of years. During that period, by trial and error, some dyes were found to be safe while others were not. By comparison, the development of synthetic dyes as food colorants has taken place over a comparatively short time. During that period, some synthetic dyes considered safe by existing health standards were used as food colors. Later, with increased knowledge, these were found to create health problems and were removed from the marketplace. The manufacture of synthetic dyes for use on foods creates more of a health and environmental problem than natural dyes, but offers greater variety and stability of color.

DYES: REACTIVE. Reactive dyes have proven to be one of the most successful classes of modern synthetic dyes. The reasons for this success lie in their shade versatility, their flexibility in application, and the all-round good fastness properties obtained from dyeings produced with reactive dyes on wool, silk, cotton, and regenerated cellulosic fibers. Reactive dyes are those dyes containing electrophilic functional groups capable of reacting with a nucleophile to form a covalent bond either through addition or displacement. Nucleophiles within fibers that typically react with dyes are hydroxyl groups in cellulose, amino, hydroxyl, and thiol groups in wool, and amino groups in polyamide. The outstanding characteristic feature of reactive dyes is their high wetfastness properties attributed to covalent bonding, an advantage over those dyes fixed through adsorption or mechanical entrapment. Unlike large bulky direct dyes, since reactive dyes are chemically bonded to the substrate, smaller molecules giving brighter colors are possible. The principal use of reactive dyes is far and away greatest for cellulose (cotton and rayon), followed by wool, with polyamide (nylon) a very distant third. Applications to silk and leather represent only very minor uses.

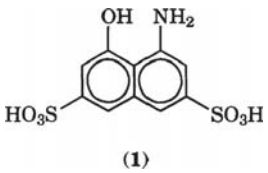
Reactive Dye Structure

Reactive dyes consist basically of three components: a dye, a bridging group (B), and the reactive group (R), dye−B−R. The reactive group may be considered in two parts as a carrying group and the reactive component.

Most commonly used chromophores parallel those of other dye classes. Azo dyes represent the largest number with anthraquinone and phthalocyanine making up most of the difference. Metallized azo and formazan dyes are important and have gained in importance as a chromophore for blue dyes during recent years. See also **Dye and Dye Intermediates**.

Yellow dyes are generally monoazo, and most are pyrazolone or pyridone couplings. Orange dyes are generally monoazo derived from couplings to pyrazolones or of slightly substituted phenyl and naphthyl groups.

Many red dyes are based on H-acid, e.g., Reactive Reds 2, 24, and 218. Others are substituted phenyl and naphthyl or metallized systems. Violet dyes are also metallized monoazo dyes.



(1)

Blue dyes are derived from anthraquinone, phthalocyanine, or metallized formazan. See also **Anthraquinone**. There are also oxazine and thiazine dyes reported.

Brown and black dyes are generally disazo with exceptions for metallized or polycyclic structures. Two disazo dyes are Reactive Brown 11 and Reactive Black 5 (CI 20505).

Green dyes are obtained by bridging an anthraquinone blue chromogen with a yellow chromogen, or from phthalocyanine.

Properties

Although fastness of reactive dyes to washing is good, once fixed on the substrate, hydrolysis during application leads to low dye fixation rate, i.e., dye that hydrolyzes in the application process is not fixed on the fiber. Reactive dyes are highly sulfonated, and as such are very water-soluble. Fairly large amounts of salt are required to force the dye into the substrate during application. The hydrolyzed dye is even more soluble than the dye, and presents concerns for the dyer because of effluent color and low biodegradability as well as economic losses. A very large part of the development effort spent on reactive dyes during recent years has been toward improving fixation on the substrate. Approaches taken have been to find different reactive groups as well as to include more than one reactive group in the dye structure and select reactive groups less sensitive to hydrolysis or more reactive to the substrate under application conditions.

During the 1980s, there was a revived interest in bireactive dyes. Every principal dye manufacturer has introduced dyes with more than one reactive group. The ones offering highest fixation hav e two or more reactive groups with different rates of reaction. Different rates of reaction may be due to selection of different groups, e.g., dichlorotriazine and trichloropyrimidine, or by varying substituents on the triazine ring; electron-donating groups decrease reactivity, and electron-withdrawing groups increase reactivity.

Reactive groups have minimal auxochrome effect on color intensity, and color yield per molecular weight decreases with increasing numbers of reactive groups. Increased dye fixation and reduced environmental impact of hydrolyzed dye more than compensate for color reduction of additional reactive groups.

The fluorotriazine reactive group was reported in the mid-1970s, and has been the subject of many literature references since that time. Monofluorotriazine dyes are especially attractive because of their high color yield at low temperatures (below 40 °C).

Reactivity in the Dyebath

The most important discovery in dyeing cellulose with reactive dyes was the application of Schotten-Baumaun principles. Reaction of alcohols proceeds more readily and completely in the presence of dilute alkali, and the cellulose anion (cell−O^-) is considerably more nucleophilic than is the hydroxide ion. Thus the fixation reaction (eq. 1) competes favorably with hydrolysis of the dye (eq. 2).

$$\text{dye} - \text{B} - \text{R} + \text{cell} - \text{O}^- \rightarrow \text{dye} - \text{B} - \text{O} - \text{cell} \quad (1)$$

$$\text{dye} - \text{B} - \text{R} + \text{OH}^- \rightarrow \text{dye} - \text{B} - \text{OH} \quad (2)$$

The most important reactive groups today are monochlorotriazine (high energy), vinyl sulfone (medium energy), and monofluorotriazine (low to medium energy), although dichlorotriazine, 2,3-dichloroquinoxaline and 2,4-difluoro-5-chloropyrimidine have a significant presence. α-Bromoacrylamide and vinyl sulfone from *N*-methyltaurine are the most important reactive dyes for wool.

Bifunctional Dyes. There are many examples of dyes with two or more reactive groups, including many mixed reactive systems. Dye fixation is increased significantly with increasing number of reactive groups. Some multiple reactive dyes are claimed to have as high as 95% fixation.

Methods of Synthesis

Reactive dyes are synthesized by *(1)* condensation of an amine function in the chromogen molecule with a reactive group; *(2)* by coupling a diazonium salt with a coupling component that has a reactive group, or by coupling a diazonium salt containing a reactive group with a coupler; or *(3)*, in the case of copper phthalocyanine (CPC), by condensing CPC sulfonyl chloride with an amino-containing bridging group attached to a reactive group.

DYES: SENSITIZING. Spectral sensitizing dyes extend the wavelengths of light to which inorganic semiconductors, organic semiconductors, and chemical (biological) reactions can be photosensitized. Spectral sensitizers are needed for the blue, green, and red portions of the visible spectrum. For infrared photographic, electrophotographic, and biological applications, sensitizing dyes are also needed to match output wavelengths of solid-state lasers (optical data storage, laser printing, range finding, and data transmission), to provide color-selective infrared photography (an effective environmental survey method), or to match transmission wavelengths of body tissue.

Spectral sensitizing dyes are considered "functional" dyes to distinguish them from conventional colorants. The absorption of radiation by a functional dye causes some additional function(s) to occur, and in many cases, the sensitizing dyes can exhibit more than one type of sensitization reaction. Many texts and reviews provide extensive details about the diversity of spectrally sensitized processes.

The detection of spectral sensitizing action often depends on amplification methods such as photographic or electrophotographic development or, alternatively, on chemical or biochemical detection of reaction products. Separation of the photosensitization reaction from the detection step or the chemical reaction allows selection of the most effective spectral sensitizers. Prime considerations for spectral sensitizing dyes include the range of wavelengths needed for sensitization and the absolute efficiency of the spectrally sensitized process. Because both sensitization wavelength and efficiency are important, optimum sensitizers vary considerably in their structures and properties.

A useful classification of sensitizing dyes is the one adopted to describe patents in image technology. In the Image Technology Patent Information System (ITPAIS), dye classes and representative patent citations from the ITPAIS file are listed as a function of significant dye class. Dye classes include cyanine, merocyanine, all other polymethine dyes, acridine, azine, azo, arylmethane, quinone type, porphine, xanthene, and pyrylium.

Spectral Sensitization of Silver Halides

The large number of patents for spectral sensitizers of silver halides indicates their extensive use in photographic plates, films, and papers. Color films that give good color reproduction under a variety of illuminants (daylight, electronic flash, tungsten) and exposure times (short for electronic flash, long for available light) have required more extensive tailoring of spectral sensitizers than imaging systems based on other semiconductors. Early reviews cover spectral sensitizing dyes specifically for silver halides, including synthetic methods, general sensitization mechanisms, electrochemical potentials and dye efficiency, dye absorption and aggregation, and supersensitization of dyes.

Photographic products are often subjected to wide variations in temperature, humidity, and time before processing. Consequently, high priorities are also given to spectral sensitizers that do not degrade either the film or image quality, as well as provide efficient spectral sensitization at the desired wavelengths. Although there are many available dyes and pigments, commercial silver halide films, papers, and plates are efficiently sensitized by just a few types of chromophores in the cyanine and merocyanine dye classes.

The suitability of these chromophores rests in large measure in being able to simultaneously optimize three properties (electrochemical potentials, J-aggregation, and solubility) by choosing various substituent and heteroatom combinations.

Spectral Sensitization of Inorganic and Organic Solids

Relatively few spectral sensitizing dyes continue to serve the large-volume color (imaging and printing) photographic markets, where silver halide is the dominant semiconductor. Technology to serve both color printing and office copy markets will employ not only silver halides but other inorganic and organic semiconductors as well. Inorganic semiconductors include selenium, germanium, CdS, HgO, HgI_2, ZnO, PbO, Cu_2O, thallium halides, and TiO_2. As noted by patent citations and the published literature, both zinc oxide and titanium dioxide have been extensively investigated. Spectrally sensitized photoconduction has also been observed for organic semiconductors, i.e., anthracene, poly(*N*-vinylcarbazole), polyacetylene, copper phenylacetylide, phthalocyanines, and other solid dyes.

Continued commercial development of nonsilver office copying into color printing and optical data storage to higher densities provides many opportunities for spectral sensitizer improvement among competing technologies. Spectral sensitizers for these other materials are already quite varied. Recent handbooks review both sensitizing dye technology and imaging systems that utilize dyes.

Spectral Sensitization in Photochemical Technology

Functional dyes of many types are important photochemical sensitizers for chemical reactions involving oxidation, polymerization, (polymer) degradation, isomerization, and photodynamic therapy. Often, dye structures from several classes of materials can fulfill a similar technological need, particularly for laboratory or small-scale reactions where production efficiency may be of secondary importance. Commercial photochemical technology, however, is more selective and requires photochemical efficiency, ease of product separation, and lack of unwanted side reactions to an extent similar to that required by imaging processes. In addition, reusability of the spectral sensitizer is also preferred in commercial photochemical reactions.

Uses

Sensitizing dyes are used primarily for specialty purposes: photographic sensitizers, electrophotographic sensitizers, laser dyes, infrared (optical disk, etc.) imaging, and certain medicinal applications. Because of this, their manufacture is limited to significantly smaller quantities than for fabric dyes or other widely used coloring agents. However, the photographic, laser, and medicinal uses place high demands on the degree of purity required, and the reproducibility of synthetic methods and purification steps is very important.

DYES (Textile). Special groups within dyestuff molecules lend color to textile substrates. These groups are termed *chromophores* and include: the azo group, $-N{=}N-$; the thio group, $=C{=}S$; the nitroso group, $-N{=}O$; the carbonyl group, $=C{=}O$; the nitro group, $-NO_2$; and the azoxy group,

$$-N{=}N-\\ \quad O$$

Organic dyestuff molecules also contain *auxochromes*, and these include the amino group, $-NH_2$; the hydroxyl group, $-OH$; the sulfonic group, $-SO_3H$; and substituted amino groups, $-N(CH_2)_2$ and $-NHCH_3$. Auxochromes increase the solubility of dyestuffs as well as influence the color.

Organic dyestuffs absorb radiation and the color of some dyes derives from the fact that absorption bands fall within the range of radiation visible to the human eye.

There are two convenient ways to classify dyes: (1) by chemical structure; and (2) by dyeing properties. For theoretical purposes and work in the development of new dyes, the chemist prefers the structural classification. The practical dyer and dyeing technologist, however, prefer the classification by dyeing properties. On this latter basis, the main

categories are: (1) basic or cationic; (2) acid and premetalized; (3) chrome and mordant; (4) direct and developed direct; and (5) sulfur, azoic, vat, disperse, and reactive dyes. Some examples of these classes of dyes are given in Fig. 1.

Three major steps are involved in fixing dyestuff molecules to fibers: (1) the dyestuff migrates from solution to the fiber interface (substrate) whereupon it is adsorbed on the surface of the fiber; (2) the dye moves or diffuses from the surface into the center of the fiber, whereupon it situates around and between fiber molecules; and (3) the actual attachment of the dye molecule to the fiber molecule, utilizing either physical forces, hydrogen bonding, or covalent bonding with the fiber molecule.

Electropotential forces, variations in temperature, and degree of agitation of the solution and substrate affect the movement of the dye molecules from solution to the fiber. Often, the feasibility of employing a specific type of dye on particular fibers is influenced by the relationship between the ionic charge of a fiber and a dyestuff. An elevated temperature helps to break dye micelles into smaller units and this enhances attachment of the dye to the fiber, and subsequently they move among the fiber molecules. Agitation helps to achieve uniformity, but it must not be too great because it can hinder assembly of dye molecules on the fiber substrate.

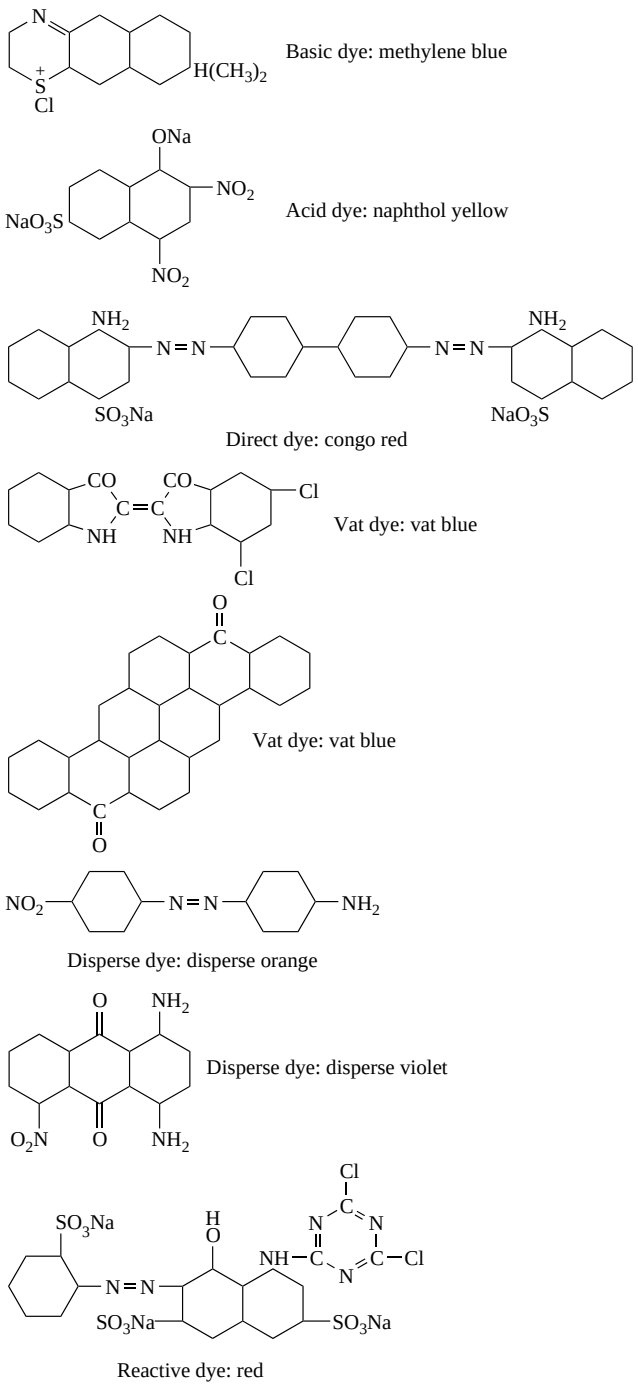

Fig. 1. Representative textile dyes.

The process of diffusing the dye into the center of the fiber is related to the pore opening of the fiber and the size of the dye molecule. Physical attachment forces are related to the shape and size of the dye molecule, to the planar relation of the dye molecule, and the size of openings between fiber molecules. Dye molecules with a linear and planar shape tend to adsorb to fiber molecules best. Where dye molecules tend to aggregate within the fiber, the molecules will be held well because of their size.

Protein fibers and anionic dyes form ionic or salt linkages, linking with the $-NH_3^+$ groups in the fiber molecules.

Hydrogen bonding occurs principally in cellulosic fibers. The hydroxyl group of cellulose molecules will form hydrogen bonds with dyes that contain hydroxyl, amino, and azo groups. Critical to hydrogen bonding is the space (expressed in angstrom units) between groups capable of forming the bond.

The most stable bond is a covalent bond, which is characteristic of reactive dyes and some acid and cationic dyes.

Dyeing Processes and Machines. The dyeing function occurs in the following major ways: (1) the substrate or fabric is moved through the dye liquor; (2) the dye liquor may be moved through the substrate, a method commonly used in connection with yarns, but also applicable to fabric; and (3) a combination of the two foregoing methods. A dyeing machine should provide adequate movement, so that the dye may penetrate the substrate uniformly; the movement must be accomplished so as not to damage the substrate; the equipment must resist corrosive factors involved; generally a uniform temperature must be provided; and facilities should be available so that additional dyes and chemicals may be added without stopping the process. *Leveling* is a term commonly used in dyeing technology and signifies the relative ease with which dye colors the substrate uniformly, evenly, and to the degree desired. See Figs. 2 and 3.

Acid Dyes. Most acid dyes are sulfonic acid salts. These dyes are commonly used for dyeing protein fibers. Acid dyes are quite soluble, allowing maximum exhaustion of the dye bath. Acid dyes derive their name because they were originally applied in a mineral or an organic acid bath; and because the anion is the colored portion of the molecule.

Basic or Cationic Dyes. These dyes possess high brilliance and intensity of color. They are not highly soluble in water and may decompose at temperatures exceeding 65 °C. Generally, these dyes are not applied along with acid or direct dyes because precipitation may occur. On most fibers, basic dyes have low colorfastness. However, on acrylic fibers, cationic dyes exhibit relatively good colorfastness resulting from some covalent bonding.

Basic or cationic dyes derive their name from the fact that the dye molecules dissociate in water, with the cation being the colored portion of the dye. If anionic sites are present in the fiber, the dye will be attracted to form a covalent bond. Because anionic sites vary in terms of availability with various fibers, the durability of cationic dyes is quite variable.

Direct Dyes. These are water-soluble dyes, easily applied to cellulose fibers, and comprise the largest group of dyes. Sometimes these dyes are called *substantive colors*. The molecules of direct dyes have a tendency to be linear and adsorb onto fiber molecules. Hydrogen bonding and Van der Waals forces also contribute to holding the dye onto the substrate. Dyeing is also helped by some aggregation of the dye molecules within the fiber. Frequently, direct dyes possess poor colorfastness and thus require special processing to improve their washability qualities.

Direct dyes are of three principal classes: (1) self-leveling, or Class A; (2) dyes that level with the addition of salt, Class B; and (3) dyes that require addition of salt and careful temperature control, Class C.

Development of the dye by diazotization is probably the most effective means for improving washfastness of direct dyes. For reacting with the free amino group on the dye molecule, developers such as betanaphthol, m-phenylenediamine, phenol, phenylmethylpyrazolone, or resorcine are used. This reaction should occur in situ on the fiber. In this procedure, the substrate is dyed in accordance with the regular direct-dye method. Then, the material is diazotized for about a half-hour in a bath containing about 3% sodium nitrate, and 3–5% sulfuric acid (or 5% hydrochloric acid). Then the dyed substrate is developed for about a half-hour in a cold bath containing one of the aforementioned developers. Developing frequently

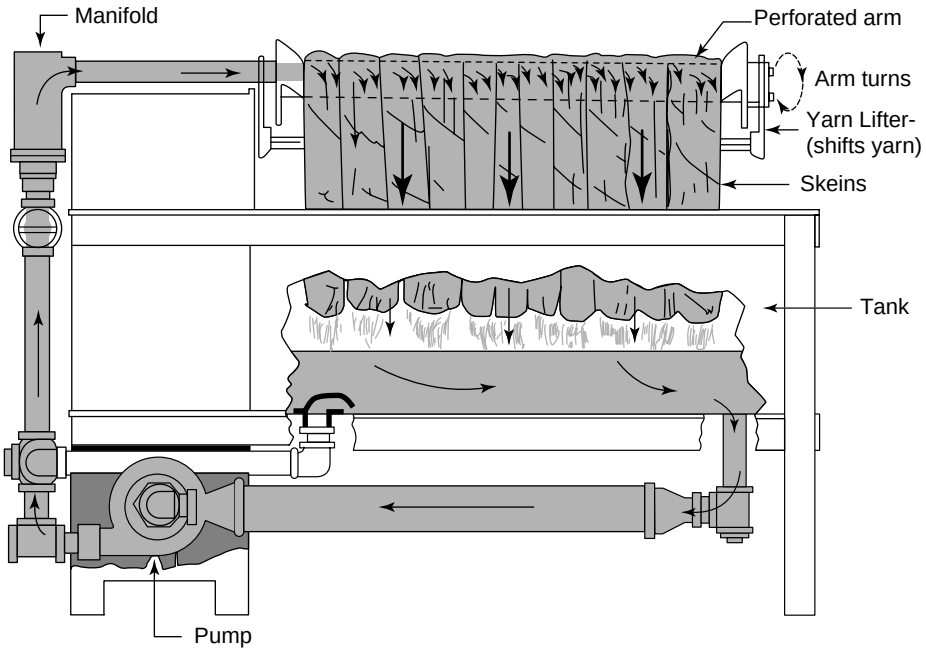

Fig. 2. Cascade machine for skein dyeing. Hanks of yarn are suspended from a perforated stainless steel arm situated above an open tank which contains the dye bath. Dye liquor is continuously pumped from tank through arm which distributes the dye to the skein, returning the liquor to the bath for recycling. The perforated arms are periodically rocked to assure uniform distribution of the dyestuff.

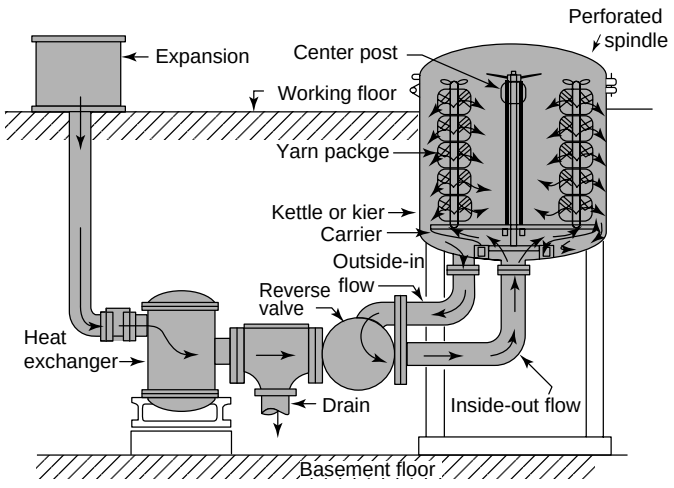

Fig. 3. Package dyeing. Packages of yarn are put on verticle spindles in a portable carrier. Carrier is lowered into dyeing vessel. The dye liquor circulates continuously through the spindle perforations and through the packages. The flow pattern then is reversed. The cycles are repeated until specified shade results.

will change the color because new chromophoric groups may be added to the dye molecule. Thus, pilot runs and experience are mandatory.

Disperse Dyes. These dyes were initially developed for cellulose acetate and at one time were called *acetate dyes*. They are now used with several fibers. Disperse dyes are not soluble in water, but do form a uniform dispersion in a water bath. It is postulated that because of their lack of affinity for water, disperse dyes migrate toward and diffuse into the organic fiber and form a solid solution within the hydrophobic fiber. A more recent postulate states that the dye is transferred from the suspension to the fiber in molecular form. There is also evidence that Van der Waals forces and hydrogen bonding also contribute to dye retention.

The colorfastness of disperse dyes varies with the fiber substrate. The dyes can be applied under pressure, necessary for dyeing polyester. In the *thermosol* method of applying disperse dyes, the dye is padded into the substrate, after which it is subjected to dry heat.

Vat Dyes. Natural vat dyes have been used for nearly 4000 years, commencing about 2000 B.C. in Egypt. Vat dyes are insoluble in water, but they reduce in an alkaline solution to a leuco form that is water-soluble and substantive to cellulose fibers. Vat dyes are colorfast to laundering and have good fastness to light. These dyes are held to cellulose molecules by van der Waals forces and hydrogen bonding. Once the dye is applied, it is oxidized to an insoluble form and thus becomes trapped within the fiber.

Reactive Dyes. These dyes form a covalent bond with the fiber molecule. They have excellent washfastness and also resist environmental factors well. Reactive dyes are used mainly on cellulose fibers, but they also have been used successfully with silk, wool, nylon, and acrylic fibers. These dyes contain a chemical group that forms a bond with either a hydroxyl group in the cellulose molecule, or with an amino group in other fibers. Reactive dyes are among the most recently developed dyes and tend to be somewhat more costly than other dyestuffs.

Dyeing of Blended Fabrics. Since each type of fiber reacts somewhat differently to dyestuffs, the dyeing of blends of fibers often presents problems. Often, blends will be dyed in steps, wherein one fiber is dyed and then the fabric is rinsed, after which the second fiber is dyed, and so on. Should the general chemistry and temperature conditions be approximately the same, sometimes two fibers can be dyed in one step.

A brief glossary of dyeing terms not already defined in the text is as follows:

Barré. A dyeing defect showing up as bars or stripes in a fabric.
Blocking. The interference of a dye with the action of another dye in the same bath.
Crocking. The rubbing off of improperly fixed dyestuff.
Dispersing Agent. A detergent or other chemical that accelerates the diffusion of dye molecules through the dye bath.
Exhaustion. The process during which dye molecules leave the liquor and attach to the fiber.
Fastness. The resistance of a dye to loss of color through fading or bleeding.
Grey or Greige Goods. Undyed and unfinished fabric as it comes from the loom or knitting machine.
Merger Number. A number designating yarn that is equivalent in its dyeing characteristics.
Migration. The movement or leveling out of dye molecules on goods during the dyeing process.
Pasting. Prewetting dyes or other chemicals and working them into a paste for easier dispersion in the dye bath.

Resisting Agent. A chemical that will repel dye molecules or slow down their rate of attachment to a fiber.
Rope Crease. A dye streak caused by gathering or roping together of a fabric during the dyeing process.
Sampling. The removal of a portion of the goods being dyed to check the color against a standard.
Shading. The deepening of color in one kind of fiber in preference to another as in various union dyeings.
Soaping Off. The removal of residual dyestuff with a soap or detergent.
Sublimation. The loss of dyestuff from a fabric through vaporization.
Union Dyeing. The uniform dyeing of two different fibers in the same yarn or fabric.

DYNAMICAL ANALOGIES. The formal similarities among the differential equations of electrical, mechanical and acoustical systems which make possible the reduction of mechanical and acoustical systems to electrical networks and the solution of such problems by electrical circuit theory.

DYNAMICAL FRICTION. 1. The drag force between electrons and ions drifting with respect to each other. In a fully ionized plasma, collisions between electrons and ions are small angle Coulomb collisions and they produce a velocity-dependent drag force which is called dynamical friction.

2. Sliding friction, in contrast to static friction.

DYNAMICAL MEAN SUN. A fictitious sun conceived to move eastward along the ecliptic at the average rate of the apparent sun. The dynamical mean sun and the apparent sun occupy the same position in January, when the earth is at perihelion.

DYNAMICAL PARALLAX. An indirect method for the determination of the distances of binary stars. In the determination of orbits of binary stars, the semi-major axis of the relative ellipse is determined in angular units. This length cannot be expressed in any linear units unless the distance of the system is known. With this distance known, the orbit may be solved and the combined masses of the two stars determined in terms of the sun's mass as unity. For the systems thus far solved, the majority of the stars are found to have between $\frac{1}{5}$ and 10 times the mass of the sun. Hence, as a first order of approximation, we may assume that the combined mass for any binary system will not differ greatly from twice the mass of the sun.

The rigorous expression for the so-called harmonic Keplerian Law of Planetary Motion is

$$M_1 + M_2 = \frac{a^3}{P^2} = \frac{\alpha^3}{\pi^3 P^2}$$

where the sum of the masses is in solar units, α is the separation in seconds, π is the parallax, and P is the period in years. Hence, assuming the combined mass of the binary system to be twice that of the sun, and knowing the period of revolution of the system in years, we may find the mean distance between the components of the system in astronomical units. Since, from the orbit, we know the distance between the components in angular units, we can immediately find the angular distance subtended by one astronomical unit at the distance of the star, or, in other words, we can find the stellar parallax of the system.

The parallax thus determined is based on the assumption that the combined mass is twice that of the sun. However, with the parallax thus computed and the apparent magnitudes of the stars known, we can then calculate the absolute magnitude of the system. With this absolute magnitude, we go to the mass-luminosity relation, and get a second approximation to the mass of the system. The process is repeated with this improved mass, and an improved value of stellar parallax obtained. By a sufficient number of approximations, values of the so-called dynamical parallax may be obtained, with an accuracy approaching that of the direct trigonometric determinations.

Several methods have been devised for obtaining dynamical parallaxes for systems that are moving so slowly that orbit determination is impossible. Although such methods do not lead to results of great accuracy, they are valuable for statistical discussions.

See also **Binary Stars**; and **Kepler's Law of Planetary Motion**.

DYNAMIC BALANCE. The condition which exists in a rotating body when the axis about which it is forced to rotate, or to which reference is made, is parallel with a principal axis of inertia. No products of inertia about the center of gravity of the body exist in relation to the selected rotational axis. Dynamic unbalance may be expressed in terms of slug-foot squared (or equivalent weight * length squared units) or in terms of inclination of the principal axis from the reference axis.

DYNAMIC BOUNDARY CONDITION. The condition that the pressure must be continuous across an internal boundary or free surface in a fluid. This condition is applied in meteorology, for example, at frontal surfaces and at the tropopause.

See also **Boundary Conditions**.

AMS

DYNAMIC CHARACTERISTICS. Important characteristics of a piece of equipment under actual operating conditions. These characteristics define the time response of component variables to changes in input signals. This type of information is important to the designer in analyzing and predicting total system response to various load changes and disturbances.

The application of this type of analysis can be found in all types of industry.

DYNAMICS. The science that deals with the motion of systems of particles under the influence of forces. Dynamics deals with the causes of motion, as opposed to kinematics, which deals with its geometric description, and to statics, which deals with the conditions for lack of motion.

See also **Kinematics**; **Kinetics**; **Mechanics**; and **Rotation (Dynamics)**.

Dynamical variables are those variables in terms of which classical mechanics is built up, and which can be given an operational definition. Examples are the coordinates, and the components of velocity, momentum, and angular momentum of particles, and functions of these quantities.

The present state of knowledge recognizes all motion as relative, since no fixed reference is known for finding the absolute motion of any body. The earth, which is frequently used as frame of reference, is rotating about its own axis and is also revolving about the sun. The solar system is a minute part of the Milky Way galaxy that is known to be revolving in space. Beyond this, there is relatively limited knowledge of the nature of motion that exists.

In the field of astronomy, measurements are evaluated in a coordinate system that is located relative to the *fixed* stars. These stars are located at such vast distance from the earth that they appear as points of light that are almost motionless in space. In this frame of reference, the motions of celestial bodies are described with extremely great precision, and the motions of bodies within the solar system can be predicted accurately over periods of hundreds of years.

Some applied areas of dynamics, exemplified by space exploration technology, also require the extreme degree of accuracy that is possible with a celestial frame of reference. In many other areas, this extreme accuracy is not essential, and measurements based upon this frame of reference would be tedious and impractical. In such cases, motion may often be adequately described in a coordinate system located relative to the earth.

DYNAMO. A dynamo is one of a general class of machines capable of transformation of electrical into mechanical energy, or vice versa. The word is a shortened form of dynamoelectric. A feature of all dynamo machines is the employment of magnetic induction in effecting the transformation.

The essential parts of an ordinary dynamo are the armature and the field. One of these is mounted on a rotating shaft, and the other is stationary. Theoretically, the dynamo is perfectly reversible, that is, it may be used either as a generator or a motor. Actually, this is not always possible.

DYNAMOMETER. A dynamometer is an instrument for measuring force, such as a spring balance. Most writers, however, apply the term to certain devices for the measurement of mechanical power. The principal classification is derived from the fact that some types of dynamometers absorb all of the power, which is converted into heat, whereas others transmit the power they receive to some other absorber of power, measuring it during the process. These are called, respectively, absorption and transmission dynamometers.

Absorption Dynamometers. The simplest example is the Prony brake as shown in Fig. 1. The mechanical output of an engine, turbine, or motor is called the brake horsepower because one of the most common methods of testing for mechanical output is with the Prony brake. However, the output available at the shaft is called brake horsepower whether measured by brake or not. For example, when an engine drives an electric generator by direct connection, the horsepower available at the coupling between the machines is termed brake horsepower, but would not, under these circumstances, be measured by a brake. In the case of direct connected electric generating sets, the brake horsepower of the prime mover is found by dividing the electrical output from the generator, converted to horsepower, by the efficiency of the generator. The result is the generator input, which is the same as the mechanical output of the prime mover.

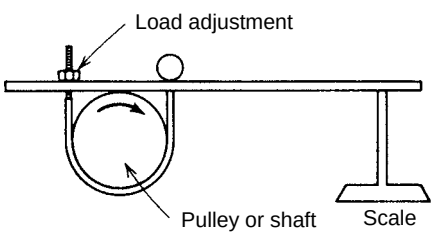

Fig. 1. Prony brake.

To measure brake horsepower by a Prony brake, readings of the weight registered on the scales and the speed of rotation of the brake drum are taken. In addition, the measured distance from the center of rotation to the force on the scales must be known. These quantities are substituted in the following formula to obtain brake horsepower:

$$\text{brake horsepower} = \frac{2\pi W R N}{33{,}000}$$

W = net load on the scales, in pounds
R = radial distance in feet to the line of action of the force registered on the scales
N = rotative speed, in revolutions per minute

(Other units are described at end of this entry.)

The W of the above formula is less than the load actually recorded on the scales because the tare weight must be deducted from the scale reading to give net effective weight. The tare weight is an allowance for the fact that the arm of the Prony brake itself gives some reading on the scale due to its unbalanced position, relative to the center of rotation. The tare weight is that weight which, acting at the scales, will give the same moment about the center of rotation that the unbalanced dead weight of the brake would produce.

In the absorption dynamometer class, there are other types that convert the mechanical to heat energy through the medium of mechanical friction. The friction surfaces are variously wooden blocks against metal drums or pulleys, bands with wooden cleats, ropes, or friction-surfaced brake bands. Also there are hydraulic dynamometers which absorb the power by fluid friction. One common arrangement is similar to a centrifugal pump, except that the casing, instead of being rigidly fixed to a bed plate, is freely supported on the propeller shaft. It is restrained from rotating by an attached arm. The restraining moment in the brake arm is measured by platform or spring scales. The energy absorbed appears as a heating of the water in the dynamometer. To prevent it from boiling it must be steadily renewed. Thus the energy is carried off in a stream of water entering the dynamometer cool and leaving warm. Air friction has also been set to use in the fan brake absorption dynamometers.

One of the most convenient means for measuring power is to convert it to electrical power (watts). In an electrical dynamometer a generator is slightly modified. The stator is mounted, free to revolve, but restrained from revolving by a brake arm which is attached to it, and to which are fastened weighing scales. The tendency of the casing to rotate with the rotor, which is connected to the source of the power, is opposed by the brake arm. The force shown on the scales becomes a torque when multiplied by its lever distance from the center of rotation. Since power is torque multiplied by rotative speed, the only other reading necessary from the dynamometer is the speed of the rotor shaft. In all absorption dynamometers the casing is mounted free to revolve under the action of mechanical friction, fluid friction, or magnetic drag. Actual rotation is prevented by the attached brake arm. Power is measured as a torque operating at the rotative speed of the driven shaft.

Transmission Dynamometers. Representative of this class of dynamometers is the torsion type, in which a shaft delivering power is twisted through a small angle by the torque. Such a shaft may be calibrated at rest by measuring the torsional deflection obtained under known torque loadings. This dynamometer has its greatest usefulness where other types are impractical. Measurement of power output from a large marine engine is such a case. Where applications permit breaking into a coupling, an electronic transducer may be used for making both static and dynamic measurements of torque. Units are available for measurement of torque, in increments, from as low as 2.5 to as high as 60,000 inch-pounds.

Range of Dynamometers. Friction (Prony-brake type) dynamometers measure horsepower up to about 200 horsepower and rotating speeds range from 1,000 to 2,000 revolutions per minute. Fluid-friction dynamometers, such as the Froude (ordinary water brake) are useful up to 25,000 horsepower and at revolutions of 10,000 per minute. Of the electric dynamometers, the eddy-current brake type can be used up to 300 horsepower and 6,000 revolutions per minute. The electric generator type has a range up to 30,000 horsepower and speed of 750 to 4,000 revolutions per minute. The torsion-type transmission dynamometer can go up to 50,000 horsepower and speeds of 1,000 to 3,000 revolutions per minute; while the Kenerson transmission dynamometer has a top range of about 100 horsepower at about 1,500 revolutions per minute. Probable errors of dynamometer measurements range from a fraction of a percent up to as much as 5%.

The units of work performed in rotational motion are: (1) In the cgs system, the dyne-centimeter or erg; (2) in the mks system, the newton-meter or joule; (3) in the English system, the foot-pound; (4) in the SI system, the kilowatt (1 kW = 1.341022 horsepower).

DYNODE. 1. An additional electrode in a photomultiplier tube, which undergoes secondary emission upon bombardment by photoelectrons, and thus effects amplification.

2. A photomultiplier tube having one or more dynodes.

DYSBARISM. A condition of the body resulting from the existence of a pressure differential between the total ambient pressure and the total pressure of dissolved and free gases within the body tissues, fluids, and cavities.

Characteristic symptoms, other than *hypoxia*, caused by decreased barometric pressure are bends and abdominal gas pains at altitudes above 25,000 to 30,000 feet. Increased barometric pressure, as in descent from high altitude is characterized by painful distention of the ear drums.

DYSLEXIA. Currently, this disorder has not been precisely defined in a way that is acceptable to all professionals engaged in research of and therapy for this neurological syndrome. Some years ago, the disorder was defined by the World Federation of Neurology as "manifested by difficulty in learning to read despite conventional instruction, adequate intelligence, and sociocultural opportunity." With more recent knowledge of the brain dysfunctions involved, many researchers no longer consider the definition adequate because it now appears that speech and hearing, in addition to reading, may be part of the syndrome. Thus, it also follows that prior

commonly used definitive phrases, such as "specific reading disability" or "specific reading retardation," no longer apply.

Until quite recently, dyslexia generally had been viewed as a *specific* reading disability quite apart from other, less specific reading problems. This position is described in the Yule-Ritter reference listed. However, in 1990, a team of researchers (Yale Univ. School of Medicine, Carnegie-Mellon Univ., and the Univ. of Texas) concluded a study project, "Reading difficulties, including dyslexia, occur as a part of a *continuum* that also includes *normal* reading ability. Dyslexia is not an *all-or-none* phenomenon, but like hypertension, occurs in degrees. The variability inherent in the diagnosis of dyslexia can be both quantified and predicted with the use of the normal distribution model."

The absence of a consistent definition of dyslexia poses problems for educators in classifying children for special education programs at the state or provincial level. Shaywitz observes that current school policy essentially is based on an all-or-none model of dyslexia.

Investigators, by monitoring the brain activity of dyslexics, have noted slight differences in the speed in which the patient's magnocellular and parvocellular pathways transmit signals. These are parallel pathways that "connect" the eye to the brain. (The magnocellular system responds mainly to fast-moving images of low contrast, whereas the parvocellular system is sensitive to slower-moving images of high contrast.) Reading depends on rapid eye movements and thus the slight difference in imaging processing distorts images "as seen." These same conditions also may apply to the ear and to listening in verbal speech perception.

At one time, dyslexia was commonly associated with word and letter reversal in reading, but subsequent experience has shown that this particular manifestation of dyslexia is quite uncommon.

A brain dysfunction in victims of stroke presents symptoms akin to dyslexia. This has been researched by Hinton (Univ. of Toronto) and described in the Beardsly reference listed. In his work, Hinton, a computer scientist, constructed a network for simulating what may occur when different areas of the brain are temporarily or permanently damaged by stroke.

DYSPNEA. Generally, the term applies to an increase in the rate or force associated with respiration. More specifically, dyspnea refers to the discomfort arising from an awareness of the necessity to exert abnormal effort to breathe. The condition may arise from several causes: (1) an interference with normal heart action; (2) some mechanical form of interference with the passage of air in or out of the lungs; (3) an increase in hydrogen ion concentration (lowering of pH) of the blood, as from acidosis; and (4) the overstimulation of sensory nerves associated with pain. Dyspnea occurs, of course, after violent exercise, but in such instances the individual is not unduly alarmed. Persistent occurrences of dyspnea may be symptomatic of heart disease, pneumonia, or emphysema. See also **Congestive Heart Failure (CHF)**.

DYSPROSIUM. Dysprosium, [CAS: 7429-91-6], chemical element, symbol Dy, at. no. 66, at. wt. 162.50, ninth in the Lanthanide Series in the periodic table, mp 1412 °C, bp 2567 °C, density 8.551 g/cm^3 (20 °C). Elemental dysprosium has a close-packed hexagonal crystal structure at 25 °C. The pure metallic dysprosium is silver-gray in color and retains its luster at room temperature. Although stable up to approximately 400 °C, the metal then oxidizes at a slow rate up to 600 °C. Because of its comparative softness, the metal can be worked by conventional equipment to form rod, foil, and ribbon configurations. There are seven natural isotopes ^{156}Dy, ^{158}Dy, and ^{160}Dy through ^{164}Dy. Twelve artificial isotopes have been identified. In terms of abundance, dysprosium is present on the average of 3 ppm in the earth's crust and is ranked forty-second in terms of total abundance, thus making it potentially more available than tin or beryllium. First identified the element by Lecoq de Boisbaudran in 1886. The metal has a low acute-toxicity rating. Electronic configuration

$$1s^2 2s^2 p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^9 4f^{10} 5s^2 5p^6 5d^1 6s^2$$

Ionic radius Dy^{3+} 0.908 Å. Metallic radius 1.775 Å. First ionization potential 5.93 eV; second 11.67 eV. Dysprosium appears to be exclusively trivalent. Other important physical properties of dysprosium are given under **Rare-Earth Elements and Metals**.

Dysprosium occurs in apatite, euxenite, gadolinite, and xenotime. All of these minerals also are processed for their yttrium content. With liquid-liquid organic and solid-resin organic ion-exchange techniques, the separation of dysprosium from yttrium is favorable.

Because dysprosium has a high neutron-absorbing capability, the metal, usually in the form of foil, is used for detecting and measuring nuclear reactions and exposures. Dy_2O_3 also is used in dosimeters. Dysprosium does not emit harmful decay radiations when it is used as a neutron sponge. Further, helium-generated alpha particles, which may ultimately crack structural parts for containing nuclear fuel, are not generated. Thus, stainless steel, containing about 3% Dy_2O_3 sometimes is used in control rod hardware for high-flux-beam reactors. Although Dy_2O_3 catalyzes the polymerization of ethylene and other synthetic reactions, the cost to date has limited these uses. Since dysprosium oxide fluoresces yellow in glass under ultraviolet radiation, it has been considered as an activator for the yellow component of the phosphors used in black-and-white television picture tubes. Investigations are continuing in connection with future uses of dysprosium in thermoelectric, semiconducting, photoelectric materials, and garnet microwave devices.

DYSTETIC MIXTURE. A mixture of two or more substances in such proportions as to yield the maximum melting point, so that upon altering the proportions the melting point is lowered. Correlative of eutectic mixture.

DYSTROPHY (Muscular). See **Muscular Dystrophy**.

E

EAGLE *(Aves, Falconiformes).* Large birds of prey with strong hooked beaks, large curved claws, and powerful flight. The American golden eagle, *Aquila chrysaetus*, is an example of the typical members of the group, which also includes the harpy eagles, hawk eagles, harrier eagles, sea eagles, and others. The bald eagle, *Haliaeetus leucocephalus*, national bird of the United States, is one of the sea eagles.

Golden Eagle. The golden eagle is a land eagle, brownish in color with purple glossy plumage. The head and neck are brown with filtered yellow. The tail is of several shades of brown and is about 3 feet (0.9 meter) in length. Wingspread is about 7 feet (2.1 meters). The legs are fully feathered. The bird ranges from Canada to Mexico, but is relatively rare in the United States. The golden eagle is found to some extent in England and even more so in Scotland. Nests are on high cliffs. Eggs are from 1 to 3 and are spotted. See Fig. 1.

Fig. 1. Golden eagle. (*John H. Gerard from National Audubon Society*.)

Bald Eagle. The so-called bald eagle is misnamed because of white feathers that make it appear bald. The size is roughly the same as that of the golden eagle. This bird nests on cliffs or in high treetops. Preferred dietary items are mainly fish which it finds in nearby lakes and rivers. This and related species of sea eagles are found in numerous locations throughout the world. See Fig. 2.

Bald Eagle Legislation. One of the first wildlife protection actions taken by government was the Act of the U.S. Congress on behalf of the bald eagle several decades ago. Because of earlier wide usage of DDT (dichlorodiphenyltrichloroethane) as an agricultural control chemical, the bald eagle faced almost certain extinction. Although the principal effect of DDT was that of destroying the native habitats of the bird, the substance also caused thinning of the egg shells of the birds, which severely reduced successful hatching and maintenance of the eagle population. Coupled with threats of the carcinogenicity of DDT to human populations, DDT was banned for use in the United States in 1972.

Fig. 2. Bald eagle.

Although, as of the early 1990s, the eagle still is considered an endangered species, the bird has accomplished a significant return in numbers, and some professionals now feel that the bald eagle could be reclassified as a "threatened" rather than an "endangered" species. The legal differences between these two classifications are explained in article on **Endangered Species**.

Legislation has been quite strict. For example, shooting an eagle in the United States may draw a 1-year prison sentence and a $5,000 fine. Anyone finding a dead eagle is legally required to turn it over to the Fish and Wildlife Service. These regulatory actions have produced good results thus far in terms of "saving" the bald eagle, and most likely were aided by the symbolic nature and general public admiration of the eagle as a desirable creature to have in our environment.

In the 1700s, experts estimate that up to 50,000 eagles populated various areas of the United States. In the 1960s, it had fallen drastically to about 800 nesting pairs. By 1991, attributed to protective measures, this number had increased to about 2,600 pairs in the lower 48 states. Prior to the imposition of protective measures, the bird had virtually disappeared from the Great Lakes region and the eastern United States,

but now bald eagle concentrations again can be noted in most of these areas. During winter months, thousands of bald eagles took refuge below dams on the Mississippi River, where fish and waterfowl were plentiful, and factors other than agricultural chemicals may be affecting a slower return of the bald eagle to these areas. An assessment of the eagle's predicament prior to passage of the Bald Eagle Act is given by J.W. Grier (North Dakota State Univ.) in *Science*, **218**, 1234 (1982). The current, improved situation is well reported by C. Casey in *American Forests*, **24** (November/December 1990). The biologist M. Amijo (Tahoe National Forest) observes, "Anytime we find a bald eagle nest, the objectives for timber harvest in that area change completely. No longer are we just growing timber — we're growing eagle nesting habitat. We write a silvicultural prescription for that stand that meets the needs of the eagle." Through long-range planning, timber stands now are managed with the target of creating bald eagle habitats that will be useful over the next century or two." As pointed out by biologist P. Detrich (Fish and Wildlife Service), "Bald eagles are relatively easy to manage in the context of forestry. We're not out there harvesting their forage habitat. They depend on lakes and wetlands for food, and they're not directly in the path of the use of forest resources, like spotted owls are. While some other animal species require old growth stands left alone, you can actually improve eagle habitat by doing a little logging."

Of the principal geographic regions of the United States, the "comeback" of the bald eagle has been best in the Pacific, Southwestern, Northern, and Chesapeake Bay locations. The slowest recovery has occurred in the Southeast.

Eagles continue to thrive in Alaska, where the species has escaped listing as endangered. In Alaska, the birds have an excellent supply of salmon and steelhead trout upon which they prey. In the lower states, the greatest concentration of bald eagles is in south-central Oregon and northern California. Annually, a Klamath Basin Bald Eagle Conference Watch takes place and draws large crowds for "eagle watching." It is reported that, during most of January and February, hundreds of the birds can be observed. The "conference" takes place between February 15 and 17. More detail can be obtained from the Department of Fish and Wildlife, 1400 Miller Island Road West, Klamath Falls, OR 97603.

Harrier. This is a moderately large eagle. There are several species, mostly limited to Africa, but one species extends to Asia and Europe. Harrier is also a term used to describe a group of hawks. These hawks are found on all continents. They are slender birds with long wings, and in general are useful as destroyers of reptiles and rodents. The marsh hawk, *Circus hudsonius*, is a North American harrier.

Honey Buzzard. This bird is related to the eagles and is named from its habit of robbing the nests of bees and wasps and eating the larvae. One species lives in Europe and Asia and others in the Oriental region.

Harpy. This is a large, crested eagle related to the true buzzards. Several species range from Mexico to Patagonia. They harpy is reputed to be the most powerful of the eagles. One species in the Philippines (*Pithecophaga jefferyi*) is known as the monkey-eating eagle. The crowned harpy (*Harpy haliaetus*) is found in southern Brazil.

Kite. This is a large bird of prey related to the eagle. The bird is found on all continents. Three species, the swallow-tailed kite (*Elanoides forficatus*), white-tailed kite (*Elanus leucurus*), and the Mississippi kite (*Ictinia mississippiensis*) are found in North America. The black kite (*Milvus nigrans*) and the black-winged kite (*Elanus caeruleus*) are found in Europe.

Secretary Bird. This bird (*Sagittarius serpentarius*) is a remarkable African bird related to the eagles and vultures. The bird is about 4 feet (1.2 meters) tall, with long legs, and is largely terrestrial in habits. It walks and runs very rapidly and is also a strong flier on the relatively rare occasions when it takes to the air.

An excellent article on the recovery of the eagle in North America is given by Peter L. Porteous and Joel Sartore, *Nat'l. Geographic*, **42** (November 1992).

EARTH. Planet Earth is one of nine planets that make up the solar system. Each planet is described separately in this Encyclopedia, and the solar system is summarized in the article on **Planets and the Solar System**.

The Earth is a slightly oblate sphere (flattened at the poles) that is comprised of several contrasting layers of various materials which, moving outwardly from the center of the planet, are in order: (1) the solid inner and the fluid outer core, with a transition zone in between; (2) the lower and upper mantle; (3) the lithosphere, which supports the crust upon which people and other life forms, including plants, insects, and fishes, exist; and (4) a gaseous and vaporous atmosphere, also consisting of several identifiable layers, which interface the sphere with outer space. The atmosphere, comprised mainly of nitrogen and oxygen (air), is described in the article on **Atmosphere (Earth)**. Approximately three-fourths of the Earth's surface is covered with liquid water (oceans) and solid water (ice caps). See also **Ocean**.

The Earth is the only planet in the solar system or, in fact, in all of the cosmos known to support life as we currently define it. Thus, while there are numerous similarities among the planets, in terms of life, the Earth is unique.

Only during the past few decades have people been able to observe their planet as an entity — that is, to see Earth in one full and continuous panorama as imaged from an artificial satellite. See Figs. 1, 2, and 3. Earlier, partial views had to be made from high-flying aircraft and presented in the form of mosaics. See also **Satellites (Scientific and Reconnaissance)**. Today, the Earth can be viewed by all manner of imaging and sensing instruments, thus dramatically expanding scientific knowledge of the planet. Weather satellites, in a very practical way, now permit the observation of cloud coverage and patterns across entire continents and oceans. Satellite-based thermal, radiation, and other sensors have markedly improved the reliability of weather forecasting. See also **Weather Technology**.

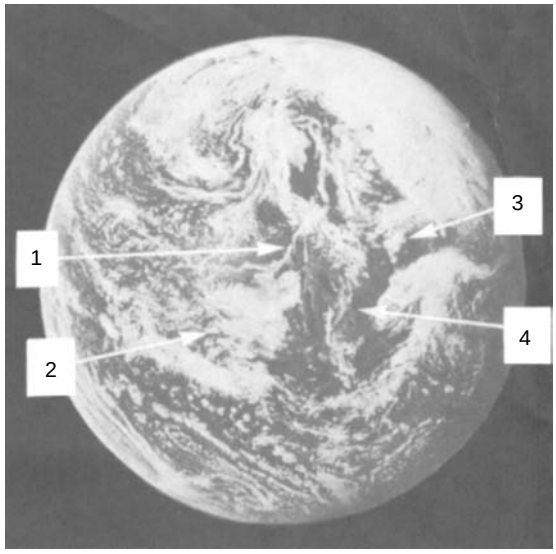

Fig. 1. The Earth as seen from outerspace. Astronauts described the Earth as "a colorful island in the vast sea of blackness." The Northern Hemisphere: (1) United States West Coast; (2) Pacific Ocean; (3) Atlantic Ocean; (4) Gulf of Mexico.

Earth is the third closest planet to the sun, with Venus being closer and Mercury being the closest. Then, further outward from the sun and beyond the Earth are the other six planets — in order, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto. Figure 4 is included here to dramatize just how great the planetary distances are. These distances are further realized when considering how long it takes for a space probe launched from the Earth to reach the region of a given planet. For example, *Voyager 2*,

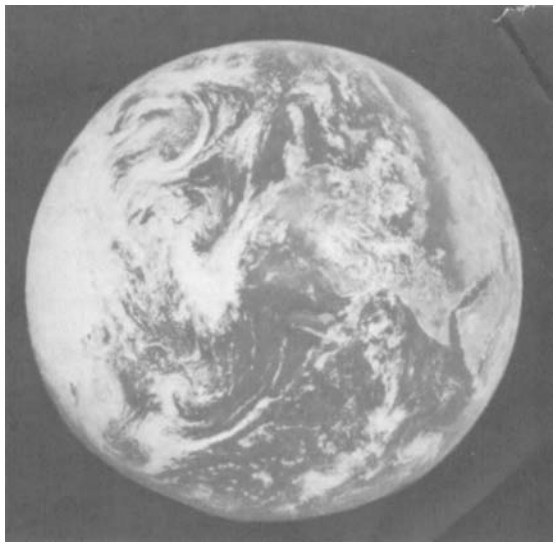

Fig. 2. The Southern Hemisphere as seen from outerspace. The South Polar area is visible under partial cloud cover.

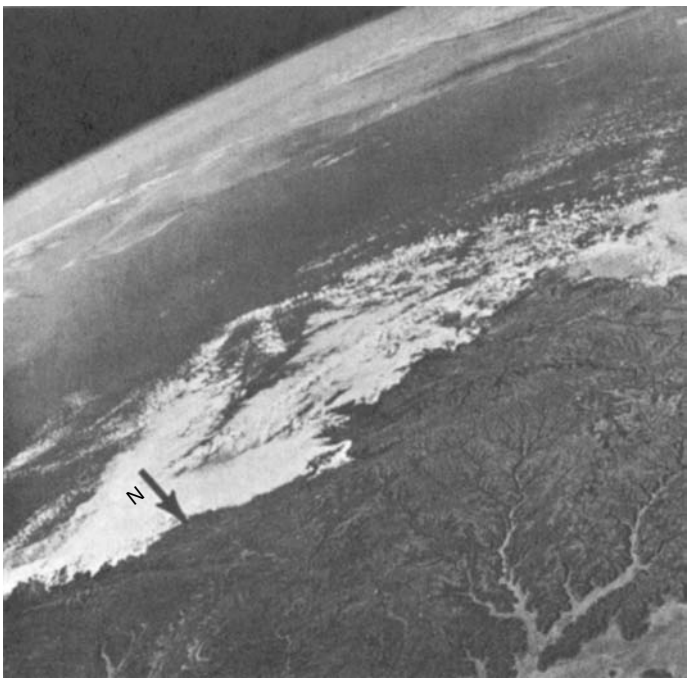

Fig. 3. Small portion of the Earth as viewed from an altitude of 100 miles (161 kilometers). View shows the Hadramaut plateau, the Gulf of Aden, and Somalia.

launched from Earth on September 1, 1977, required 22 months to reach Jupiter, a total of 49 months to reach Saturn, a total of 137 months to reach Uranus, and a total span of 145 months (12 years, 1 month) to fly by Neptune. See also **Voyager Missions**.

In terms of size, the Earth is larger than four of the planets (Pluto, Mercury, Mars, and Venus), but is much, much smaller than Jupiter, Saturn, Uranus, and Neptune. See Fig. 5.

The Earth has a single satellite (the Moon). Mercury and Venus have no satellites, but all other planets have from one to two or more satellites, with Jupiter leading with over a dozen moons.

The solar system, including the Earth, is believed to be part of a spiral galaxy M31 (the Andromeda Galaxy), which, with a few dozen other small galaxies, constitute what is known as the Local Group and part of the Milky Way.

For a number of years, some cosmologists have voiced an assumption, based upon statistical probability, that other solar systems, supported by other stars, may have planetary bodies, some of which may be similar to the Earth. None of these postulated systems and bodies have been

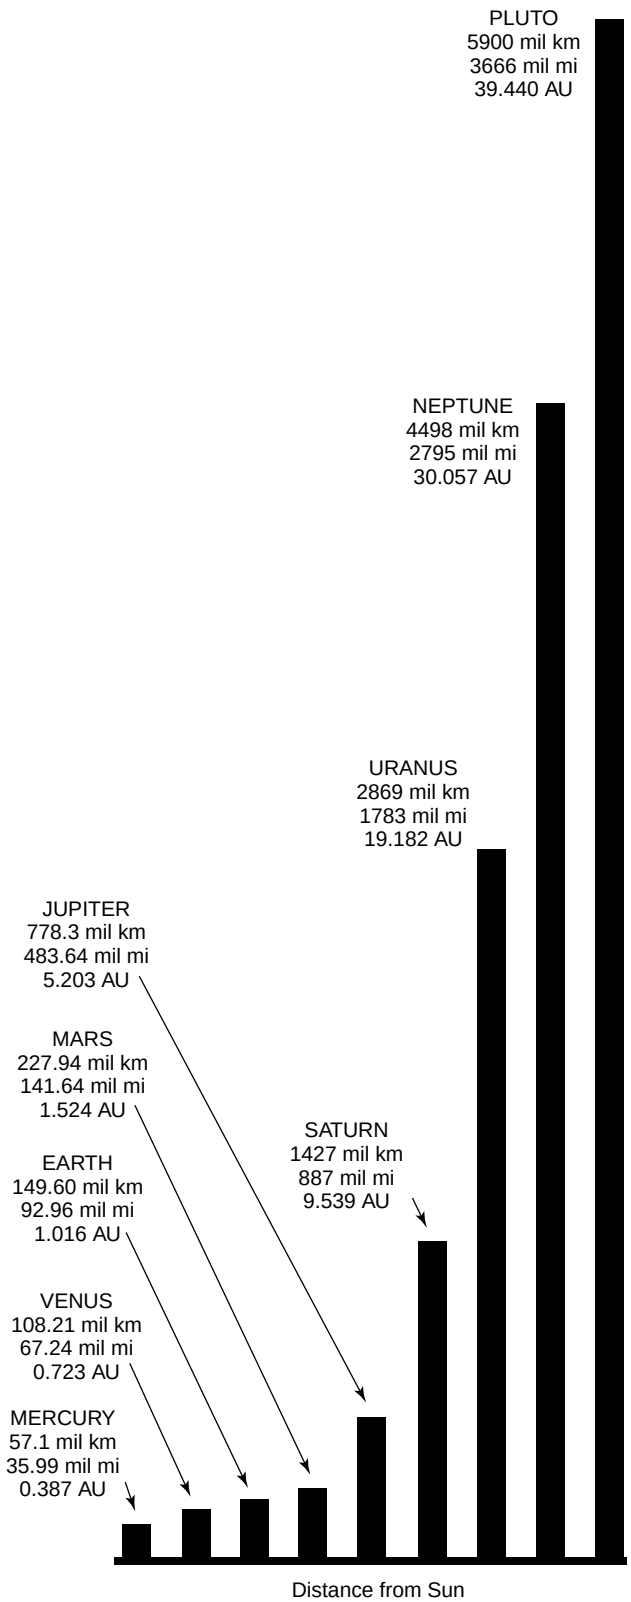

Fig. 4. Comparison of the distances of the nine planets of the solar system from the sun. Distances are given in millions of kilometers and miles and in Astronomical Units (AU).

"discovered," let alone confirmed. But, on the basis of such hypothecation, a search has been underway to "communicate to and from" speculative other intelligences located elsewhere in the cosmos.

Prior to describing some of what is known about the Earth's interior and other earthly features, Tables 1 through 9 summarize useful facts pertaining to geodetic parameters, geometric parameters, major physical features (continents, oceans, lakes, and rivers), meteorological extremes

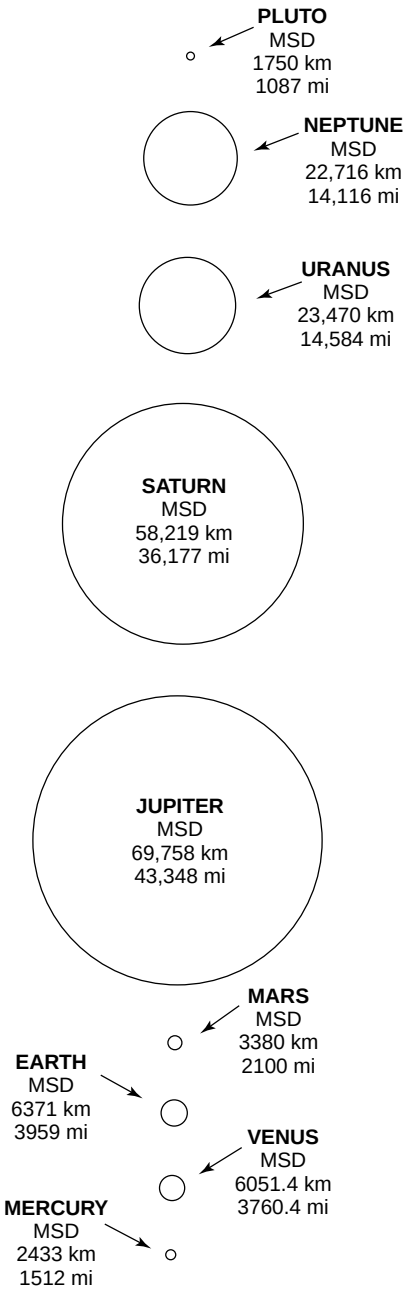

Fig. 5. Comparison of dimensions of the nine planets of the solar system. Figures given in kilometers and miles are for the mean semidiameter (MSD) of each planet shown.

(temperature and precipitation), and major floods, tidal waves, earthquakes, volcanoes, and eruptions. Also there are separate articles on **Earth Tectonics and Earthquakes**, and **Volcano**.

The age of the Earth has been variously estimated, with a figure of something less than 4.6 billion years sometimes used. Such figures are based upon theoretical calculations and extrapolations made by some cosmologists, but on which solid agreement does not apply. See also Cosmology. In any event, when plotted against any humanly comprehensible time scale, the Earth is very, very old. The word ancient simply does not adequately convey a time scale of this magnitude.

Later, in this article, the topic of the presently changing state of the Earth, commonly referred to in contemporary literature as "Global Change," is addressed. As will be developed in this area, it is becoming increasingly difficult to sort opinions and facts.

Geophysics

Geophysics is the physics of the Earth and the space immediately surrounding it and the interactions between the Earth and extraterrestrial forces and phenomena. Geophysics consists of a number of interlocking sciences dealing with physical properties of the Earth, its interior and atmosphere, its age, motions and paroxysms, and their practical applications. All of these sciences use the methods of physics for measurements and analysis. From observational material, often of an indirect nature, attempts are made to derive abstract models of states and processes through advanced mathematical concepts and, in some cases, through statistical relations.

In essence, geophysics is the study of the Earth as a planet — with three basic divisions of activity — the solid Earth, the atmosphere and hydrosphere, and the magnetosphere (solar-terrestrial physics). As a convenience, the term geophysics sometimes has been extended to similar studies of the planets and their satellites. However, for extraterrestrial studies, there are more specific terms, such as selonography which relates to the moon.

Geophysics may be described as an ancient science. In its early stages, it was developed by the Greeks who attempted to determine the shape and size of the Earth (Eratosthenes, 275–194 B.C.). Among its most illustrious contributors have been Galileo Galilei (1564–1642); Sir Isaac Newton (1642–1727), who dealt with the motions of the Earth and its gravitational field; Karl Friedrich Gauss (1777–1855), who developed the theory of the magnetic field; and Vilhelm Bjerknes (1862–1951), who laid the foundation for the hydrodynamic theories of the atmosphere and the oceans. The roster of distinguished scientists who contributed to this field during the 20th century includes: L. Vegard (polar aurora); Sidney Chapman (aeronomy); C.G. Rossby (meteorology); H.U. Sverdrup (oceanography); Sir Harold Jeffreys; F.A. Vening-Meinesz (structure of the Earth); and B. Gutenberg and J.B. Macelwane (seismology).

A major series of milestones toward the advancement of scientific knowledge of the Earth commenced, on the basis of international cooperation, in the late 19th century, with the First International Polar Year (1882–1883), followed by the Second International Polar Year (1932–1933), fifty years later. For the International Geophysical Year (1957–1959), over 8,000 scientists of 66 nations collaborated and spawned the more recent ventures, including satellite investigations of the Earth (Skylab and its predecessors), increased exploration of the Antarctic continent, the International Years of the Quiet Sun (IQSY, 1964–1965), and numerous different and subsequent activities. The International Decade of Ocean Exploration (1970–1979) was a very rewarding program. Other international programs proposed or underway, as of the late 1980s, include the International Geosphere-Biosphere Program (IGBP), targeting the global climate, the biosphere, and the biogeochemical cycles of all major nutrients; the World Climate Program, and the International Biological Program. A number of geoscientists have expressed, however, that limiting such programs to a single year or even a decade has the disadvantage of breaking up a complex infrastructure of specialists and procedures involved in projects that naturally are of a much longer-term nature.

Structure of the Earth

One contemporary concept of the structure of the Earth is diagrammed in Fig. 6. An estimate of the various parameters which apply to the numerous layers and regions of the planet are given in Table 1.

Crust (Lithosphere). Discounting the atmosphere and hydrosphere, the crust is sometimes defined as that part of the Earth that is situated above the Mohorovicić discontinuity, defined later. It is on the crust where living creatures exist — a layer of the Earth that accounts for less than 0.2% of the whole planet. The lithosphere consists of three shells: (1) a *stratified sedimentary shell*, composed mainly of sedimentary rocks; (2) a *granitic shell*, distributed only beneath the continents and thinning out at the ocean boundaries; and (3) a *basaltic shell*, the structure of which differs somewhat when situated under continents or under oceans.

Sedimentary Shell. The total volume of the sedimentary shell is about 1.05 billion cubic kilometers, taking into consideration the consolidation of recent sediments, and 900,000,000 cubic kilometers without volcanic rocks, i.e., about 10% of the volume of the crust and 0.1% the volume of the whole Earth. The average thickness of the sedimentary shell is 2.0 kilometers; if the area of the shields not covered by sediment is excluded, the average is 2.2 kilometers.

On the continents, about 75% of the volume of all sedimentary rocks is found in geosynclinal areas and only 25% in the platforms, their average thickness being 10 kilometers and 1.8 kilometers, respectively. Clay and shale are the most widespread sedimentary rocks on the continents (42%). Arenaceous, volcanic, and carbonate rocks are approximately equally

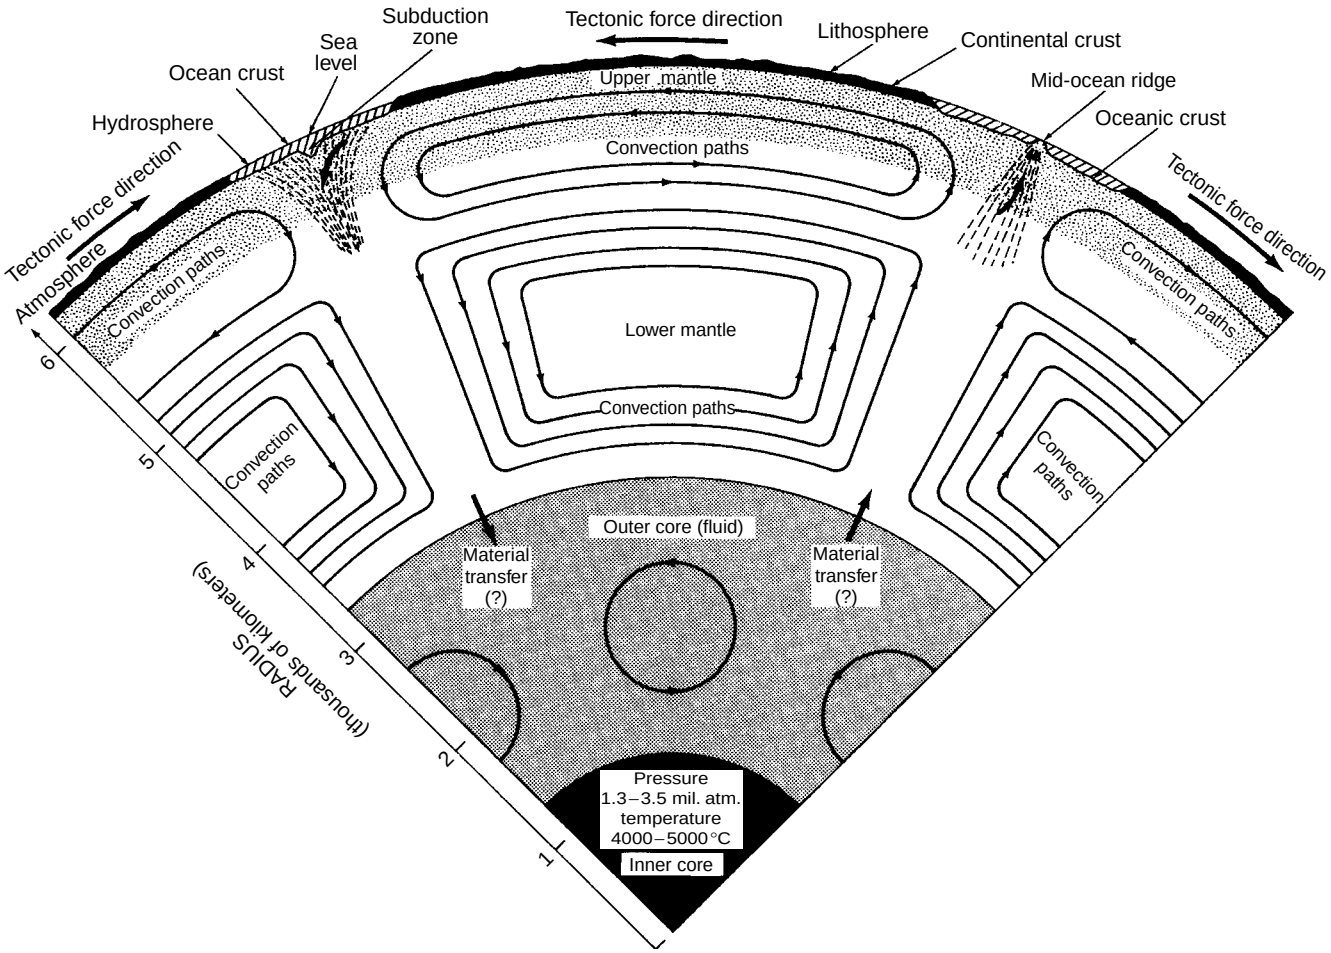

Fig. 6. Tentative, contemporary concept of structure of the Earth. (*After Siever*.)

TABLE 1. APPROXIMATION OF EARTH'S INTERNAL LAYERING AND VALUES OF SOME PHYSICAL PARAMETERS

Depth (km)		Fraction of Volume[a]	Density (g/cm^3)	Pressure (10^{12} dyn/cm^2)	Gravity (cm/sec^2)	Rigidity (10^{12} dyn/cm^2)	Characteristics of *P*, *S* Velocities[b]	Features
0	Crust	0.0155					Complex	Heterogeneous
33	Moho discontinuity		3.3	0.01	985	0.6		
	Upper mantle (Region B)	0.1667					Normal gradient	Probably homogeneous
410								
	Upper mantle (Region C)	0.2131					Greater than normal gradients	Transition layer
1000			4.7	0.4	995	1.9		
	Lower mantle (Region D′)						Normal gradients	Probably homogeneous
2700		0.4428						
	Lower mantle (Region D″)						Gradient near zero	Transition layer
			5.7	1.3	1030	3.0		
2900	W-G Discontinuity							
			9.7	1.3	1030	0.0		
	Outer core	0.1516					Normal *P* gradient	Homogeneous fluid
4980								
	Transition region	0.0028	(12.5)	3.2	(500)	(0.2)	Negative *P* gradient	Transition layer
5120								
	Inner core	0.0076					Smaller than normal *P* gradient	Solid
6370[c]			(13.0)	3.7	0	(1.3)		

[a] Volume ratio, crust:mantle:core = 1 : 51 : 10.
[b] *P* = pressure wave; *S* = shear wave.
[c] The value of 6,370 km depth refers to center of earth.

abundant (20, 19, and 18%). All other rock types, mainly evaporites, comprise about 1%.

Granitic Shell. This shell is restricted to the continents and its volume and mass are approximately 3.6 billion cubic kilometers and 9.8×10^{24} grams, respectively. Acidic granitoids and metamorphic rocks are the main rock types of the granitic shell; the basic and ultrabasic rocks make up less than 15% of the shells' volume. These volumetric ratios of rocks lead to the acidic chemical composition of the shell, its typical high content of silica, the concentrations of alkalies K > Na, and of the rare elements (uranium, thorium; rare earths; zirconium, niobium, etc.).

Basaltic Shell. This shell consists of two parts, the continental and the oceanic, differing in structure and apparently in composition. According to one hypothesis, the basaltic shell of the continental crust is formed of strongly metamorphosed rocks of both basic and acid composition, together with a significant portion of magnetic rocks.

The *continental crust* has considerable thickness and a diversity in composition. The more homogeneous oceanic crust is 86% original oceanic theoleiitic basalts and their metamorphic equivalents. These basalts are characterized by a low content of potassium, rubidium, strontium, barium, phosphorus, uranium, thorium, and zirconium, and high ratios of K/Rb and Na/K, which strongly distinguish them from analogous continental rocks.

The *oceanic crust* is essentially characterized by the occurrence of ultrabasic rocks, seen in the zones of deep faulting (mid-ocean rift valleys), these rocks being considered outcrops of mantle material.

In summary, about 64% of the whole crustal volume is continental, or 79% when the shelf and subcontinental (quasicratonic) crust are included. The other 21% is oceanic crust. The average thicknesses of the various crustal types decrease from 43.6 kilometers for continental, to 23.7 kilometers for subcontinental, to 7.3 kilometers for oceanic crust. The average thickness of the entire crust amounts to about 20 kilometers.

The chemical composition of the crust as a whole approaches that of intermediate rocks, though it is impossible to find its close analog among them. In rough approximation, the crust's composition can be described as a mixture of the two prevailing types of rocks: (1) granite, and (2) basalt (geosynclinal basalt plus oceanic theoleiite) at a ratio of 2:3. The average chemical composition of the crust changes with depth from the sedimentary shell to the basaltic shell, with a continuous increase in the content of iron, magnesium, and alumina; and a decrease in the amount of combined water. The contents of alkalis (potassium) and silica first increase from the sedimentary shell toward the granitic; and then decrease toward the basaltic shell of the continents and oceans.

Mohorovicić Discontinuity. Often simply termed the *Moho discontinuity*, this is the boundary surface or sharp seismic-velocity discontinuity that separates the Earth's crust from the subjacent mantle. The discontinuity marks the level in the Earth at which *p*-wave velocities change abruptly from 6.7–7.2 kilometers per second (in the lower crust) to 7.6–8.6 kilometers per second, or an average of 8.1 kilometers per second (at the top of the upper mantle). The depth of the Moho discontinuity varies from about 5–10 kilometers beneath the ocean floor to about 35 kilometers below the continents. Its depth below some mountain regions may reach 70 kilometers. It is reasoned that the discontinuity represents a chemical change between the basaltic materials above to periodotitic or dunitic materials below, rather than a phase change (basalt to eclogite). The discontinuity should be defined in terms of seismic velocities alone until more fundamental findings are made. The discontinuity is variously estimated to be between 0.2 and 3 kilometers thick. The discontinuity is named after Andrija Mohorovicić (1857–1936), the Croatian seismologist who discovered the phenomenon.

The Mantles. For many years, that immense layer or region of the Earth's interior that lies between the Moho discontinuity and the core of the planet was referred to simply, in the singular, as the mantle. Over the years, possible layers among the mantle were proposed and discussed, but it has only been comparatively recently that there is broad acceptance of the existence of two layers in the mantle, an *upper mantle* (sometimes called *asthenosphere*), which intersects with the Moho discontinuity, on its upper side; and a *lower mantle*, which intersects with the upper mantle and on its bottom side, with the outer core approaching the center of the Earth. Much has been learned, and even more speculated, concerning the materials and characteristics of the upper mantle. There is considerable speculation concerning the lower mantle, how it may interact with the upper mantle and with the outer core and whether or not it may mimic the general behavior of the upper mantle.

When considered together, the upper and lower mantle, these layers account by far for the major portion of the inner volume of the Earth.

As early as 1910, Alfred Wegener proposed that the continents drift. Many years later, the plate tectonics concept was developed and widely accepted, not only for explaining the apparent very slow movement of land masses borne by underlying plates that float on the upper mantle, but also for elucidating the cause of most earthquakes and volcanic activity. The concepts of currents flowing within the upper mantle as plate driving forces had been proposed and studied from time to time, but remained for the late 1970s and early 1980s for more concerted research to find more convincing evidence for the existence of such currents. The logic and scenario followed by several researchers during this latter time frame is most interestingly developed by D.P. McKenzie in a review report (see reference). Unfortunately there is insufficient space available to present many of the details.

D.P. McKenzie and N.O. Weiss (University of Cambridge), both authorities on tectonics, found that the mass of data collected pertaining to plates (for example, where they are located, approximate rates of movement, reactions resulting from such movements, their size, on the average 100 km thick, and other factors) simply was insufficient to help in providing leads pertaining to probable convection currents operating in the underlying mantle. It was, of course, almost self-evident that some underlying force had to be present and in sufficient magnitude to cause the plates to move. At the estimated temperatures and pressures existing in the upper mantle, as learned from observing volcanoes, earthquakes, and other tectonic related events, it seemed logical to assume that the mantle was fluid and that some force, most likely flow resulting from temperature and/or pressure gradients, was present. It is interesting to note that a number of geophysicists for several years had insisted that the mantle cannot flow like a liquid, at least when taking into consideration the probable composition of the materials that make up the mantle. A number of researchers, using various techniques, such as laboratory and computer modeling of fluid dynamic processes, the use of satellite gravity field and surface deformation measurements, precise seismic investigations, and isotope ratio studies, have contributed to the establishment of the mantle convection currents concept.

For example, McKenzie and Weiss found from laboratory fluid dynamics studies, where flows were measured and observed in experimental tanks and supported by some numerical modeling, that mantle convection probably consists of at least two scales of motion. Transposed to terms relating to the mantle situation, the researchers suggested that a small-scale circulation with a distance of about 1500 km between cold, sinking regions be superimposed on a larger-scale circulation that returns materials from a trench to a ridge. Both of these processes are now well understood by investigators in plate tectonics. McKenzie and Weiss believed that the two-scale model of circulation in the mantle could reconcile the geophysical observations with the behavior of convecting fluids as observed in the laboratory. A problem remained, however — the existence of the small-scale circulation could not be directly observed. This remained pending the availability of satellite instrumentation that could be used to map the Earth's gravity field very accurately. As observed by McKenzie, numerical calculations had shown that upwelling regions of convection should be associated with small, positive gravitational anomalies and that flow should push up the Earth's surface. Plates are too thin to have much effect on either the gravity field or the surface deformation. Therefore, it was reasoned that if the gravity field and the surface deformation can be accurately mapped, it should be possible to "see through" the plates and map the convective circulation under them.

McKenzie, in cooperation with B. Parsons (Massachusetts Institute of Technology), A. Watts (Lamont-Doherty Geological Observatory of Columbia University), M. Roufosse (Center for Astrophysics of the Harvard College Observatory and the Smithsonian Astrophysical Observatory) were indeed able to map the small-scale convection cells in the mantle. Even though the maps confirm the general features of the two-scale model previously mentioned, at least two further questions remained unresolved.

As previously mentioned, some geophysicists did not feel that the mantle can flow like a liquid mainly based upon materials considerations. It became evident to some investigators, however, that the answer may be found in what metallurgists term *creep*. (This is evidence of the multidisciplinary nature of geophysical research.) The flow behavior of materials close to their melting point had been examined in connection with jet engines and nuclear reactors. Investigators learned that under these conditions all crystalline materials flow under any stress, regardless of how

small it may be. It was found that high-temperature creep differs in many respects from low-temperature creep. Incidentally, the concept of solid rock at high temperatures has resolved a number of puzzling situations in geology.

Gravitational and bathymetric data contributed to confirming circulation of the mantle. See Fig. 7. Although the investigations of residual depths and gravitational anomalies made it possible to map rising and sinking regions, they provided little information about the depth to which the circulation extends and no information concerning its evolution with time. The researchers then turned to data on isotope ratios as possible clues. In the early stages of the formation of the Earth, certain elements, such as strontium and rubidium, were concentrated in the Earth's crust, but were depleted in the upper mantle because the Sr and Rb ions, for example, did not easily fit into the lattice framework of most minerals present in the upper mantle. However, relatively more Rb concentrated in the crust than Sr. Similarly, relatively more neodymium (Nd) concentrated in the crust than samarium (Sm). Applying the knowledge of how these various radioactive isotopes decay, one can ultimately determine the migration of materials, and hence deduce the transfer of materials that had to occur to effect such results. See Fig. 8. The research and logic followed by the investigators is further detailed in the paper by McKenzie, who, in 1983, summarized as follows: "Twenty years ago many earth scientists considering the evidence for or against continental drift were consciously or unconsciously thinking in terms of a static model of the earth. This situation changed completely with the general acceptance of sea-floor spreading and plate tectonics. The effect on the study of the dynamics of the mantle was particularly profound, since plate tectonics established the existence of mantle convection without providing much information about the forces involved. Some of the first attempts to understand mantle dynamics limited the circulation to the plate motions and a return flow that carried the mantle material from trenches to ridges. The dynamic models and observations of the gravity field have now clearly shown that much of the convective circulation is not related to the movements or boundaries of the plates. I believe we now understand the outlines of the dynamics of the upper mantle; the challenge is to discover how the more massive lower mantle behaves."

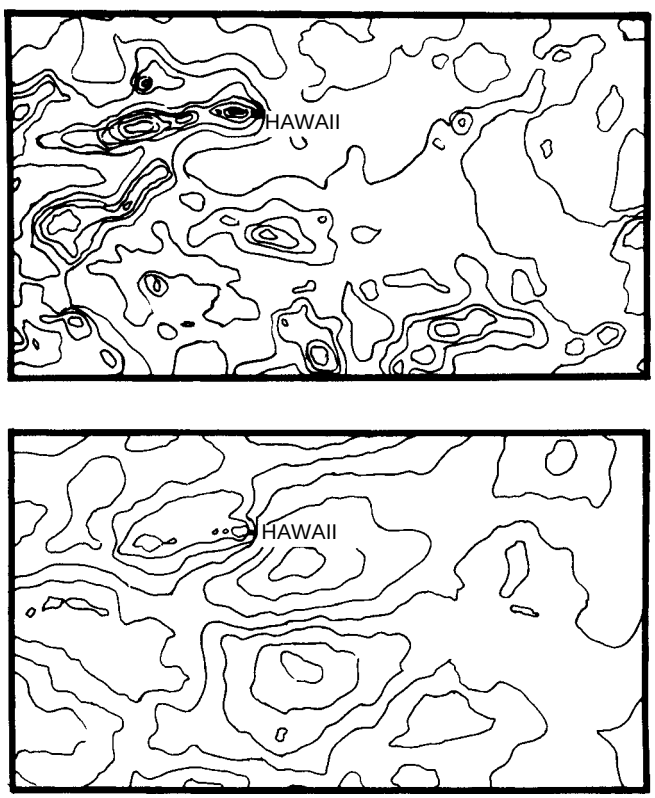

Fig. 7. Black-and-white facsimiles of color enhanced bathymetric anomaly (top) and gravitational anomaly (bottom) maps of portion of Pacific Ocean. These data were important in developing concepts pertaining to mechanisms involved in tectonics and, notably, a better understanding of the upper mantle of the Earth, including the presence of convection currents. Both maps have been smoothed to eliminate fluctuations less than 500 km. The bathymetric anomaly is plotted at "residual depth," which is the difference between the depth that can be attributed to the contraction of the oceanic plate as it cools and the observed depth. The gravitational anomaly is observed as a fluctuation in the height of the sea surface, measured by radar altimeters carried aboard satellites. To investigators, the maps revealed that where the sea surface tends to bulge, the residual depth is positive and that both features are expected above an upwelling region in the mantle. Similarly, the sea surface tends to be depressed where the residual depth is negative, as expected above a downwelling region. The map is projected so that the motion of the plate with respect to the mantle is always to the left over the entire region. This motion generates a small but detectable elongation of the anomalies in the direction of the motion, causing them to appear like ellipses whose long axes run horizontally across the diagrams. (*After McKenzie.*)

Surface Clues of the Mantle. The mantle beneath the continents is usually buried beneath many kilometers of continental crust. In the Ivrea zone of northern Italy, geological and geophysical data indicate that the rocks have been thrust upward and exposed to view. Ultrabasic rocks outcrop in the mountains near the town of Finero.

The Red River near Yuanjiang in Yunnan, China, flows along a marked crustal discontinuity between underformed late Precambrian rocks to the north and deformed and metamorphosed Mesozoic rocks to the south. Geological discontinuities of this sort can be used to identify ancient plate boundaries.

At Dead Horse Point, Utah, large-scale vertical movements are clearly demonstrated in the western United States, where major uplift has produced some of the most spectacular scenery. Other movements, often oscillatory in character with rates that sometimes are on the scale of centimeters per year, are less obvious. The relationship between these vertical movements and the simple plate tectonics model is not clear.

These rare locations are illustrated in article by Drake and Maxwell (see reference).

Deep Holes. Ironically, it is many orders of magnitude easier to probe the depths of outer space than the interior of the Earth and, consequently, a large percentage of our knowledge pertaining to the inner Earth is inferential. Deep mines and deep exploratory drill holes have provided a glimpse of the top 10 km or so of the continental crust. The *Glomar Explorer and Glomar Challenger* have drilled into the oceanic crust. See also **Ocean Research Vessels**. Much of the data potentially obtainable from commercially oriented drill holes either is not observed at all or it is not readily available to scientists. In the early 1980s, the National Academy of Sciences established a Continental Scientific Drilling Committee with the objective of advising scientists of opportunities for obtaining samples and for performing various kinds of geophysical observations, such as regional stress determinations.

In addition to the Glomar vessels previously mentioned, a number of scientific-sponsored drilling projects have been undertaken or are currently underway. Others remain in the proposal stage. A large and ambitious drilling program has been in progress in Russia, and just a few years ago, foreign scientists were permitted to visit the Kola hole, located near the Arctic Circle. At that time the hole was 12 km in depth. The drilling derrick is 64 meters (210 feet) high, and an entire scientific and supporting community has been built around it. The Kola hole is only one of several Russian drilling programs, which also include a second superdeep hole now underway. This hole is located at Saatly, near the Caspian Sea and already has reached a depth of well over 8 kilometers. The plans also include a web of geophysical profiles that will connect eleven deep and superdeep boreholes as part of an effort to elucidate the geology of Russia and to identify new mineral resources. At Kola, the drill bit can progress from 2 to 3 meters per hour of drilling. Drill rig automation permits full retrieval and reinsertion of 12 km of drill pipe in 18 hours. This is considered exceptional on ordinary drilling standards.

Drilling projects do not have to be spectacular to gain useful scientific information. The Inyo Domes Project on the eastern edge of the Sierra Nevada just east of Yosemite National Park is an example. Here, scientists were investigating the flat-topped domes which were formed where thick lava had oozed to the surface — in an effort to study how fluid rock makes its way through the brittle upper crust and either quietly flows out or is explosively shattered into ash and strewn across the adjoining land. This project involved slant-drilling to a depth of about 650 m below the center of Obsidian Dome, at which depth the drill bit encountered the dike demonstrating that at least above that depth, the dike rises vertically to

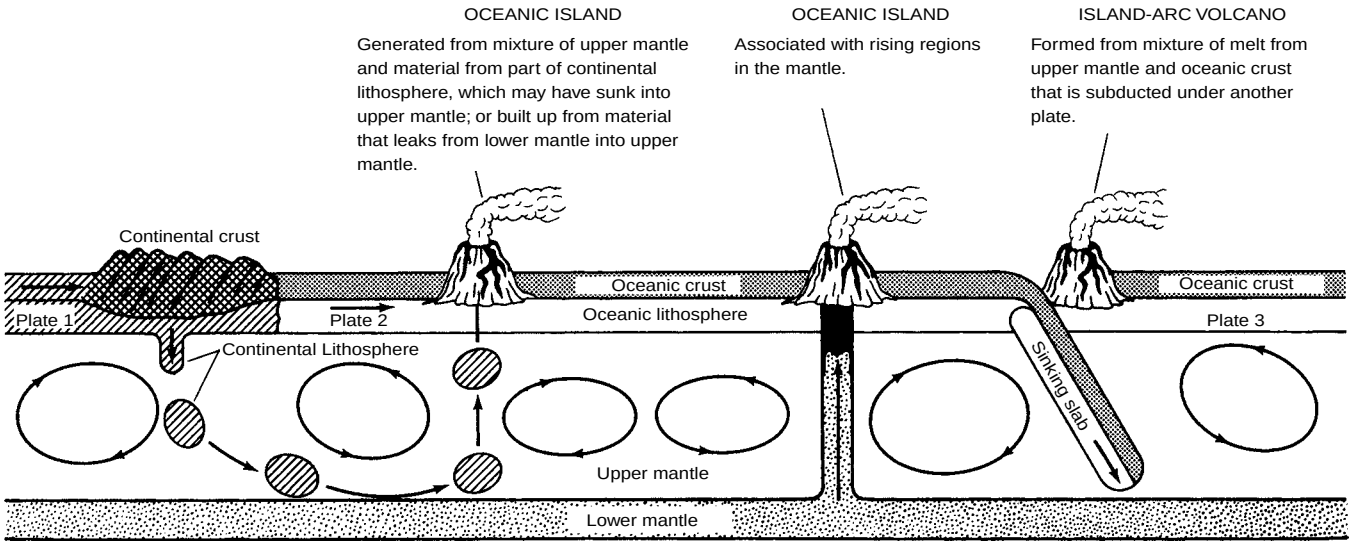

Fig. 8. Highly schematic diagram depicting probable scenarios for formation of continents, oceanic islands, and island-arc volcanoes. Relationship between upper mantle and oceanic and continental lithosphere, continental crust, oceanic crust, and patterns of circulation as proposed for the upper mantle are also shown. As reported by McKenzie, the origin of material erupted onto volcanic islands can be inferred from the isotopic ratios of certain elements. In the early phases of the Earth's history, some specific elements, such as strontium (Sr) and rubidium (Rb) were concentrated in the Earth's crust and thence depleted from the upper mantle, these actions deduced from the fact that the ions of these elements do not easily mesh into the lattice framework of common minerals. Data indicate that the concentration of Rb in the crust was relatively greater than that of Sr. Because all isotopes are chemically equivalent, the ratio of Sr 87 to Sr 86 remained the same after differentiation of the crust and upper mantle. However, thereafter, the ratio of Rb to Sr varies because half of the Rb 87 radioactively decays to Sr 87. Thus, radioactivity becomes a clue in tracing how materials are transferred in the formation of the major features of the Earth and ultimately assists in determining the probable convection circulation occurring in the upper mantle. Because of an initial surplus of Rb 87 in the crust, the ratio of Sr 87 to Sr 86 increases most rapidly in the crust, less rapidly in the Earth as a whole, and least rapidly of all in the upper mantle. Thus, the ratio of Sr 87 to Sr 86 becomes the key to this kind of analysis. Two other elements, samarium (Sm) and neodymium (Nd), also were both concentrated in the crust, with relatively more Nd than Sm transferred to the crust. Through radioactive decay, half of the Sm 147 decays to Nd 143. Thus, as in the case of the Sr isotopes, the ratio of the Nd isotopes serves as a similar clue for this type of analysis. Although most of the major features of tectonic activity near the surface of the Earth have been known for several years, tracing materials origins and transfers and hence upper mantle circulation has been enhanced through these isotopic studies and comparisons. (*Sketch is after McKenzie.*)

the surface. Much geophysical information was obtained from the project. Further findings are reported in the Kerr (1985) reference.

For a number of years, an ambitious continental drilling project in the United States, sometimes referred to as the Southern Appalachian Superdeep Hole, has been under consideration. The 10-kilometer hole would be nearly twice as deep as any drilled through hard, crystalline rock other than the Kola hole. Drilling specialists do not envision many difficult problems. The drilling rig would have to lower and raise a 15-kilometer long, 450,000-kilogram pipe and its attached drilling bit. By comparison, oil and gas strings are only about one-third that weight. The drilling would have to be straighter than that achieved in normal drilling practice — with deviations of less than a few degrees per 100 meters. Straightness is important because abrasion at the slightest of bends would wear out the drill string. Conditions in the lower portions of the borehole are envisioned as comparatively cool (165 °C) as compared with about 250 °C for a deep gas well. It is also envisioned that all but the uppermost section of the borehole would be sufficiently strong to forego the lining usually required in deep wells.

Deep drilling experience in hard rock in the United States has been quite limited. As reported by Kerr (1984), two boreholes of about 4 km were sunk at Fenton Hill near Valles Caldera in New Mexico as part of the hot dry rock geothermal project of the Los Alamos National Laboratory. The deepest hard-rock hole in North America was an accident, drilled by Phillips Petroleum Company in a search for oil and gas in Arizona. As reported by Kerr, deep drilling programs are also underway in Belgium, France, and Germany.

Some years ago, the Mohole Project had the single target of a deep ocean hole through the Moho discontinuity, an uncompleted task now envisioned as much more difficult than drilling the southern Appalachian hole.

The Cores. From the total mass of the Earth and its moment of inertia in conjunction with seismic information, it has been deduced that the core contains about 1.95×10^{27} grams of material, constituting about one-third of the mass of the earth, while occupying only one-sixth of its volume. Seismological data indicate that the core extends from a depth of about 2900 km (1800 mi) to the center of the earth, which is at a depth of 6370 km (3960 mi). Such data also indicate that the inner core is solid and has a radius of about 1200 km (1920 mi). The inner core is surrounded by a liquid outer core. Pressures in the core are estimated to range between 1.3 and 3.5 million atmospheres and the temperature is estimated to range from 4000 to 5000 °C (7200–9000 °F).

An interest in what occurs under the surface of the Earth and particularly of what the Earth is like at its center has fascinated people for centuries. Much of the information from the past has been derived from studies of the magnetization of rocks. Inspection of some of the oldest known rocks suggests that the mechanism which generates the geomagnetic field has been in place for at least 3.5 billion years. For many years, the generator of the geomagnetic field has been likened to a dynamo, but only quite recently has further new evidence been obtained to strengthen that concept.

As more is learned of *what* appears to be the main function of the Earth's core, clues are produced about how it may function. Thus, much research in recent years has been directed to determine *how* the geomagnetic field interacts with other phenomena and, in particular, how it interacts with the solar wind to learn about the nature of the Earth's magnetotail. A number of other questions remain. When did the geomagnetic field first appear? How was it started? How has it evolved? Has it changed over the past eons? It is undergoing change, even if change is measured in millions upon millions of years? The why of the Earth's dynamo is elusive.

Traditional View of Geomagnetic Field. Many geoscientists over the years have compared the geomagnetic field with a bar magnet at the center of the Earth, with lines of force looping from the South Magnetic Pole to the North Magnetic Pole. This is a rather limiting comparison, however, because in reality the magnetic field behaves like that of a dipole only near the surface of the Earth. It is now known that the geomagnetic field is distorted by the solar wind. Even before the concept of the solar wind was developed, a connection between disturbances in the geomagnetic field and solar activity (sun spots) had been well established. Space exploratory missions have taught much about the magnetic fields and the effects of solar radiation on the magnetic fields of other planets. Studies of aurora phenomena have revealed a direct connection between the solar wind and the geomagnetic field. This is described in greater detail later in this article.

It is of interest to review briefly the research and lines of reasoning brought to bear on the question of the Earth's core dynamo. For a more penetrating analysis, R. Jeanloz' paper (see reference) is suggested.

The concept that the geomagnetic field generator takes the form of a magnetohydrodynamic machine was proposed by W.M. Elasser (Johns Hopkins University) and E.C. Bullard (University of Cambridge), among others. Jeanloz points out that these processes entail convection in an electrically conducting fluid, with the result that the core acts as a dynamo, maintaining and regenerating the magnetic field. An article on **Magnetohydrodynamic Generator** in this encyclopedia describes the consideration of this technology as an emergency source of electrical energy by electric utilities.

As field lines directed toward the center of the Earth (*poloidal lines*) enter the outer core, they are pulled in the direction of the Earth's rotation. Thus rotation of the solid inner core probably tends to wrap the field lines around the Earth's axis, producing a toroidal component. It is also speculated that the field lines may become-contorted by smaller-scale cyclonic motions that result from the assumption that the core is rotating essentially in synchronism with the rest of the Earth. These cyclonic motions may be likened to the hurricane patterns that arise in the atmosphere. The exact origin and detailed pattern of the contortions remain unknown.

It is interesting to note that in the absence of the dynamo process, the Earth's magnetic field most likely would have died out within 10,000± years and yet it is still performing a few billion years after the Earth was formed.

Matching Core Characteristics with the Geomagnetic Field. Traditionally, the inner core of the Earth has been regarded as consisting mainly of iron (Fe). This assumption agrees well with most seismic data. There are at least two other clues which add to the credibility of Fe in the core: (1) From our present knowledge of electricity and magnetism, the generation of a magnetic field requires the core to be metallic, that is, electrically conducting in order for the geodynamo to function. (2) Studies of the abundance of materials throughout the cosmos, other than Fe, that would serve the dynamo function, fail to suggest any alternatives for Fe. Probably the principal consensus concerning the Earth's core pertains to acceptance of Fe as the primary element of the core. There is no consensus concerning the degree of purity of the core iron. Ferric alloys that would seem feasible at the extremes of temperature and pressure in the core have been proposed by some researchers. Other materials suggested have included iron sulfide (FeS), which is a good electrical conductor. The presence of iron oxides in the core has been suggested. Some investigators point to the composition of meteorites, iron and stony, as possibly indicative of the two core layers of Earth. Silicon-oxygen compounds make up rocks. As pointed out by Jeanloz, however, beyond this, there is no evidence for a more detailed analogy between the Earth's core and the nature of meteorites.

If the accuracy of core density estimates hold up, then it is evident that the percentage of lighter-than-iron elements cannot be extensive.

There has been much speculation pertaining to the driving force which propels the dynamo. Two distinct mechanisms have been proposed; one thermal, the other compositional. The thermal concept requires no difference in composition between the inner and outer cores, but it requires a source of energy. Radioactive isotopes, such as U-238 or K-40, which are present in the crust and the mantle, have been suggested. According to present theory, radioactive decay is the leading candidate as the dominant source of energy driving the flow in the core. John Verhoogen (University of California at Berkeley) has investigated another hypothesis, namely, that if the inner core is freezing out of the surrounding liquid, there could be sufficient heat from the latent heat of crystallization to power the geodynamo. There is also the "primordial heat" hypothesis. This is briefly explained in Fig. 9. Considerably more detail is given in the Jeanloz paper.

The composition concept for powering the dynamo is based upon the differences in densities of materials. No temperature differential is required to support this concept. The concept does require that the liquid of the outer core can separate into two phases (presumably solid and liquid) of significantly different composition, and thus significantly different densities. As concisely described by Jeanloz, a liquid with a composition different from that of a solid is exactly what would be expected for a partially frozen alloy under equilibrium conditions. This is why an alloy melts and freezes at slightly different temperatures. The presumption is that the solid inner and liquid outer parts of the core are at equilibrium and that accordingly they differ in composition. The presence of a seismic attenuating zone at the top of the inner core — possible seismological evidence for a crystal-liquid mush — tends to support this concept. Geophysicists are evaluating this model, but more seismological data and experiments at high pressure are needed. Regarding the laboratory production of high pressure, see article on **Diamond Anvil High Pressure Cell**.

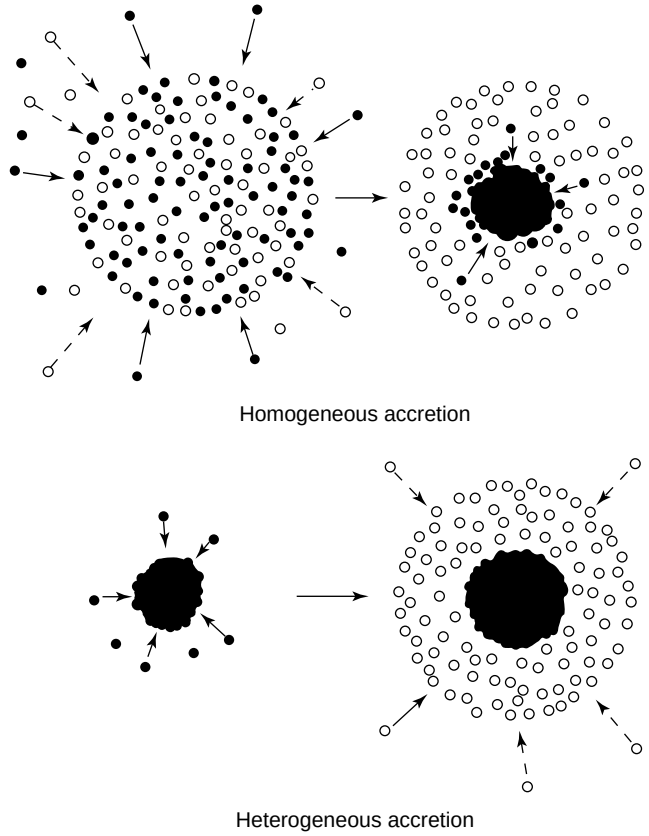

Fig. 9. In the *homogeneous accretion model* (top diagram), silicate and iron accumulated to form the complete planet as shown at the left. Sometime later, the core formed as the result of separation of the metal from the silicates. As the core formed, the iron sank to the center of the planet. Heat was generated by the release of gravitational energy.

In the *heterogeneous accretion model* (bottom diagram), it has been proposed that the core accumulated first as shown at left, after which the silicate mantle accreted around it. This is a sequence that could have taken place during or after condensation of solids out of the solar nebula, as governed by whether chemical, physical, or both processes were involved. In these models, accretion of the planet is proposed to result from infall of meteoritic bodies, as indicated at right. There are numerous variations of these models, as explained in the Jeanloz reference. (*Diagram is after Jeanloz.*)

In considering the two foregoing concepts regarding the powering of the core dynamo, it is interesting to note that a thermally driven geodynamo would require no composition difference; and a composition-driven geodynamo would require no temperature difference.

Explanation of Mantle Dynamics

As of the early 1990s, geophysicists are giving much attention to how the lower and upper mantle regions of the Earth's interior function and possibly interact with each other to produce the numerous tectonic (earthquakes) and volcanic (eruptions) phenomena that almost continuously affect some portion of the Earth's crustal (outer) surface. Surface effects are well known, and the fact that these effects arise from forces within the Earth's interior is self-evident. What remains poorly understood is how mantle regions produce such effects — that is, what is going on in the mantle areas? There are numerous hypotheses, some of which have been described in this article. At a meeting of the American Geophysical Union (held in Montreal, Canada, in May 1992), three schools of thought were described by groups of geophysicists, with differing findings and opinions. One group essentially claimed that materials and energy rather freely circulate between

the upper and lower mantle. Another group stressed that there is little, if any, mixing of upper and lower mantle materials — that is, there is a barrier between the two mantles. Still another group suggested that mixing between the two mantles may occur sometimes and at varying locations. This latter group, in essence, accepted a combination of the other two viewpoints.

Understanding the Earth's interior machine is far more difficult than learning about its exterior — that is, scientists can look back at the Earth from spacecraft and probes. Attempts to get inside the Earth by way of sinking deep holes and drilling cores is difficult and costly. Experiments with materials in laboratories under high-temperature and high-pressure conditions have contributed knowledge, and computer models can be created from known and assumed statistics. Some evidence of this type is less than convincing, but progress is being made toward achieving answers, but at a comparatively slow pace.

For further clarification, the Kerr article (December 4, 1992), listed at the end of this article, is suggested reading. Also, more information can be found in the articles on **Earth Tectonics and Earthquakes** and on **Volcano** contained in this Encyclopedia.

The Geomagnetic Field

The North Magnetic Pole*. During the 16th century, mariners believed that somewhere in the North was a magnetic mountain which was the source of attraction for compasses and an unfortunate object for any ships which strayed too close. It was not until 1600 that a better explanation was suggested. Sir William Gilbert, physician to Queen Elizabeth I, suggested that the Earth itself was a giant magnet and that the force which directs the compass originates inside the planet. Using a model of the Earth made from lodestone, Gilbert also showed that there should be two points where a magnetized needle would stand vertically — the North and the South Magnetic Poles.

This is basically the same definition used today. At the magnetic poles, the Earth's magnetic field is perpendicular to the Earth's surface. Consequently, the magnetic dip, or inclination, is 90 degrees. Since the magnetic field is vertical, there is no force in a horizontal direction to direct a compass needle — thus it will not point to any preferred direction. The magnetic declination, the angle between true geographic North and magnetic North, therefore, cannot be determined at the magnetic pole.

Where Is the North Magnetic Pole? Gilbert believed that the magnetic pole coincided with the geographic pole. Magnetic observations made by explorers in subsequent decades have shown that this is not true. By the early 19th century, it became established that the pole must be located somewhere in Arctic Canada.

In 1829, Sir John Ross set out to discover the Northwest Passage, but his ship became trapped in ice off the northeast coast of the Boothia Peninsula, where it was to remain for the next four years. Sir John's nephew, James Clark Ross, used the time to take magnetic observations along the Boothia coast. These observations convinced him that the pole was not far away. In the spring of 1831, he set out to reach it. On June 1, 1831, at Cape Adelaide on the west coast of Boothia, he measured a dip of 89°59′. For all practical purposes, he had reached the North Magnetic Pole.

The next attempt to reach the magnetic pole was made some 70 years later by the Norwegian explorer, Roald Amundsen. In 1903, Amundsen left Norway on his famous voyage through the Northwest Passage, which, in fact, was his secondary objective. His primary goal was to set up a temporary magnetic observatory in the Arctic and to determine the position of the magnetic pole.

A pole position was next determined by Canadian government scientists shortly after World War II. Paul Serson and Jack Clark of the Dominion Observatory of Canada measured a dip of 89°56′ at Allen Lake on Prince of Wales Island. This, in conjunction with other observations in the vicinity, showed that the pole had moved some 250 kilometers northwest since Amundsen's observation.

Subsequent observations have been made by Dominion Observatory personnel in 1962, by personnel from the Canadian Department of Energy, Mines and Resources in 1973, and most recently in May 1984. This latest survey located the pole at 77.0°N, 102.3°W off the southeast tip of Lougheed Island and showed that the general northwesterly motion of the pole is continuing. See Fig. 10. During the 20th century, the pole moved an average of 10 km per year.

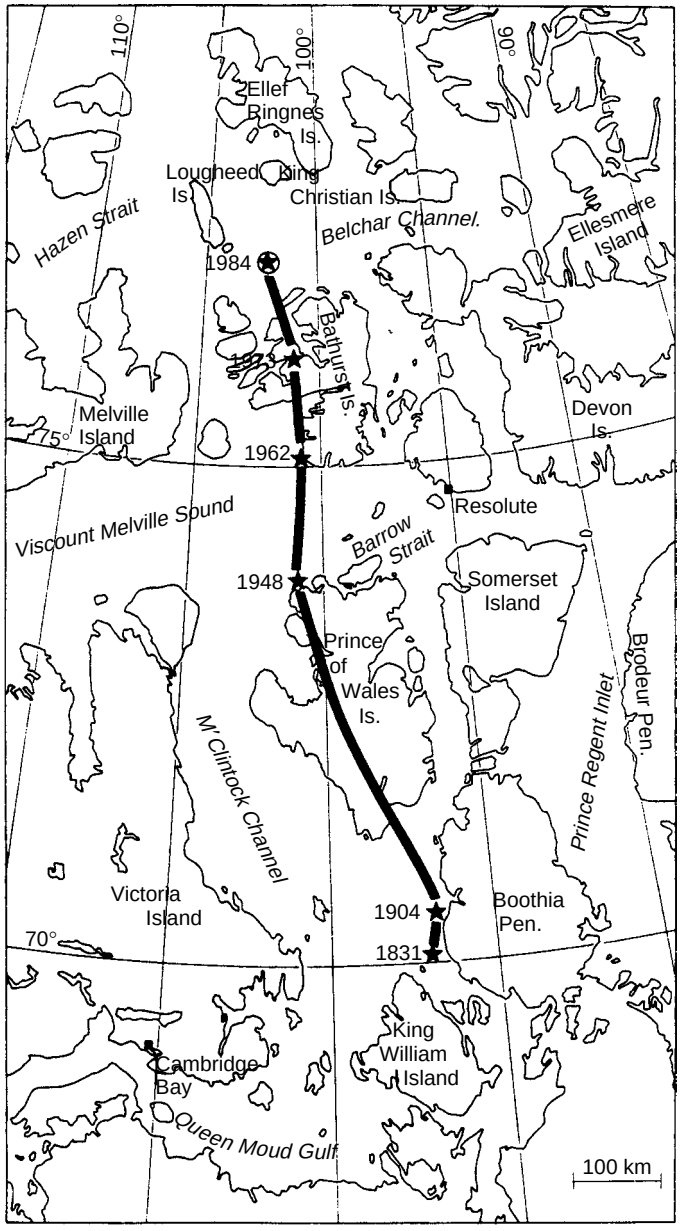

Fig. 10. Migration of the Earth's North Magnetic Pole in a northwesterly direction since first determined in 1831. In 1984, the pole was located at 77.0°N, 102.3°W off the southeast tip of Lougheed Island, Northwest Territories, Canada. The next official survey of the pole position will take place in 1994. Estimated position as of 1993 is 77.9°N, 103.2°W. (*Geological Survey of Canada, Geophysics Section, Ottawa, Ontario, Canada.*)

It is important to appreciate that when referring to the location of the pole, we are referring to an average position. The pole wanders daily in a roughly elliptical path around the *average position*, and may frequently be as much as 80 km away when magnetic conditions are disturbed.

Why Is the Pole Moving? If, as Gilbert believed, the Earth acts as a large magnet, the pole would not move, at least not as rapidly as it does. We now know that the cause of the Earth's magnetic field is much more complex and believe that it is produced by electrical currents that originate in the hot core of the planet.

In nature, processes are seldom simple. The flow of electric currents in the core is continually changing — so the magnetic field those currents produce also changes. Thus, at the surface of the Earth, both the strength and direction of the magnetic field will vary over the years. This gradual change is called the *secular variation* of the magnetic field.

The position of the North Magnetic Pole is strongly influenced by the secular variation in its vicinity. For example, if the dip is 90° at any given

* Prepared by L.R. Newitt and E.R. Niblett, Geological Survey of Canada, Geophysics Division, Ottawa, Ontario, Canada.

point this year, that point will be the pole by definition. However, because of secular variation, the dip at that point will change to 89°55′ in about two years and it will no longer be the pole. However, at some nearby point, the dip will have increased to 90° and that point will then be the pole. In this manner, the pole slowly moves across the Arctic.

The more rapid daily motion of the pole around its average position has an entirely different cause. If we record the Earth's magnetic field continually, as is done at a magnetic observatory, we will see that it changes continuously during the course of a day — sometimes slowly, sometimes rapidly. The ultimate cause of these fluctuations is the sun. The sun constantly emits charged particles which upon encountering the Earth's magnetic field cause electric currents to be produced in the upper atmosphere. These electric currents disturb the magnetic field, resulting in a shift in the pole's position. The distance and speed of these displacements will, of course, depend on the disturbances in the magnetic field, but they occur constantly. When scientists try to determine the average position of the pole, they must average out all of these transient wanderings.

Importance of the Pole. The reasons that the magnetic pole causes so much interest have changed with time. For Ross, the search for the pole was a byproduct of scientific nationalism. For Amundsen, it offered a good excuse to sail through the Northwest Passage. Today, we are interested in the pole as a tool for magnetic cartography.

To understand why it is important, we must recall magnetic declination is the angle between *true north* and the direction in which a compass needle will point, that is, *magnetic north*. Declination changes from one location to the next. For example, it is 21°E in Vancouver, B.C., but in Boston it is 16°W. A knowledge of magnet declination is extremely important for navigational purposes. Therefore, maps showing the magnetic declination are revised and published every 5 years. These maps show contour lines along which the magnetic declination is equal. All these lines converge on the magnetic pole — so if the position assigned to the pole is wrong, the entire pattern of magnetic contours in the Arctic regions would be wrong.

Earth's Magnetotail. The solar wind is a continuous flow of subatomic particles, emanating from the sun, into space. These particles cannot easily penetrate the earth's magnetic field and in the region of the earth, the particles stretch out several millions of kilometers, forming an approximately cylindrical volume which E.W. Hones, Jr. (Los Alamos National Laboratory) likens to a *huge wind sock*. More officially, it is called the *earth's magnetotail*. Hones observes that the solar wind and the earth's magnetosphere form a vast electrical generator — one in which the interaction of magnetic fields and plasma (gaseous part of solar wind) converts the kinetic energy of the solar wind's motion into electricity. The solar wind also has been the target of considerable research in connection with space probe studies of other planets, notably of Venus, Mars, Jupiter, and Saturn.

Research in recent years has shown that the electricity generated through conversion of energy in the solar wind accounts for a number of interesting phenomena that for many years remained mysterious. Of central interest has been the beautiful displays of the auroras (See also **Aurora and Airglow**). Another phenomenon is the presence of the Van Allen radiation belts which encircle the earth at altitudes of about 1000 and 6000 kilometers. (See also **Van Allen Radiation Belts**.) Another phenomenon is the presence of plasmoids, which have been described as bodies of hot plasma held together by magnetic fields. Satellite research has shown that plasmoids behave like projectiles, achieving speeds in terms of millions of kilometers per hour.

The earth's magnetosphere is defined as that region around the earth to which the earth's magnetic field is confined, due to interaction between the solar wind and the geomagnetic field. On the sunlit side, the magnetosphere is approximately hemispherical, with a radius of about ten Earth radii under quiet conditions. It may be compressed to about six Earth radii by magnetic storms. On the side opposite the sunlit side, the magnetosphere extends in a "tail" of several hundred Earth radii.

Although detailed description is beyond the scope of this encyclopedia, three interacting forces exist in the magnetotail. These have been succinctly described by Hones as the Lorentz force, the **E**-cross-**B** drift, and the **J**-cross-**B** force. The Lorentz force causes electrons and protons to move in circles in opposite directions, thus "tying" the particles to magnetic field lines. If an electric field is imposed perpendicular to the magnetic field, the charged particles acquire a further motion known as the **E**-cross-**B** drift. The drift carries the centers of the particle's circular paths in a direction perpendicular to the directions of the field and thus plasma in the lobes of the magnetotail is driven toward the plasma sheet. Finally, plasma carrying an electric current that flows perpendicular to a magnetic field experiences a **J**-cross-**B** force. This force accelerates the plasma in a direction perpendicular to both the direction of the current and that of the magnetic field. This distorts the original field, bending the field lines in the direction opposite to that of the force. The **J**-cross-**B** force resisting the flow of solar-wind plasma distorts the earth's magnetic field, thus producing the magnetotail. See also **Magnetism**; and **Sun (The)**.

Geomagnetic Anomalies. As previously mentioned, apparently the geomagnetic generator in the Earth's core is a mechanism (process) that does not operate with the precision and predictability associated with human-engineered electric power generators, as witnessed by the meandering North Magnetic Pole, by historically reported reversals of the geomagnetic field, and by specific situations such as the frequently mentioned East Coast Magnetic Anomaly. These anomalies (departures, abnormalities) do not all arise, of course, from some unsteadiness on the part of the core dynamo, but also from solar influences, as previously mentioned, and from underlying structures in the crust, lithosphere, and other layers of the Earth's interior, i.e., the mantles and possibly the outer core.

Scientists who have investigated magnetism recorded in a sequence of lava flows at Steens Mountain (Oregon) speculate that a reversal of the geomagnetic field occurred some 15 million years ago. Data indicate that the switch was from a reverse field to what is now considered the normal field (magnetic and geographical north being in the same direction). Investigators estimate that the North Magnetic Pole followed a convoluted path for nearly 15,000 years.

Still subject to some debate, scientists at the University of Paris reported in 1978 that the Earth's magnetic field had "shivered" or "jerked" in the late 1960s. There is agreement that the westward drift over Europe speeded up abruptly in 1969. As presently organized, data from magnetic observatories are considered inadequate. Most observatories are located in the Northern Hemisphere. Wide areas of the Pacific and Southern Hemisphere are not covered. Frequently data detected in Europe may not be evidenced in North America. No really profound explanations have been given for the 1969 instant; nor for another which some scientists believe occurred in 1912. Most geophysicists agree that a satellite or a series of satellites may be the only practical solutions to magnetic data problems.

Magnetotactic Bacteria. Several species of magnetotactic bacteria, as reported by Frankel, et al., have been observed in aquatic sediments of the Northern and Southern Hemispheres. Each bacterium contains magnetosomes consisting of enveloped, single-domain magnetite particles. The magnetosomes are often arranged in chains with a magnetic dipole moment parallel to the axis of motility sufficiently large that the cell is oriented along the geomagnetic field lines as it swims. Cells with North-seeking pole forward swim North along the magnetic field lines; the opposite occurs in cells with the South-seeking pole forward. Because of the inclination of the geomagnetic field, North-seeking cells migrate downward in the North Hemisphere and upward in the Southern Hemisphere. Magnetotactic bacteria are present in fresh water and marine sediments of Fortaleza, Brazil, situated close to the geomagnetic equator and, not surprisingly, are found roughly in equal numbers in samples taken.

Geodesy

Geodesy is principally concerned with the size and shape of the Earth and its gravitational field (from a practical and application standpoint rather than theoretical). Key geodetic parameters of the Earth are given in Table 2. The first recorded effort to estimate the circumference of the Earth dates back to Eratosthenes of Alexandria in the 3rd century B.C. Eratosthenes observed that the sun was overhead at Aswan at mid-summer because it shone directly down a well, but in Alexandria, it was 7.2° or $\frac{1}{50}$th of a circle away from the vertical. The distance between Aswan and Alexandria was calculated by estimating the time required by a camel to traverse the distance. The calculation was amazingly correct — within 1% of the currently accepted value. This was an example of space geodesy, i.e., using the sun as the reference object, a technique that surfaced again after the launching of the first artificial satellite, Sputnik, in 1957.

The Geoid. Because of the rotation of the Earth, its lack of absolute rigidity, crustial mass distribution, and tidal forces, the shape is not perfectly spherical, but approximates that of a triaxial ellipsoid. There is flattening at the poles (polar diameter is shorter than the equatorial). The actual figure of the Earth, which is irregular (not just at the poles) is referred

TABLE 2. GEODETIC PARAMETERS OF THE EARTH

Parameter	Standard Value	Current Estimate and Standard Deviation
Mean sidereal rotation rate, ω	$0.7292115085 \times 10^{-4}$ sec^{-1}	$0.729115085 \times 10^{-4}$ sec^{-1}
Equatorial gravity, γe	9.780490 m/sec^2	$9.780306 \pm .000013$ m/sec^2
Equatorial radius, a	6378388 m	6378160 ± 15 m
Flattening, f	$1/298.25 \pm .03$	$1/298.25 \pm .03$

to as *the geoid*. See Fig. 11. The largest departure of the actual geoid from the reference geoid (mapped) occurs in a depression of approximately 113 meters (371 feet) south of India. Off New Guinea, the highest hump occurs, about 81 meters (266 feet). There are two other significant humps, one located south of the British Isles and about 61 meters (200 feet) high; and the other hump located south of Madagascar and about 56 meters (184 feet) high.

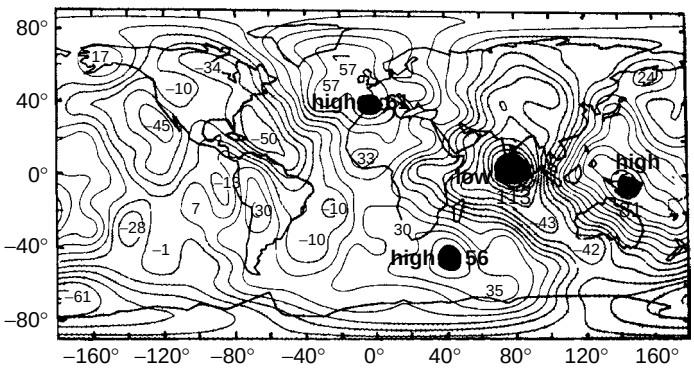

Fig. 11. In 1970, the Smithsonian Institute released what became known as the Smithsonian Standard Earth II. Preparation of the contours shown represented many years of work, using cameras and gravimetric surveys, as well as the first results of measurements by laser tracking of satellites. Over 100,000 photographic observations became part of the data bank. Calculations involved some 200,000 simultaneous equations, solving for about 400 unknowns. These included nearly 300 harmonic coefficients and the station coordinates. This map shows contours of the geoid at 10-meter (32.8-foot) intervals, which are relative to a reference spheroid of flattening 1 part in 198.25. Depressions are shaded areas. The three largest highs and the principal low are indicated. See test. (*After Smithsonian Institution map.*)

In constructing the dimensions of the geoid, one is not concerned with the regular physiographic features of the Earth — mountains, ocean basin, etc. The concern is the shape of the mean sea-level surface, continued under the land in a logical fashion. This surface is exclusively defined by measuring the variations of the Earth's gravitational attraction, both with latitude and longitude. To this must be added the acceleration produced by the earth's rotation. Bomford (1971) defines the geoid as "an equipotential surface of the Earth's gravitational potential plus the rotational potential." The geoid is the basic reference shape on which the Earth's topography (height above sea level) is superposed.

There is a dual relationship between the geoid and orbiting satellites. As pointed out by King-Hele (1976), one effect of the Earth's flattening on a satellite orbit is to make the plane of the orbit rotate about the Earth's axis in the direction opposite to the satellite's motion, while leaving the orbit inclined at the same angle to the equator. See Fig. 12. As further explained by King-Hele, the most helpful way of analyzing the shape of the geoid is to assume that if it made up of an infinite number of harmonics, the second harmonic defining the flattening, the third harmonic often being called pear-shaped, the fourth harmonic square-shaped, etc. See Fig. 13. Shapes of these kinds would be obtained if one sliced the Earth through the poles if only one particular harmonic existed. But, in fact, all harmonics exist. Thus the procedure is one of calculating them separately and then putting them together to yield the final shape.

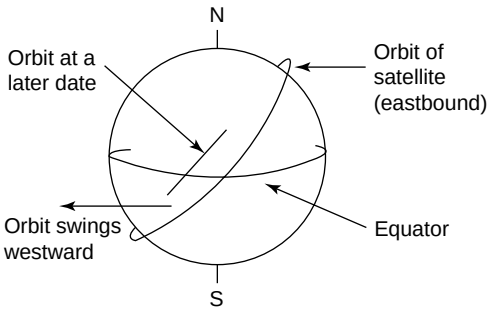

Fig. 12. Gravitational pull of the Earth's equatorial bulge causes orbital plane of an eastbound satellite to swing westward. (*After King-Hele.*)

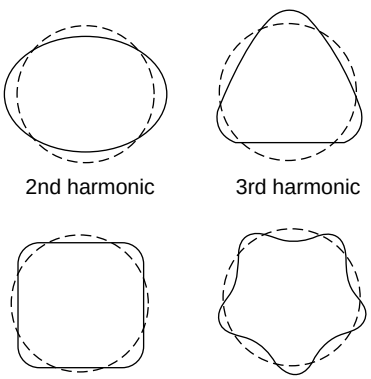

Fig. 13. Harmonics defining the characteristics of the geoid. There are many more harmonics. (*After King-Hele.*)

Laser tracking of satellite has been used for a number of years in making observations for determining the geoid, but these methods have been greatly improved since the mid-1970s. A satellite with corner reflectors was put in orbit in 1965 and followed by a number of like satellites for laser tracking. One method of investigation is to consider the satellite as points in the sky for geometrical triangulation; the other method analyzes the effect of the Earth's gravitational attraction on satellite orbits, thus determining how gravity changes over the Earth. The earlier satellites were in the *Beacon* and the *Lageos* series. The first of the *Magsat* (Magnetic Field Satellite), jointly sponsored by the National Aeronautics and Space Administration (NASA) and the U.S. Geological Survey was launched in October 1979. This was designed as a pole-crossing satellite with a range from 350 to 500 kilometers (217 to 311 miles) with an expected life of about 120 days.

One may ask, why is it so important to accurately determine the shape of the geoid? The effect of the gravitational pull of the Earth's equatorial bulge and other irregularities affect the orbit of an artificial satellite. But why were these humps and depressions important prior to the satellite age? For one thing, it has been determined that these humps and depressions tend to migrate with time and undoubtedly are related to migrations of the magnetic poles. (It has not been determined which is the cause and which is the effect.) With greater accuracies of measurement obtainable, as from Doppler radar and laser methods, satellite geodesy is making and will continue to impact all of the Earth sciences. This knowledge will assist in making crucial tests of theories about the Earth's interior, with some aspects of tectonic plate maps already being reflected in geoid mappings. Further, patterns of convection currents or density irregularities within the Earth will have to be meshed with the observed gravitational field. Combined with satellite altimeter measurements, gravitational field determinations will provide an accurate profile of the geoid surface, including earth tides and ocean tides. More knowledge of the polar motion (locus of the point where the earth's axis of rotation cuts the surface) most likely will also be obtained from this line of research. This knowledge may also assist in refining present theories of the Earth's magnetism and provide more plausible explanations of how the Earth's magnetic field is created in the first place.

The measured values of gravity depend on latitude because of the flattening and the variation of the centrifugal force from pole to equator. The normal value of gravity at the Earth's surface in centimeters per second

per second is represented by

$$\gamma = 978.0516[1 + 0.005291 \sin^2 \phi - 0.0000057 \sin^2 2\phi$$
$$+ 0.0000 \cos^2 \phi \cos 2(\lambda + 6^\circ)]$$

where ϕ and λ are latitude and longitude, respectively.

Gravity measurements have shown that in spite of large mass difference at the surface, the Earth is nearly in isostatic equilibrium. Various crustal blocks act as if they floated in a dense subcrustal material. The undulations of the geoid do not exceed 80 meters. Approximate dimensional figures for the Earth are: surface area, 510.1×10^6 square kilometers; volume 1.083×10^9 cubic kilometers; average density 5.517 grams per cubic centimeter; mass; 5.975×10^{27} grams; equatorial radius, 6.378 388 kilometers.

The deformation of the solid Earth by tidal forces form a specialty. The twice-daily occurring tides are observed by deflections of the vertical or variations of gravity. For the lunar tide, the variations amount to about 0.168 milligal; for the sun, up to 0.075 milligal. (One milligal equals 10 micrometers per second per second.) The maximal elevation of the geoid is 36 centimeters, the largest depression 18 centimeters, for the lunar effect; the total solar tide can reach 25 centimeters. The combined total at new and full moon is 79 centimeters.

There are five principal systems of measurement in geodesy:

(1) *Horizontal control* comprises the determination of the horizontal components of position — latitude and longitude — starting from fixed values for a certain point. It includes measurement of distances over the ground by metal tapes or by pulsing or modulating radio or light signals, and measurement of angles about a vertical axis by theodolites. Over the land, the relative horizontal position of points is obtained either by triangulation — a system of overlapping triangles with nearly all angles measured, but only occasional distances measured; or by traverse — a series of measured distances at measured angles with respect to each other; or by trilateration — a system of overlapping triangles with all sides measured. Much of the land area of the world is covered by triangulation, which gives the difference in latitude and longitude between points in the same network with a relative error of about 10^{-5}.

(2) *Vertical control* comprises the determination of heights, which is performed separately from horizontal control because of irregularities in atmosphere refraction. The most accurate method, leveling, measures successive differences of elevation on vertical staffs by horizontal lines of sight taken at intermediate points over short distances (less than 150 meters) balanced so as to minimize differential refraction effect. The datum to which vertical control refers is mean sea level as determined by tide gages. The accuracy is such that the error in difference of elevation between points on the same principal network should be a few tens of centimeters or less.

(3) *Geodetic astronomy* comprises the determination of the direction of the gravity vector and the direction of the north pole at a point on the ground. Astronomic longitude is the angle between the meridian of the gravity vector and the Greenwich meridian and is determined by measuring the time of intersection of a line of sight by a star. In these types of astronomic observation, several stars are normally observed which are selected so as to minimize error due to atmospheric refraction. Astronomic azimuth is determined by the measurement of the horizontal angle between a target and Polaris or other reference star.

(4) *Gravimetry* comprises the determination of intensity of gravitational acceleration. Most gravimetric observations are made differentially, by determining the change, with change in location, of the tension on a spring supporting a constant mass. These measurements are connected through a system of reference stations to a few laboratory determinations of absolute acceleration of gravity. The relative accuracy of gravimetry is about ± 0.001 centimeters per second squared on land and ± 0.005 centimeters per second squared at sea. The principal difficulty in its geodetic application is irregular distribution of observations.

(5) *Satellite tracking* comprises the determination of the directions, ranges, or range rates of Earth satellites from ground fixed stations. These observations will be affected both by errors in positions of the station with respect to the Earth's center of mass and by perturbations of the orbit by the Earth's gravitational field; hence, in conjunction with a suitable dynamical theory for the orbit, they are used to determine the position of tracking stations and the variations of the gravitational field. To minimize refraction effect, directions are determined by photographs of the satellite against the background of fixed stars. Satellites also can be used as elevated targets by simultaneous observations from several ground stations.

The principal practical application of geodesy is to provide a distribution of accurately measured points to which to refer mapping, navigation aids, engineering surveys, geophysical surveys, and so on. The principal scientific interest in geodesy is the indication of the Earth's internal structure by the variations in the gravity field.

Meteorology and Aeronomy

These fields are concerned with the physical state and the motions of the atmosphere, which is divided into a number of layers. The lowest is the troposphere with an average thickness of 7 to 8 kilometers in polar regions and 13 kilometers in the equatorial zone. Temperatures decrease to the interface, called tropopause, with the next layer the stratosphere. At the tropopause, polar temperatures average around $-55\,^\circ$C; in equatorial regions, $-80\,^\circ$C. In the stratosphere, temperatures stay nearly isothermal with height and increase again above 25 kilometers. Above the stratosphere are the mesosphere and ionosphere, and the outermost layer, the exosphere, gradually fades into the plasma continuum between earth and sun. In these higher layers of the atmosphere, complex interactions between the fluxes of electromagnetic radiation of various wavelengths and corpuscular radiation from the sun on one side and the low-density concentrations of atmospheric gases on the other side take place. The particulate radiations are also governed by the Earth's magnetic field. Radiations of short wavelength cause a variety of photochemical reactions, the most notable of which is the creation of a layer of ozone acting as an effective absorber of solar ultraviolet and thus causing a warm layer at 30 kilometers in the atmosphere sphere. The upper atmosphere as an absorber of primary cosmic rays shows many interesting nuclear reactions and is an important natural source of radioactive substances, including tritium and carbon 14 which are used as tracers of atmospheric motions and as a criteria of age.

Most manifestations of weather take place in the troposphere. They are governed by the general atmospheric circulation which is stimulated by the differential heating between tropical and polar zones. The resulting motions in the air are subject to the laws of fluid dynamics on a rotating sphere with friction. They are characterized by turbulence of varying time and space scale. Evaporation of water from the ocean and its transformation through the vapor state to droplets and ice crystals, forming clouds and precipitation, are important symptoms of the weather-producing forces. See also **Atmosphere (Earth)**; and **Meteorology**.

Geology and Mineralogy

Much of the scientific information pertaining to the Earth has been derived from the investigations of geologists and mineralogists over the years. Both geology and mineralogy are old, well established scientific fields, but generally are not included in delineations of geophysics. This illustrates the overlapping of fields of scientific interests that will continue as more and more knowledge of the earth and the cosmos is collected. The more established fields expand their spheres of interest, whereas some of the newer specializations encroach upon the older fields. An interesting, fine distinction between geophysics and geology is noted the "Glossary of Geology" (American Geological Institute). The definition of geology commences, "Geology — study of the planet Earth." The definition of geophysics commences, "Geophysics — study of the Earth as a planet." Mineralogy, of course, is the study of minerals, their formation, and occurrence. See also **Geology**; and **Mineralogy**.

Geochemistry

Goldschmidt (1954) defined geochemistry as the study of the distribution and amounts of the chemical elements in minerals, ores, rocks, soils, water, and the atmosphere, and the study of the circulation of the elements in nature, on the basis of the properties of their atoms and ions; also, the study of the distribution and abundance of isotopes, including problems of nuclear frequency and stability in the universe. A more succinct definition would be that geochemistry is the study of the chemical constitution of the Earth and its chemical changes, either taking place now or having taken place.

Many inferences about the nature and composition of the different zones of the Earth are speculative to varying degrees because of the inaccessibility of the interior and because of the differentiated nature of the Earth. The overall composition may be deduced from spectroscopic evaluation of solar and stellar radiation, from nuclear chemical and astronomical theories of the origin of the elements and the evolution of the solar system, and from analytical study of the meteorites.

Oceanography

Several major articles in this encyclopedia are devoted to this important phase of the earth sciences. See **Ocean** and the articles which follow. Also, consult alphabetical index.

Selected Parameters and Characteristics of the Earth

GLOBAL CHANGE: THE CONCEPT

Prolog. "Global change" is a phrase generally used to connote some form of degradation of the Earth's atmosphere, land surface, and hydrosphere which may result from human actions and disregard. Thus, depending upon what geobiological, geochemical, or geophysical consequence of the moment may be, global change will suggest numerous other phrases. Among these are air pollution, acid rain, smog, greenhouse effect, ozone layer depletion, water pollution, waste disposal, biodegradability, product recycling, environmental protection, population pressure, famine, species

TABLE 3. PARAMETERS OF THE PLANET EARTH

Geometric

	Metric Units	English Units
Mass	5.9763×10^{27} grams (1/331950 mass of sun)	6 sextillion, 588 quintillion short tons
Volume	1083.1579×10^{9} km^3	259.8 bil cu mi
Surface Area	510.0501×10^{6} km^2	196,950,711 sq mi
Mean Radius	6370.949 km	3958.7 mi
Length of Equator	40,075.16 km	24,901.6 mi
Length of Meridian	40,008 km	24,860.0 mi
Distance from Sun	149,599,000 km	92,956.5 mi
Distance from Moon	356,410 to 406,697 km	221,463 to 252,710 mi
Length:		
Degree of Longitude of Equator*	111.324 km	69.173 mi
Degree of Latitude at Equator	110.551 km	68.693 mi

Magnetic North Pole (See Fig. 8)	77.0 °N; 102.3 °W (1987)	

Axis and Rotation

Tilt of Earth's Axis away from Perpendicular or Orbit	23°27′
Period of Rotation on its Axis:	
Mean Solar Day	24 hours
Mean Sidereal Day	23 hours, 56 minutes, 4.091 seconds of mean solar time
Period of Revolution about the Sun Tropical Year	365 days, 5 hours, 48 minutes, 46 seconds (decreasing at rate of 0.530 second per century)

Variations in Rotation of the Earth

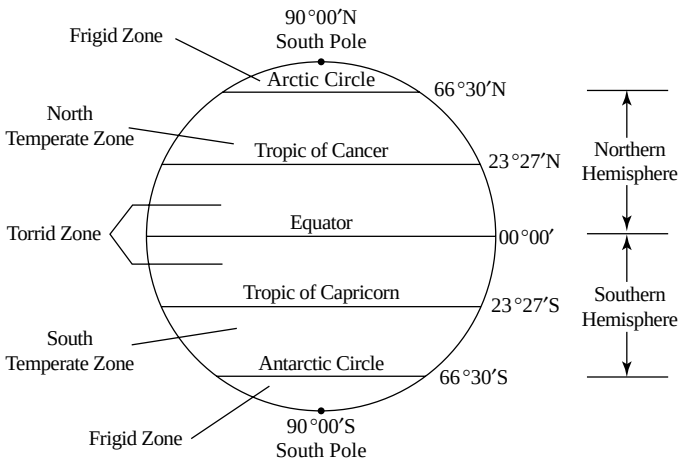
Secular — A slow secular increase in the length of the day (about 1 millisecond per century) is caused by tidal friction acting as a brake.

Irregular — Believed to be caused by turbulent motion in the core of the Earth, the speed of rotation may increase for a short period, such as 5 to 10 years, and then commence decreasing. During a century, the maximum difference from the mean in the length of a day is about 5 milliseconds. Since 1900, the accumulated *difference* (although a compensating effect) has amounted to approximately 40 seconds.

Periodic — There are seasonal variations with periods of 1 year and 6 months. The resulting cumulative effect is that each year the Earth is late about 30 milliseconds near June 1 and is ahead that same amount near October. It is believed that the semi-annual effect arises from tidal action of the sun, which distorts the shape of the Earth slightly. The maximum seasonal variation in length of the day is about 0.5 millisecond. This annual effect is probably due to the seasonal change in the wind patterns of the Northern and Southern Hemispheres.

Zonal Points and Parallels

		Latitude	
	North Pole	90°00′N	
Frigid Zone			
	Arctic Circle	66°30′N[a]	Northern Hemisphere
North Temperate Zone			
	Tropic of Cancer	23°27′N	
Torrid Zone	Equator	00°00′	
	Tropic of Capricorn	23°27′S	Southern Hemisphere
South Temperate Zone			
	Antarctic Circle	66°30′S[a]	
Frigid Zone			
	South Pole	90°00′S	



*Varies as the cosine of the latitude.

[a] Commonly defined as 23°30′ from the respective pole.

TABLE 4. MAJOR PHYSICAL FEATURES OF THE PLANET EARTH

Continents

Dimensions of Continents

Continent	Area km²	Area mi²	Dimensions: North to South km	North to South mi	East to West km	East to West mi
Asia, including islands	44,750,000	17,276,909	8528	5300	9654	6000
Africa	30,280,000	11,688,728	8045	5000	7652	4700
North America, including islands	24,260,000	9,368,446	8528	5300	6436	4000
South America	18,050,000	6,970,760	7642	4750	4988	3100
Antarctica	13,380,000	5,165,000	—	—	—	—
Europe	10,220,000	3,947,441	3862	2400	6275	3900
Australia	8,530,000	3,294,866	3170	1970	3862	2400

Highest Continental Points

	Elevation above Sea Level	
Asia — Mount Everest, Nepal-Tibet*	8,847.7 m	(29,028 ft)
South America — Mount Aconcagua, Argentina	6,959.8 m	(22,834 ft)
North America — Mount McKinley (U.S.A.)	6,193.5 m	(20,320 ft)
Africa — Kibo (Kilimanjaro), Tanzania	5,894.8 m	(19,340 ft)
Europe — Mount El'brus (U.S.S.R.)	5,641.8 m	(18,510 ft)
Antarctica, Vinson Massif	4,138.9 m	(16,860 ft)
Australia, Mount Kosciusko	2,228 m	(7,310 ft)

Lowest Continental Points

	Depth below Sea Level	
Asia — Dead Sea, Israel-Jordan	395.9 m	(1,299 ft)
Africa — Lake Assal, Djibouti	156.1 m	(512 ft)
North America — Death Valley (U.S.A.)	86 m	(282 ft)
South America — Salinas Grandes, Peninsula Valdés, Argentina	39.9 m	(131 ft)
Europe — Caspian Sea (U.S.S.R.)	28 m	(92 ft)
Australia — Lake Eyre	15.9 m	(52 ft)

*Based upon Surveyor General of the Republic of India (1954); ±3 m (10 ft) because of snow. Concern has been expressed in recent years that another peak, K2, in the Himalayas may be slightly higher than Mt. Everest.

Economic Areas

Deserts	12.7×10^6 km²	(4,904,593 mi²)

and biodiversity endangerment, deforestation, light pollution, noise pollution, toxic and nuclear wastes, fossil fuels, carcinogenicity, nuclear proliferation, and numerous other practices that do or that ultimately will affect the planet Earth and the life which it supports.

The term "global change" generally embraces those deleterious effects which arise from the life-styles and industrial pursuits of humankind, rather than the threatening effects which stem from purely natural causes that are not humanly manipulated. Some of these causes include leakage of petroleum into the oceans at subterranian depths, fouling of the atmosphere by ejecta from active volcanoes, and the introduction of massive volumes of carbon dioxide and other greenhouse gases from "inactive" volcanoes, not to mention large amounts of CO_2 created by the natural metabolisms of mammals, insects, and other living species.

Society's concern with pollution dates back at least to the period of the industrial revolution which commenced in England in the mid-1800s, when steam-powered machinery was introduced, serving at least as a partial replacement of horse and human muscle power. Abhorrence of human disregard for the Earth's clean air was well portrayed by Charles Dickens in his novel, Hard Times.[1] Later, other writers (Sandburg, Munford, et al.)

[1] Dickens, an early social reformer, observed, "(Coketown) was a town of red brick, or of brick that would have been red if the smoke and ashes had allowed it; but as matters stood it was a town of unnatural red and black like the painted face of a savage. It was a town of machinery and tall chimneys, out of which interminable serpents of smoke trailed themselves for ever and ever, and never

1977	Bucharest, Rumania	1,540	
1978	Eastern Iran	25,000	
1980	Italy (Naples Region)	2,735	7.2
1980	Algeria (Northwest)	4,500	7.5
1983	Colombia (Southern)	250	5.5
1983	Turkey (Eastern)	1,300	7.1
1985	Chile	146	7.8
1985	Mexico City and Coastal States	25,000	8.1
1987	Whittier Narrows, California	0	5.9
1988	Armenia (Most damage caused by after shock of 5.8)	25,000	6.9
1989	Loma Prieta (Near San Francisco)	67	7.1
1990	Iran (Northwest near Caspian Sea)	110,000	7.7
1990	Luzon Island (Philippines)	1,600	7.7
1991	Afghanistan (Northern "Hindu Kush" Region)	400	6.8
1992	Landers, California	0	

Note: What constitutes a major earthquake? The number of human fatalities usually is a major criterion, but does not correlate necessarily with magnitude because some very strong earthquakes occur in sparsely populated areas, not in heavy population centers. Often, there is no correlation between lives lost and scientific interest. Property damage frequently is better correlated with building and housing construction than with the magnitude of an earthquake. This also pertains to lives lost because the majority of earthquake deaths result from falling construction materials that kill and injure (and even bury and suffocate) victims.

wrote of the veiled threats of industrialization, but mainly from a societal viewpoint rather than in terms of the direct effects, difficulty reversible, that were injuring the well being of the planet per se. Many years passed before a few forward-looking scientists warned of the long-term effects of Earth abuse. The scientific community, however, acted slowly. Within the last score of years, scientists have addressed a number of factors that are determining global change. In parallel, numerous advocacy groups were formed, each with specific agendas — "Save the Air," "Save the Fishes," "Save the Forests," and the like. Although such groups contributed to awareness, the tendency was that of developing a very mixed menu of objectives, seriously lacking any coordination.

Thus, until very recently, the problems of global change have been addressed in a partial, fragmented manner. That is why the Global Change Research Program, proposed by the National Aeronautics and Space Administration (U.S.) and announced in 1992, is a welcome first step toward conducting a concerted effort in the field.[2]

The NASA Global Change Research Program (GCRP). The overall objective of the NASA plan is that of gaining predictive understanding of the interactive physical, geological, chemical, biological, and social processes that regulate the total Earth system. Participants of the GRCP include NASA, the National Oceanographic and Atmospheric Administration (NOAA), the U.S. Departments of Energy, Defense, Agriculture, and the Interior, the Environmental Protection Agency, the National Science Foundation, and the Smithsonian Institution. Agencies from advanced foreign countries also will participate in some of the projects. Such participants include the World Meteorological Organization, the United Nations Environmental Program, the Inter-governmental Oceanographic Commission, and complementary Canadian, European, and Japanese Earth observing missions.

In total, the program is referred to as "Mission to Planet Earth." Some details of the program delineated in Figs. 14 and 15, include: extensive use of polar, geosynchronous, and other unmanned satellites equipped with a variety of the most advanced sensors, such as the cryogenic limb array Etalon spectrometer, which operates in the 3.5–12.7 microwave spectrum for determining thermal emissions from atmospheric water vapor, methane, ozone, nitrogen oxides, and chlorofluorocarbons; the advanced stratospheric and mesospheric sounder which operates in the 4.6–16.6 micrometer bands for determining nitrogen compounds; the halogen occultation instrument which operates at the 2.43–10.25 micrometer range for measuring vertical distribution of hydrofluoric and hydrochloric acids, methane, ozone, water vapor, and nitrogen compounds; the high-resolution Doppler imager, which observes emission lines of neutral and ionized atomic oxygen in the visible and near-infrared regions at altitudes above 15 km (9.3 mi); and a wind imaging interferometer that uses a high-resolution Michelson interferometer and detector array for measuring Doppler shifts in the emission lines of neutral and ionized atomic oxygen, two lines in the OH molecule, and a molecular oxygen line.

Further details of the GCRP are given in other articles throughout this Encyclopedia. In particular, reference is made to **Satellites (Scientific and Reconnaissance)** and **Atmosphere (Earth)**. Also check Alphabetical Index.

got uncoiled. It had a black canal in it, and a river that ran purple with ill-smelling dye, and vast piles of buildings full of windows where there was a rattling and a trembling all day long, and where the piston of the steam engine worked monotonously up and down like the head of an elephant in a state of melancholy madness."

[2] It is only fair, however, to report that a lot of progress, although not well coordinated, has been made to ameliorate several causes of global change in recent years. One needs only to compare the improved conditions in several of the advanced countries with the photographs of damage caused by careless, uncontrolled polluters in the former Soviet block.

TABLE 8. REPRESENTATIVE MAJOR VOLCANOES AND ERUPTIONS

Eruptions

7000 B.C.	Mazama (now Crater Lake, California)	1976	White Island Volcano, New Zealand
79 A.D.	Mt. Vesuvius, Italy (also 1139, 1631, 1779, 1793, 1872, 1906, 1944)	1978	Poas, Costa Rica
		1978	Etna, Italy (over 70 eruptions in 2000 years)
1815	Tambora, Indonesia (also 1913)	1978	Arboukaba, Djibouti
1883	Krakatau, Netherlands East Indies	1979	Fuego, Guatemala
1902	Santa Maria, Guatemala	1979	Soufrière, St. Vincent
1902	Mt. Pelée, Martinique	1979	Karkar, Papua New Guinea
1912	Katmai, Alaska	1979	Mt. Sinila, Java
1914/1917	Lassen Peak, California	1980	Mt. St. Helens, Washington (over 20 eruptions since 1900 B.C.)
1964	Mt. Agung, Bali	1983	El Chichón, Mexico
1964	Huascaran, Peru	1985	Nevado del Ruiz, Colombia
1968	Mt. Batur, Bali	1991	Mt. Unzen, Japan
1976	St. Augustine, Alaska (also 1812, 1883, 1902, 1935, 1963–1964)	1991	Mt. Pinatubo, Philippines

Major Active and Inactive Volcanoes (Abridged List)

Name of Volcano	Location	Elevation		Name of Volcano	Location	Elevation	
		Meters	Feet			Meters	Feet
Asia—Oceania				Westdahl (1978)	Aleutians (U.S.)	1,532	5,026

Africa							
Kilimanjaro	Tanzania	5,895	19,341				
Cameroon	Cameroons	4,070	13,354				

Note: Volcanoes listed with no dates within parentheses have been inactive for several decades.
*Prior to May 18, 1980 eruption, elevation was 2,950 meters (9,677 feet).

TABLE 9. CHEMICAL COMPOSITION OF EARTH'S CRUST, OCEANS, AND ATMOSPHERE

Average Density	5.517 grams/cm^3
Estimated Density of Mantle	3–6 grams/cm^3
Estimated Density of Core	10–17 grams/cm^3

Occurrence of Elements in Earth's Crust

Element	%	Element	%	Element	%
Oxygen	47.	Sodium	2.5	Sulfur	0.1
Silicon	28.0	Potassium	2.5	Nickle	0.02
Aluminum	8.0	Titanium	0.4	Copper	0.002
Iron	4.5	Hydrogen	0.2	Lead and Zinc	0.001
Calcium	3.5	Carbon	0.2	Tin	0.00001
Magnesium	2.5	Phosphorus	0.1	Silver	0.000001
				All others	<0.48

Average Percentage of Metals in Igneous Rocks

Metal	%	Metal	%	Metal	%
Silicon	27.72	Copper	0.010	Niobium and Tantalum	0.003
Aluminum	8.13	Tungsten	0.005		
Iron	5.01	Lithium	0.004	Hafnium	0.003
Calcium	3.63	Zinc	0.004	Thorium	0.002
Sodium	2.85	Chromium	0.037	Lead	<0.002
Potassium	2.60	Zirconium	0.026	Cobalt	0.001
Titanium	0.63	Nickel	0.020	Beryllium	0.001
Manganese	0.10	Vanadium	0.017	Strontium	<0.001
Barium	0.05	Rare earths	0.015	Uranium	<0.001

Average Salt Content of Ocean Water 3.5% (wt)

	(Of Total Salts)
Sodium chloride NaCl	77.76%
Magnesium chloride $MgCl_2$	10.88
Magnesium sulfate $MgSO_4$	4.74
Calcium sulfate $CaSO_4$	3.60
Potassium sulfate K_2SO_4	2.46
Magnesium bromide $MgBr_2$	0.22
Calcium carbonate $CaCO_3$	0.34

Composition of the Atmosphere

Element	% (vol)
Nitrogen	78.03
Oxygen	20.99
Argon	<0.94
Carbon dioxide	0.03
Hydrogen	0.01
Neon	0.00123
Helium	0.004
Krypton	0.00005
Xenon	0.000006

EARTH AXIS. Any one of a set of mutually perpendicular reference axes established with the upright axis (the Z-axis) pointing to the center of the Earth, used in describing the position or performance of an aircraft or other body in flight. The Earth axes may remain fixed or may move with the aircraft or other object.

EARTH CURRENT. A large-scale surge of electric charge within the Earth's crust, associated with a disturbance of the ionosphere. Current patterns of quasi-circular form and extending over areas the size of whole

continents have been identified and are known to be closely related to solar-induced variations in the extreme upper atmosphere.

EARTHLIGHT. The illumination of the dark part of the moon's disk produced by sunlight reflected onto the moon from the Earth's surface and atmosphere. Also called *earthshine*. Spectroscopic observations reveal that earthlight is relatively richer in blue light than is direct sunlight; this condition results from the fact that an appreciable part of the total Earth reflection is backward-scattered light which, in accordance with Rayleigh law, is relatively rich in the blue and poor in the red.

EARTHMOVING EQUIPMENT. See **Coal**.

EARTH OBSERVING-1 (NMP EO-1) MISSION. See **Earth Observing System (EOS); New Millennium Program**; and **Space Science Missions: Sun**.

EARTH OBSERVING SYSTEM (EOS). The Earth Observing System (EOS) is a major component of NASA's Earth-Sun System Missions. The mission includes a series of satellites, a science component, and a data system supporting a coordinated series of polar-orbiting and low inclination satellites for long-term global observations of the land surface, biosphere, solid Earth, atmosphere, and oceans. EOS is enabling an improved understanding of the Earth as an integrated system. The EOS Project Science Office (EOSPSO) is committed to bringing program information and resources to program scientists and the general public alike.

Since its creation in 1958, NASA has been studying the Earth and its changing environment by observing the atmosphere, oceans, land, ice, and snow, and their influence on climate and weather. We now realize that the key to gaining a better understanding of the global environment is exploring how the Earth's systems of air, land, water, and life interact with each other. This approach — called Earth System Science — blends together fields like meteorology, oceanography, biology, and atmospheric science.

In 1991, NASA launched a more comprehensive program to study the Earth as an environmental system, now called the Earth Science Enterprise. By using satellites and other tools to intensively study the Earth, we hope to expand our understanding of how natural processes affect us, and how we might be affecting them. Such studies will yield improved weather forecasts, tools for managing agriculture and forests, information for fishermen and local planners, and, eventually, the ability to predict how the climate will change in the future.

The Earth Science Enterprise has three main components: a series of Earth-observing satellites, an advanced data system, and teams of scientists who will study the data. Key areas of study include clouds; water and energy cycles; oceans; chemistry of the atmosphere; land surface; water and ecosystem processes; glaciers and polar ice sheets; and the solid Earth.

Phase I of the Earth Science Enterprise was comprised of focused, free-flying satellites, Space Shuttle missions, and various airborne and ground-based studies. Phase II began in December of 1999 with the launch of the first Earth Observing System (EOS) satellite Terra (formerly AM-1). EOS is the first observing system to offer integrated measurements of the Earth's processes. It consists of a science component and a data system supporting a coordinated series of polar-orbiting and low-inclination satellites for long-term global observations of the land surface, biosphere, solid Earth, atmosphere, and oceans. NASA has initiated an era of unprecedented observational capability for understanding the planet.

Just as the first weather and communications satellites fundamentally changed our way of thinking about those fields, so the elements of the Earth Science Enterprise will expand our perspective of the global environment and climate. Working together with our partners around the world, NASA is on the way to improving our knowledge of the Earth and using that knowledge to the benefit of all humanity. See also **Satellites (Scientific and Reconnaissance)**.

Mission Profiles

SeaWiFS/OrbView-2. The purpose of the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) Project is to provide quantitative data on global ocean bio-optical properties to the Earth science community. Subtle changes in ocean color signify various types and quantities of marine phytoplankton (microscopic marine plants), the knowledge of which has both scientific and practical applications. SeaWiFS was successfully launched on the OrbView-2 satellite in August 1997. OrbView-2 is not provided or operated by NASA. NASA purchases the data.

See also **Seastar Satellite**; and **Sea-Viewing Wide Field-of-View Sensor (SeaWiFS)**.

The Tropical Rainfall Measuring Mission (TRMM). TRMM is a joint mission between NASA and the National Space Development Agency (NASDA) of Japan. It was designed to monitor and study tropical rainfall and the associated release of energy that helps to power the global atmospheric circulation shaping both weather and climate around the globe. NASA's TRMM satellite was successfully launched from the Tanegashima Space Center at 4:27 PM EST. on November 27, 1977. See also **Tropical Rainfall Measuring Mission (TRMM)**.

Landsat 7. The Landsat Program is the longest running enterprise for acquisition of imagery of the Earth from space. The first Landsat satellite was launched in 1972. The government-owned Landsat 7 was successfully launched on April 15, 1999 from the Western Test Range of Vandenberg Air Force Base, California, on a Delta-II expendable launch vehicle. The Earth observing instrument on Landsat 7, the Enhanced Thematic Mapper Plus (ETM+), replicates the capabilities of the highly successful Thematic Mapper instruments on Landsats 4 and 5. See also **Satellites (Scientific and Reconnaissance)**.

QuickScat (SeaWinds). The SeaWinds instrument on the QuikScat mission is a "quick recovery" mission to fill the gap created by the loss of data from the NASA Scatterometer (NSCAT), when the satellite lost power in June 1997. The SeaWinds instrument is a specialized microwave radar that measures near-surface wind speed and direction under all weather and cloud conditions over the Earth's oceans. See also **Quick Scatterometer (QuikSCAT)**.

Terra Satellite. Terra (formerly EOS AM-1) is the flagship satellite of NASA's Earth observing systems. Terra is the first EOS (Earth Observing System) platform and provides global data on the state of the atmosphere, land, and oceans, as well as their interactions with solar radiation and with one another. Terra launched aboard an Atlas-Centaur IIAS expendable launch vehicle from Vandenberg Air Force Base, California at 1:57 p.m. EST on December 18, 1999. See also **Terra Satellite (EOS AM-1)**.

Acrimsat. A series of Active Cavity Radiometer Irradiance Monitors (ACRIMs) provides long-term, precise measurements of the total amount of the Sun's energy that falls on our planet's surface, oceans, and atmosphere.

The purpose of the Active Cavity Radiometer Irradiance Monitor III (ACRIM III) instrument is to study total solar Irradiance from the Sun. The ACRIM III package is flying on a spacecraft called ACRIMSAT. The spacecraft was launched on December 20, 1999 as a secondary payload on a Taurus launch vehicle from Vandenberg Air Force Base, California. ACRIM III, third in a series of long-term solar-monitoring tools built for NASA by the Jet Propulsion Laboratory, will continue to extend the database first created by ACRIM I, which was launched in 1980 on the Solar Maximum Mission (SMM) spacecraft. ACRIM II followed on the Upper Atmosphere Research Satellite (UARS) in 1991. ACRIMSAT data will be correlated with possible global warming data, ice cap shrinkage data, and ozone layer depletion data. It is theorized that as much as 25 percent of the Earth's total global warming may be solar in origin due to small increases in the Sun's total energy output since the last century. By measuring incoming solar radiation and adding measurements of ocean and atmosphere currents and temperatures, as well as surface temperatures, climatologists will be able to improve their predictions of climate and global warming over the next century. Related applications include: energy forecasting, carbon management, and public health.

NMP EO-1 (New Millennium Program Earth Observing-1). One of the key responsibilities of NASA's Earth-Sun System Missions is to ensure the continuity of future Landsat data. The New Millennium Program's (NMP) first flight, Earth Observing-1 (EO-1), is validating technologies contributing to the reduction in cost of follow-on Landsat missions.

Earth Observing-1 (EO-1) is an advanced land-imaging mission that will demonstrate new instruments and spacecraft systems. EO-1 will validate technologies contributing to the significant reduction in cost of follow-on Landsat missions. Launched on a Delta 7320 from Vandenberg Air Force Base, California, November 21, 2000. EO-1 has a 1-year primary mission but was designed to operate for an additional year.

The NMP EO-1 mission includes three advanced land imaging instruments and five revolutionary cross cutting spacecraft technologies. The

hyperspectral instrument is the first of its kind to provide images of land-surface in more than 220 spectral colors. The Hyperion will demonstrate the ability to perform detailed spectral mapping with high radiometric accuracy. In the future, an operational version of the Hyperion will allow complex land ecosystems to be imaged and accurately classified. The Advanced Land Imager (ALI) instrument yields almost four times better performance at only one-fourth the cost and weight of the Landsat ETM+. Finally the Linear Etalon Imaging Spectral Array/Atmospheric Corrector (LEISA/AC) is an infrared camera, which can be used to remove the effects of the atmosphere from surface pictures obtained by instruments such as the ALI on EO-1 and Landsat. This instrument will provide scientific return both in terms of improved imagery and hyperspectral sensing capabilities. It will also test a number of new technologies. Because the AC is small and adaptable to different spacecraft configurations, it is a bolt-on instrument, which can be attached to any future Earth imaging spacecraft. The three advanced imaging instruments will lead to a new generation of lighter weight, higher performance and lower cost Landsat-type Earth surface imaging instruments.

The future of Earth science measurements requires that spacecraft have even greater capabilities packaged in more compact and lower cost spacecraft. To this end, EO-1 tests, for the first time, five new technologies that will enable new or more cost-effective approaches to conducting science missions in the 21st Century. These are: the X-band Phased Array Antenna, used for downlinking data gathered by the EO-1 science instruments; Enhanced Formation Flying, an autonomous, onboard, relative navigation and formation flying control; the Pulse Plasma Thruster, used for fine attitude precision control; the Lightweight Flexible Solar Array, an advanced photo-voltaic solar array which utilizes a lightweight solar blanket and shockless, shapedhinge deployment mechanism to achieve two to three times the specific power over conventional solar arrays; and the Carbon-Carbon Radiator, which has superior thermal radiating properties over conventional materials. Future NASA spacecraft will be an order of magnitude smaller and lighter than current versions, and the EO-1 Mission provides the on-orbit demonstration and validation of several technologies to get us there.

See also **New Millennium Program (NMP)**.

Jason 1. Jason is a joint U.S.-France (Centre National d' Etudes Spatiales) oceanography mission designed to monitor global ocean circulation, discover the tie between the oceans and atmosphere, improve global climate predictions, and monitor events such as El Niño and La Niña and ocean eddies.

Jason is an oceanography mission to monitor global ocean circulation, improve global climate predictions, and monitor events such as El Nino conditions and ocean eddies. The Jason-1 satellite carries a radar altimeter, and it is a follow-on mission to the highly successful TOPEX/Poseidon mission, that measured ocean surface topography to an accuracy of 4.2 centimeters (1.7 inch), enabled scientists to forecast the 1997–1998 El Niño, and improved understanding of ocean circulation and its effect of global climate. Jason-1 altimeter data is part of a suite of data provided by other NASA missions — the GRACE mission uses two satellites to accurately measure Earth's mass distribution, and the QuikSCAT scatterometer mission will measure ocean-surface winds. The Delta vehicle was shared with the Thermosphere, Ionosphere, Mesosphere, Energetics and Dynamics (TIMED) mission.

Meteor 3M-1 (SAGE III). The SAGE III (Stratospheric Aerosol and Gas Experiment) mission on the Russian Meteor 3M-1 spacecraft seeks to enhance our understanding of natural and human-derived atmospheric processes by providing high latitude long-term measurements of the vertical structure of aerosols, ozone, water vapor, and other important trace gases in the upper troposphere and stratosphere.

SAGE III was successfully launched onboard a Meteor-3M spacecraft on December 10, 2001 at 17:18:57 UTC from the Baikonur Cosmodrome in Kazakhstan. The satellite is in a sun-synchronous orbit with an ascending node time of about 9 AM. The orbit yields solar measurement opportunities between 50–80 degrees north latitude and 30–50 degrees south latitude. The high northern latitude coverage provides insight into the processes leading to ozone depletion during boreal winter and provides coverage that complements the mid- and low-latitude coverage provided by SAGE II and other SAGE III missions.

The Meteor-3M spacecraft is an advanced model of the Meteor spacecraft that was developed over 30 years ago. The payload includes SAGE III and other instruments designed to measure temperature and humidity profiles, clouds, surface properties, and high energy particles in the upper atmosphere.

The instrument is commanded and controlled by personnel at the SAGE III Mission Operations Center at NASA Langley Research Center. Data are downlinked twice daily to Wallops Flight Facility and to a Russian receiving station. It will be processed and will be made available at the Langley Research Center's Atmospheric Sciences Data Center.

The International Laser Ranging Service (ILRS) provides tracking of the Meteor-3M retro reflector array from its global network of laser ranging stations to support the mission.

Routine measurement operations began in March 2002.

ESSP/GRACE. A Pathfinder mission, GRACE (Gravity Recovery and Climate Experiment) employs a satellite-to-satellite microwave tracking system between two spacecraft to measure the Earth's gravity field and its time variability over five years. Such measurements are directly coupled to long-wavelength ocean circulation processes and to the transport of ocean heat to the Earth's poles. See also **Earth System Science Pathfinder (ESSP) Program**.

Aqua. The name "Aqua", Latin for "water", is tied to the large amount of information that the mission will be collecting about the Earths water cycle, including evaporation from the oceans, water vapor in the atmosphere, clouds, precipitation, soil moisture, sea ice, land ice, and snow cover on the land and ice. Additional measurements also include radiative energy fluxes, aerosols, vegetation cover on the land, phytoplankton and dissolved organic matter in the oceans, and air, land, and water temperatures. Comprehensive measurements taken by its onboard instruments will allow scientists to assess long-term change, identify its human and natural causes and advance the development of models for long-term forecasting.

Aqua was launched on May 4, 2002, and has six Earth-observing instruments on board, collecting a variety of global data sets.

- **MODIS** — Moderate Resolution Imaging Spectroradiometer
- **AIRS** — Atmospheric Infrared Sounder
- **AMSU-A** — Advanced Microwave Sounding Unit-A
- **HSB** — Humidity Sounder for Brazil
- **AMSR-E** — Advanced Microwave Radiometer for EOS
- **CERES** — Cloud's and the Earth's Radiant Energy System

See also **Aqua**.

ADEOS II (SeaWinds). The Advanced Earth Observing Satellite II ADEOS (ADEOS II), the successor to the Advanced Earth Observing Satellite (ADEOS) mission, is a joint mission with the National Space Development Agency (NASDA) of Japan. The mission is taking an active part in the research of global climate changes and their effect on weather phenomena.

The SeaWinds scatterometer is a specialized microwave radar that measures near-surface wind velocity (both speed and direction) under all weather and cloud conditions over Earth's oceans. The experiment is a follow-on mission and continues the data series initiated in 1996 by the NSCAT.

SeaWinds uses a rotating dish antenna with two beams. The antenna radiates microwave pulses at a frequency of 13.4 gigahertz across broad regions on Earth's surface. SeaWinds will collect data in a continuous 1,800-kilometer-wide band (1,118 miles), making approximately 400,000 measurements per day.

The primary science objectives include: Acquire all-weather, high-resolution measurements of near-surface winds over the global oceans; Determine atmospheric forcing, ocean response and air-sea interaction mechanisms on various spatial and temporal scales; and Combine wind data with measurements from scientific instruments in other disciplines to understand mechanisms of global climate change and weather patterns; and the operational objectives include: Improve weather forecasts near coastlines by using wind data in numerical weather- and wave-prediction models; and Improve storm warning and monitoring.

SeaWinds was scheduled to launch on board ADEOS-II from Tanegashima, Japan in February 2002, but NASA was advised by the National Space Development Agency of Japan (NASDA) that the Japanese Space Activities Commission (SAC) wants to have 3 successful H-IIA rocket launches prior to the ADEOS-II launch. This sets the ADEOS-II launch to take place no earlier than November 2002. SeaWinds was finally launched on December 13, 2002. The SeaWinds Project is managed for NASA's

Earth Science Enterprise by the Jet Propulsion Laboratory, a division of the California Institute of Technology.

Ice, Clouds, and Land Elevation Satellite (ICESat). The primary goal of ICESat is to quantify ice sheet mass balance and understand how changes in the Earth' atmosphere and climate affect polar ice masses and global sea level. ICESat is also measuring the distribution of clouds and aerosols, as well as surveying land topography, sea ice, and vegetation cover.

The Ice, Cloud and land Elevation Satellite (ICESat) launched 12 January 2003, AT 7:45 p.m. EST, aboard a Boeing Delta II launch vehicle from Vandenberg Air Force Base in California. ICESat was placed into a 94 degree inclination so each successive ground track will precess to the West as the Earth rotates, at an initial altitude 590 kilometers (367 miles) above the Earth. ICESat's designed lifetime is for three years of operation with a five-year goal. See Fig.1

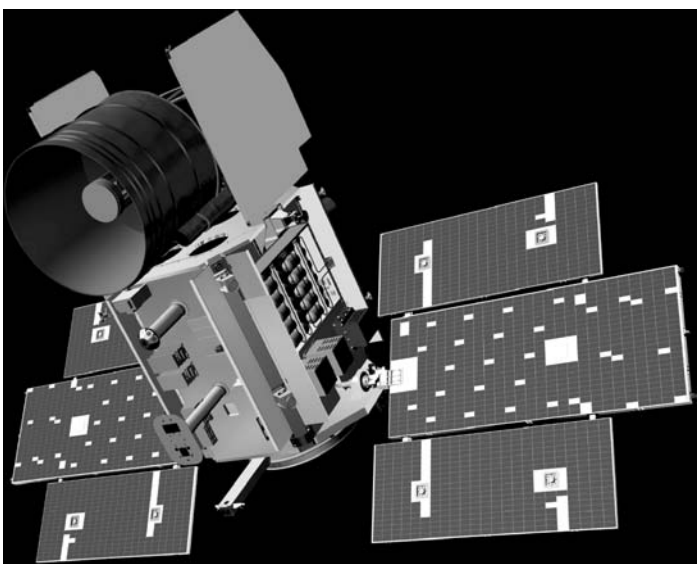

Fig. 1. Artist rendering of the Ice, Clouds, and Land Elevation Satellite (ICESat).

The spacecraft provides 350 W orbit averaged payload power. A redundant Solid State Recorder provides 56 Gb of payload data storage, or 24 hours of science data. The payload data is downlinked through a 40 Mbps X-band transmitter which allows 4 hours of data dump within a typical station pass.

The spacecraft is a fully redundant design that provides a probability of success of >86% for a 5-year mission life. The spacecraft bus and payload are powered by two single-axis articulated solar array wings, consisting of three winglets each. Two star trackers provide precision pointing and stability. A fixed X-band antenna is mounted on a post to provide a high bandwidth downlink. Spacecraft command and telemetry uplink/downlink on S-band frequency allows for simultaneous command and telemetry operation. The attitude control and determination subsystem is designed to allow payload operation from any orientation, and provides rapid slewing, tracking of targets, and minimizes vibrations and induced jitter. Two BlackJack GPS receivers from NASA's Jet Propulsion Laboratory provide precision orbit determination, timing and geolocation. A hydrazine propulsion system corrects for any launch insertion errors, and maintains the correct orbit for ground track repeatability.

The primary instrument and integral part of the ICESat spacecraft is the Geoscience Laser Altimeter System (GLAS). See Fig. 2a, b, and c. GLAS is the first laser-ranging (lidar) instrument for continuous global observations of Earth, which will make unique atmospheric observations as an important component of the Earth Science Enterprise (ESE) climate change program. GLAS is a facility instrument designed to measure ice-sheet topography and associated temporal changes, cloud and atmospheric properties and give us information on the height and thickness of radiatively important cloud layers which is needed for accurate short term climate and weather prediction. In addition, operation of GLAS over land and water will provide along-track topography.

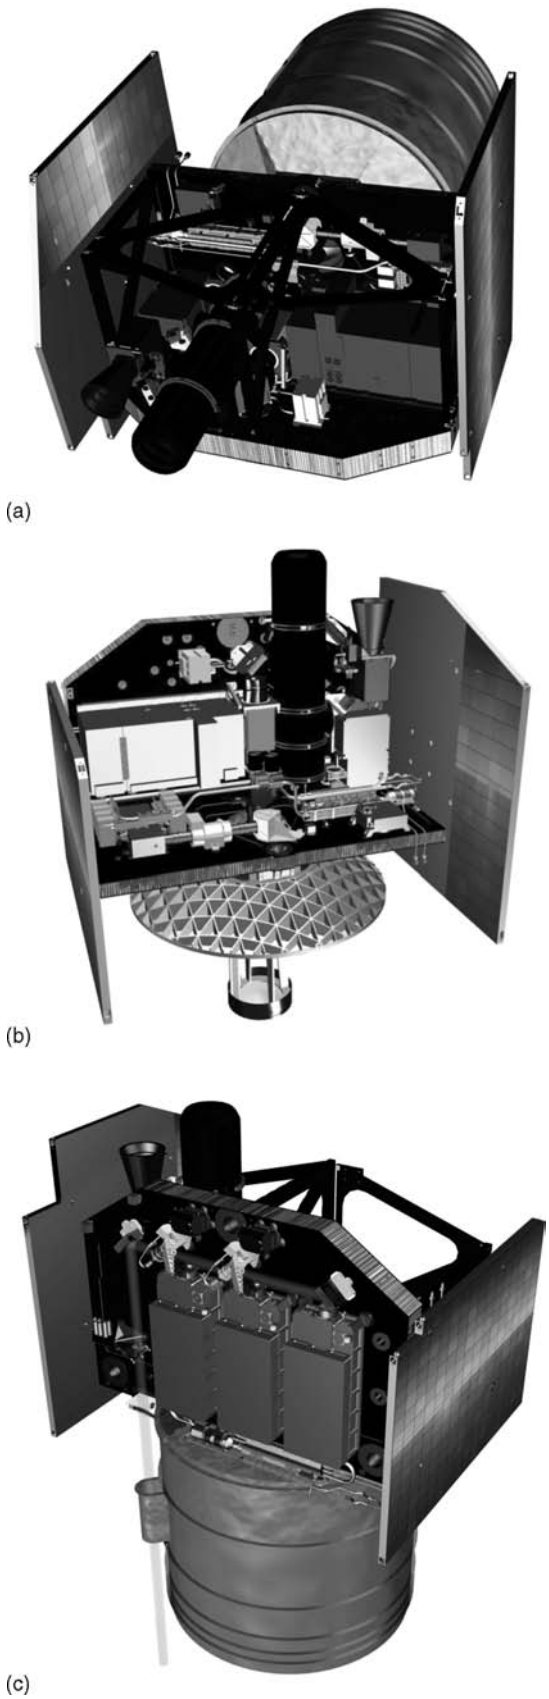

Fig. 2. Renderings of the GLAS Instrument.

GLAS includes a laser system to measure distance, a Global Positioning System (GPS) receiver, and a star-tracker attitude determination system. The laser will transmit short pulses (4 nano seconds) of infrared light (1064 nanometers wavelength) and visible green light (532 nanometers). Photons reflected back to the spacecraft from the surface of the Earth and

from the atmosphere, including the inside of clouds, will be collected in a 1 meter (3.3 foott) diameter telescope. Laser pulses at 40 times per second will illuminate spots (footprints) 70 meters (230 feet) in diameter, spaced at 170-meter (558 foot) intervals along Earth's surface.

Solar Radiation and Climate Experiment (SORCE). SORCE is a NASA-sponsored satellite mission that will provide state-of-the-art measurements of incoming x-ray, ultraviolet, visible, near-infrared, and total solar radiation. SORCE represents the merging of the EOS Solar Stellar Irradiance Comparison Experiment (SOLSTICE) and the Total Solar Irradiance Mission (TSIM). The measurements provided by SORCE specifically address long-term climate change, natural variability and enhanced climate prediction, and atmospheric ozone and UV-B radiation. These measurements are critical to studies of the Sun, its effect on our Earth system, and its influence on humankind.

Solar radiation is the dominant, direct energy input into the terrestrial ecosystem, and it affects all physical, chemical, and biological processes. The Sun provides a natural influence on the Earth's atmosphere and climate. In order to understand mankind's roles in climate change, the Sun's impact must first be understood.

SORCE measures the Sun's output with the use of state-of-the-art radiometers, spectrometers, photodiodes, detectors, and bolometers engineered into instruments mounted on a satellite observatory. The SORCE satellite orbits around the Earth accumulating solar data. Spectral measurements identify the irradiance of the Sun by characterizing the Sun's energy and emissions in the form of color that can then be translated into quantities and elements of matter. Data obtained by the SORCE experiment will be used to model the Sun's output and to explain and predict the effect of the Sun's radiation on the Earth's atmosphere and climate.

The SORCE spacecraft launched on January 25, 2003 on a Pegasus XL launch vehicle from the Eastern Test Range, Kennedy Space Center, FL., to provide NASA with precise measurements of solar radiation. It launched into a 645 kilometer (401 mile), 40 degree orbit and is operated by the Laboratory for Atmospheric and Space Physics (LASP) at the University of Colorado, http://lasp.colorado.edu/sorce/. It will continue the precise measurements of total solar irradiance (TSI) that began with the ERB instrument in 1979 and has continued to the present with the ACRIM series of measurements. SORCE will also provide the measurements of the solar spectral irradiance from 1 nm to 2000 nm, accounting for 95% of the spectral contribution to TSI. SORCE carries four instruments including the Total Irradiance Monitor (TIM), Solar Stellar Irradiance Comparison Experiment (SOLSTICE), Spectral Irradiance Monitor (SIM), and the XUV Photometer System (XPS). See Fig. 3.

Aura. Aura is the third in a series of major Earth observing satellites to study the environment and climate change. The first and second missions, Terra (launched December, 1999) and Aqua (launched May, 2002), are designed to study the land, oceans, and the Earth's radiation budget. Aura's chemistry measurements also follow up on measurements which began with NASA'S Upper Atmospheric Research Satellite and continues the record of satellite ozone data collected from the TOMS missions. The United Kingdom and the Netherlands are providing instruments for this mission. See also **Aqua Mission**; and **Terra Satellite (EOS AM-1)**.

The Aura spacecraft was successfully launched on July 15, 2004 aboard a Delta II 7920-10L, a two stage expendable rocket, from the Western Test Range, Vandenberg Air Force Base, California.

Aura was launched into a sun-synchronous, near polar (98.2 degree inclination) orbit. It orbits 705 km (438 miles) above the Earth with a sixteen-day repeat cycle and 233 revolutions per cycle. The ascending node is in daylight and crosses the equator at approximately 1:45 PM. The Aura spacecraft is flying in formation with other Earth observing satellites called the A-Train. See Fig. 4

See also **Space Science Missions: Earth**.

ESSP/CloudSat. CloudSat's primary goal is to furnish data needed to evaluate and improve the way clouds are parameterized in global models thereby contributing to better predictions of clouds and, thus, to their poorly understood role in affecting climate change through what is referred to as cloud-climate feedback. See also **CloudSat**; and **Earth System Science Pathfinder (ESSP)**.

ESSP/CALIPSO. CALIPSO will fly in formation with Aqua to provide a global set of data on aerosol and cloud properties, radiative fluxes, and atmospheric state. This enables new assessments of the radiative effects of aerosol and clouds that will greatly improve our ability to predict future climate change. See also **Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO)**; and **Earth System Science Pathfinder (ESSP) Program**.

NPOESS Preparatory Project (NPP). The NPOESS Preparatory Project (NPP) is a joint mission to extend key measurements in support of long-term monitoring of climate trends and of global biological productivity. It extends the measurement series being initiated with EOS Terra and AQUA by providing a bridge between NASA's EOS missions and the National Polar-orbiting Operational Environmental Satellite System (NPOESS) of the Integrated Program Office (IPO). The NPP mission will provide operational agencies early access to the next generation of operational sensors, thereby greatly reducing the risks incurred during the

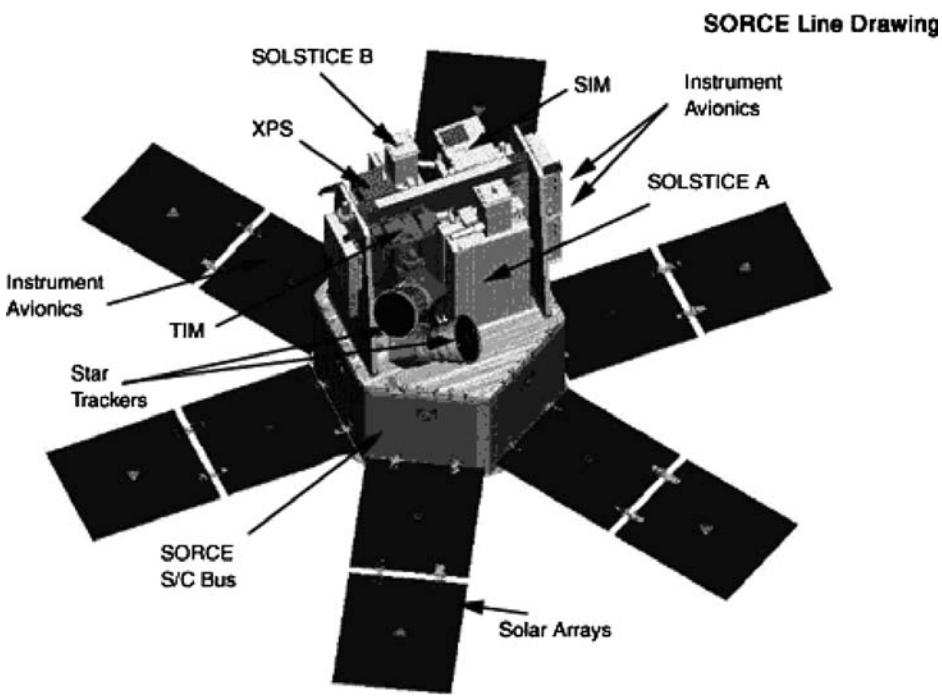

Fig. 3. SORCE Line Drawing.

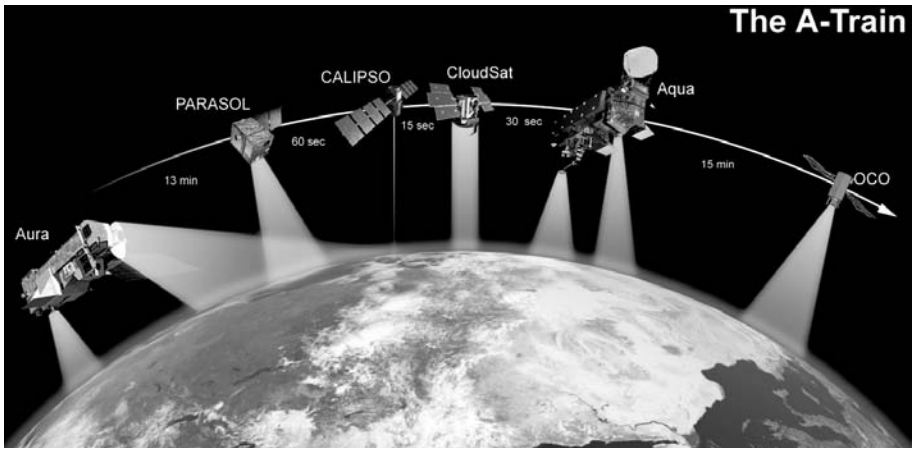

Fig. 4. Aura spacecraft flying in formation.

transition. This will permit testing of the advanced ground operations facilities and validation of sensors and algorithms while the current operational systems are still in place. This new system will provide nearly an order of magnitude more data than the current operational system.

NPOESS will provide long-term systematic measurements of key environmental variables beginning about 2009. In preparation for this system, NPP will provide risk reduction for this future operational system and it will maintain continuity of certain environmental data sets that were initiated with NASA's Terra and Aqua satellites. These measurements will be taken by three different sensors; Visible Infrared Imaging spectroRadiometer Suite (VIIRS), Crosstrack Infrared Sounder (CrIS), and Advanced Technology Microwave Sounder (ATMS). These sensors will collect data on atmospheric and sea surface temperatures, humidity soundings, land and ocean biological productivity, and cloud and aerosol properties. This data will be used for long-term climate and global change studies.

The NPP satellite will be launched from the Western Range at Vandenberg Air Force Base from SLC-2, California, by a Boeing Delta II-7920-10 launch vehicle Delta II. The NPP mission will be launched into an 824 kilometer (512 mile) circular, sun-synchronous orbit with a 10:30 a.m. local-time descending node crossing.

KSC Range Services at Vandenberg AFB provides the integration facilities, launch pad services, electrical power, communication links, and range commanding required to process, erect, fuel, and launch the NPP spacecraft and its associated launch vehicle.

ESSP/OCO. OCO will provide space-based observations of atmospheric carbon dioxide (CO2), the principal anthropogenic driver of climate change. This mission will use mature technologies to address NASA's highest priority carbon cycle measurement requirement. OCO will generate the knowledge needed to improve projections of future atmospheric CO2. See also **Earth System Science Pathfinder (ESSP)**; and **Orbiting Carbon Observatory (OCO)**.

ESSP. The Earth System Science Pathfinder (ESSP) Program is a component of the Earth-Sun System Missions that address unique, specific, highly-focused mission requirements in Earth science research. The ESSP program is an innovative approach for addressing Global Change Research by providing periodic "Windows of Opportunity" to accommodate new scientific priorities and infuse new scientific participation into the Earth-Sun System Program. See also **Earth System Science Pathfinder (ESSP)**.

ESSP/Aquarius. Aquarius is a focused satellite mission to measure global Sea Surface Salinity (SSS). Scientific progress is limited because conventional in situ SSS sampling is too sparse to give the global view of salinity variability that only a satellite can provide. Aquarius will resolve missing physical processes that link the water cycle, the climate, and the ocean.

Aquarius is named after the Water Bearer constellation because of its objective to explore the role of the water cycle in ocean circulation and climate. Aquarius will launch in March of 2009 and will orbit the earth for at least three years, repeating its global pattern every 7 days. Within two months, Aquarius will collect as many sea surface salinity measurements as the entire 125-year historical record from ships and buoys, and provide measurements over the 25 percent of the ocean where no previous observations have been made. See also **Earth System Science Pathfinder (ESSP)**.

Ocean Surface Topography Mission (OSTM/Jason-2). OSTM will measure sea surface height to an accuracy of <4 centimeters (<1.6 inches) every ten days. Sea surface topography measured by satellite altimeters has numerous applications important to global environmental monitoring including predicting hurricane intensification, improving tide models, mapping deep ocean bathymetry, monitoring and forecasting El Niño Southern Oscillation, measuring the rate of global sea level rise, and charting surface currents. Applications: coastal zone management, disaster management.

OSTM is a cooperative effort between NASA, the National Oceanic and Atmospheric Administration (NOAA), the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT) and the Centre National d'Etudes Spatiales (CNES), the space agency of France. OSTM is a follow-on to Jason-1 and will provide continuity of ocean topography measurements beyond Jason-1 and TOPEX/Poseidon. It is scheduled to launch in June of 2008. See also http://sealevel.jpl.nasa.gov/mission/ostm-fact-sheet.html.

Glory Observatory Mission. Glory is a remote-sensing Earth-orbiting observatory designed to achieve two separate mission objectives. One is to collect data on the chemical, microphysical, and optical properties, and spatial and temporal distributions of aerosols. The other is to continue collection of total solar irradiance data for the long-term climate record.

The Glory mission's scientific objectives are met by implementing two separate science instruments, one with the ability to collect polarimetric measurements along the satellite ground track within the solar reflective spectral region (0.4 to 2.4 micrometers) and one with the ability to monitor changes in sunlight incident on the Earth's atmosphere by collecting high accuracy, high precision measurements of total solar irradiance. Glory accomplishes these objectives by deploying two instruments aboard a low earth orbit satellite, the Aerosol Polarimetry Sensor (APS) and the Total Irradiance Monitor (TIM). Additionally, a cloud camera system will provide images that allow the APS scans along the spacecraft ground track to be put into spatial context and to facilitate determination of cloud occurrence within the APS instantaneous field of view.

The Glory mission will respond to the U.S. Climate Change Science Program (CCSP) by continuing and improving upon NASA's research of the forcing influencing climate change in the atmosphere. As summarized below, measurements produced by this mission and the scientific knowledge such observations will provide are essential to predicting future climate change, and to making sound, scientifically based economic and policy decisions related to environmental change.

The science objectives of the Glory mission include: 1. The determination of the global distribution, microphysical properties, and chemical composition of natural and anthropogenic aerosols and clouds with accuracy and coverage sufficient for a reliable quantification of the aerosol direct and indirect effects on climate. 2. The continued measurement of

the total solar irradiance to determine the Sun's direct and indirect effect on the Earth's climate.

The launch readiness date is December 2008, from Vandenberg Air Force Base, California, aboard a Taurus XL launch vehicle. See also http://glory.gsfc.nasa.gov/overview-scinst.html.

Landsat Data Continuity Mission (LDCM). LCDM, the next-generation Landsat satellite is projected to be launched during the summer of 2001. This important mission will ensure continued acquisition and availability of Landsat-like data well beyond the duration of current Landsat missions.

For more than 30 years, Landsat satellites have collected data of the Earth's continental surfaces to support global change research and applications. This data constitutes the longest continuous record of the Earth's surface as seen from space. By imaging Earth's land environment at a resolution sufficient to record the impacts of human activities, Landsat provides an important complement to U.S. global imagers such as MODIS, MISR, and AVHRR. The first satellite in the Landsat family, Landsat 1, was launched in 1972. The most recent, Landsat 7, was launched in April 1999 and continues to collect data. Because its design lifetime is five years, the next Landsat satellite system needs to be launched as soon as possible in order to minimize risks to data continuity. See also **Satellites (Scientific and Reconnaissance)**.

The Land Remote Sensing Policy Act of 1992 directs the National Aeronautics and Space Administration (NASA) and the United States Geological Survey (USGS) to assess various system development and management options for a satellite system to succeed Landsat 7. NASA and USGS are working together on the Landsat Data Continuity Mission (LDCM) to meet this goal, and to ensure continued collection of Landsat data. In addition to the primary goal of maintaining "data continuity with the Landsat system," the Land Remote Sensing Policy Act of 1992 set two additional goals for LDCM. They are to serve "the civilian, national security, commercial, and foreign policy interests of the United States," and to "incorporate system enhancements . . . which may potentially yield a system that is less expensive to build and operate and more responsive to users."

The 1992 Act expressed a preference for "private-sector funding and management". To that end, NASA and USGS pursued a private-public partnership for procuring LDCM data, and awarded study phase contracts to two commercial companies (DigitalGlobe and Resource21) during 2002. NASA cancelled the final Request for Proposal (RFP) on September 26, 2003, following an evaluation of the responses to the solicitation. NASA decided that awarding a contract was not in the best interest of the U.S. Government on the basis of proposal evaluations. Since that time, other options for implementing LDCM have been under consideration.

On August 5, 2004, a Request for Information (RFI) was issued to solicit information on innovative approaches for the development and incorporation of a new Operational Land Imager and also for a potential stand-alone mission. All the RFI documents can be found at this web site under procurement or at the NASA Acquisition Internet Service, http://prod.nais.nasa.gov/cgi-bin/nais/index.cgi.

One of the key objectives of LDCM is to make all Landsat-type data available at affordable cost. This will enable the many different sectors of the population - farmers, school children, business leaders, scientists, state and federal governments and many others to continue to utilize this data for high quality research and applications.

The launch readiness date is July 11, 2011, from Vandenberg Air Force Base, California. See also http://ldcm.usgs.gov/.

Global Precipitation Measurement (GPM). GPM is a joint mission with the Japan Aerospace Exploration Agency (JAXA) and other international partners. Building upon the success of the Tropical Rainfall Measuring Mission (TRMM), it will initiate the measurement of global precipitation, a key climate factor. See also **Tropical Rainfall Measuring Mission (TRMM)**. Its science objectives are: to improve ongoing efforts to predict climate by providing near-global measurement of precipitation, its distribution, and physical processes; to improve the accuracy of weather and precipitation forecasts through more accurate measurement of rain rates and latent heating; and to provide more frequent and complete sampling of the Earth's precipitation. GPM is envisioned to consist of a core spacecraft to measure precipitation structure and to provide a calibration standard for the constellation spacecraft, an international constellation of NASA and contributed spacecraft to provide frequent precipitation measurements on a global basis, calibration/validation sites distributed globally with a broad array of precipitation-measuring instrumentation, and a global precipitation data system to produce and distribute global rain maps and climate research products.

Core Spacecraft. Carrying both a dual frequency radar instrument and a passive microwave radiometer, the Core Spacecraft will serve as a calibration standard for the other members of the GPM spacecraft constellation. See Fig. 5

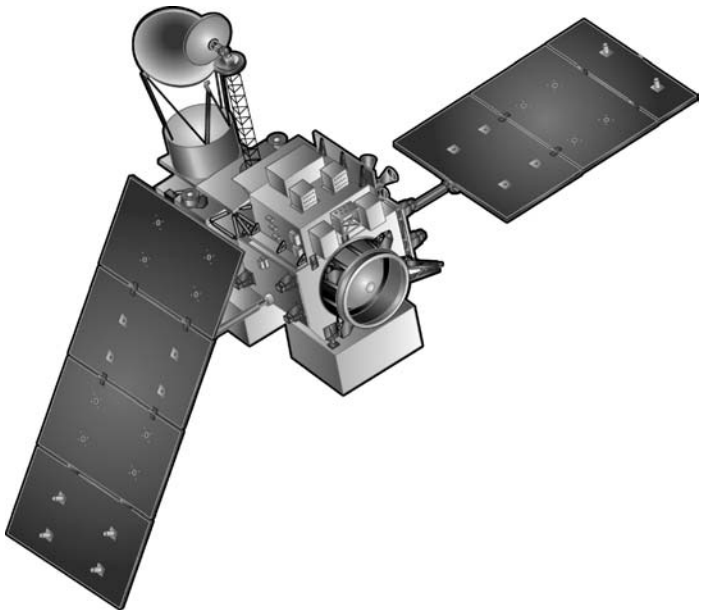

Fig. 5. GPM Core Spacecraft Illustration.

The Core Spacecraft will be developed in-house at GSFC with the avionics procured through Goddard's Rapid Spacecraft Development Office (RSDO). This Hybrid approach provides substantive work for GSFC engineers while taking advantage of the best features of RSDO (rapid procurement and minimizing cost).

A scientific spacecraft carries numerous instruments designed to measure specific phenomena. Scientists must control, very precisely, where each instrument on the spacecraft is pointing, so that data is collected from the intended targets. Not only do the instruments have to be moved from target to target, they must be held steady on a target long enough, as the spacecraft moves through space, to collect the needed data.

The Core launch is scheduled for December 1, 2010, from the Tanegashima Space Center, Japan. The design life is 3 years and a goal of 5 years.

GPM Instruments. GPM will be pointing toward Earth to measure precipitation. It will be vital to control the attitude (or physical orientation) of the Core Spacecraft accurately, so that we can map exactly where the resulting data originates on Earth. The Core observatory is uniquely instrumented with a conically-scanning radiometer and a cross-track scanning radar; **GPM Microwave Imager (GMI)**; and **Dual-frequency Precipitation Radar (DPR)**.

The well calibrated GPM Microwave Imager (GMI) measurements and the well characterized scene obtained from the Dual-frequency Precipitation Radar (DPR) will combine to provide an excellent reference against which to calibrate other microwave radiometers in the GPM constellation when overlapping measurements of same Earth scene are made. The DPR, will have the capability to make detailed, three-dimensional measurements of cloud structure, rainfall, and rain rates. These detailed measurements will provide further understanding of the microwave radiometric measurements made by the GMI.

GPM Microwave Imager (GMI). The Global Precipitation Measurement (GPM) Microwave Imager (GMI) instrument is a multi-channel, conical-scanning, microwave radiometer serving an essential role in the near-global-coverage and frequent-revisit-time requirements of GPM. See Fig. 6

The instrumentation enables the Core spacecraft to serve as both a 'precipitation standard' and as a 'radiometric standard' for the other GPM constellation members. The GMI is characterized by thirteen microwave channels ranging in frequency from 10 GHz to 183 GHz.Ê In addition

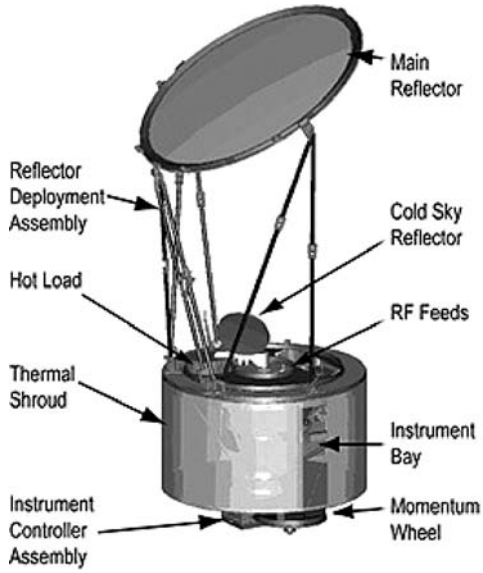

Fig. 6. GPM Microwave Imager (GMI).

to carrying channels similar to those on the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI), the GMI carries four high frequency, millimeter-wave, channels about 166 GHz and 183 GHz. With a 1.2 meter (4 foot) diameter antenna, the GMI will provide significantly improved spatial resolution over TMI.

Scan Geometry. The off-nadir-angle defining the cone swept out by the GMI is set at 48.5 degrees which represents an earth- incidence-angle of 52.8 degrees. See Fig. 7. To maintain similar geometry with the predecessor TMI instrument, the-earth- incidence angle of GMI was chosen identical to that of the TMI. Rotating at 32 rotations per minute, the GMI will gather microwave radiometric brightness measurements over a 140 degree sector centered about the spacecraft ground track vector. The remaining angular sector is used for performing calibration; i.e. observation of cold space as well as observation of a hot calibration target.

The 140 degree GMI swath represents a swath of 904 kilometers (562 miles) on the Earth's surface. For comparison, the DPR instrument is characterized by cross-track swath widths of 245 kilometers (152 miles) and 120 kilometers (75 miles), for the Ku and Ka-band radars respectively. Only the central portions of the GMI swath will overlap the radar swaths (and with approximately 67 second duration between measurements due to the geometry and spacecraft motion). These measurements within the overlapped swaths are important for improving precipitation retrievals, and in particular, the radiometer-based retrievals.

In March 2005, NASA chose Ball Aerospace & Technology Corporation to provide the GMI instrument(s).

Dual-Frequency Precipitation Radar (DPR). One of the prime instruments for the GPM Core Observatory and is called the Dual-frequency Precipitation Radar (DPR). The DPR consists of a Ku-band precipitation radar (KuPR) and a Ka-band precipitation radar (KaPR). The KuPR (13.6 GHz) is an updated version of the highly successful unit flown on the TRMM mission. See also **Tropical Rainfall Measuring Mission (TRMM)**. The KuPR and the KaPR will be co-aligned on the GPM spacecraft bus such that that the 5 kilometer (3 mile) footprint location on the earth will be the same.

Data collected from the KuPR and KaPR units will provide the 3-dimensional observation of rain and will also provide an accurate estimation of rainfall rate to the scientific community. The DPR instrument will be allocated 190 Kbps bandwidth over the 1553B spacecraft data bus. The collection of the DPR data will be transmitted to the ground using the TDRSS multiple access (MA) and single access (SA) services.

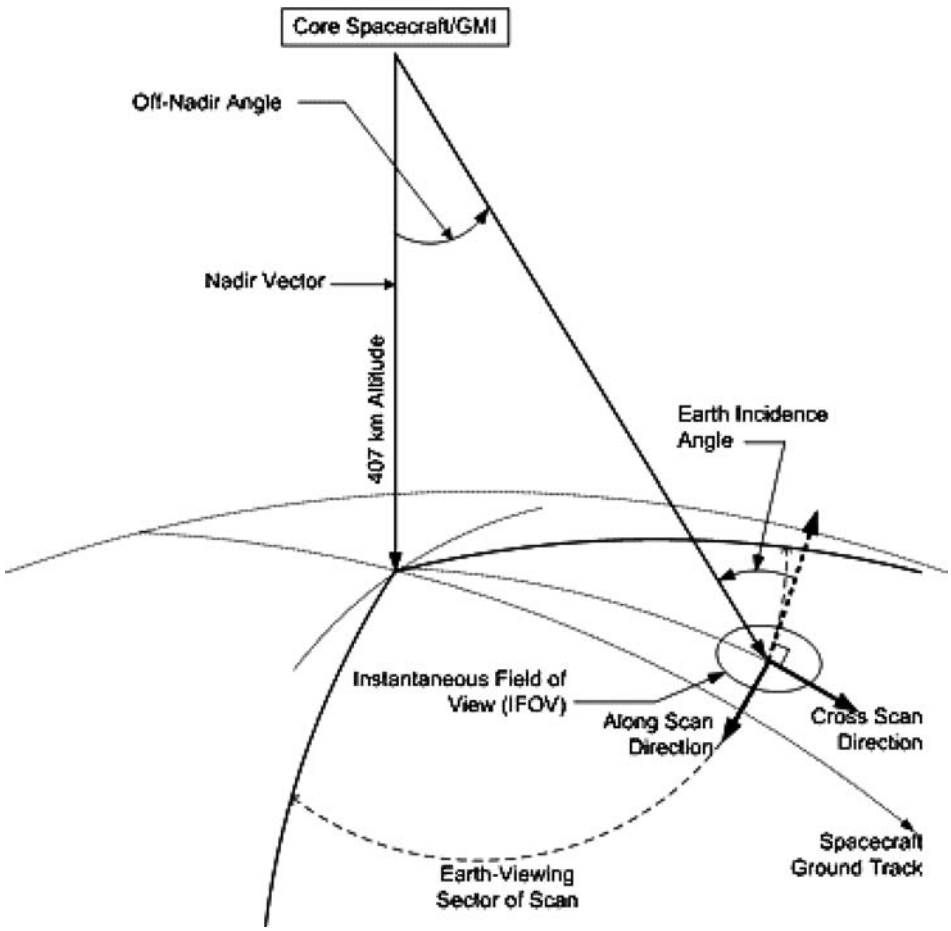

Fig. 7. Conical Scanning Geometry.

TABLE 1. TOP-LEVEL GENERAL DESIGN SPECIFICATIONS

Item	KuPR	KaPR
Swath Width	245 kilometers (152 miles)	120 kilometers (75 miles)
Range Resolution	250 meters (820 feet)	250/500 meters (820/1,640 feet)
Spatial Resolution	5 km (3 mi) (Nadir)	5 km (3 mi) (Nadir)
Beam Width	0.71 degrees	0.71 degrees
Transmitter	128 Solid State Amplifiers	128 Solid State Amplifiers
Peak Transmit Power	1000 Watts (W)	140 Watts (W)
Pulse Repetition Freq. (In nominal operations mode)	4100 to 4400 Hertz (TBD)	4100 to 4400 Hertz (TBD)
Pulse Width	two 1.667 microseconds (μs) pulses	two 1.667 microseconds (μs) pulses in matched beams two 3.234 microseconds (μs) pulses in interlaced scans
Beam Number	49	49 (25 in matched beams and 24 in interlaced scans)

The DPR instrument is being developed by Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT) for a flight on the GPM Core Observatory. NEC Toshiba Space Systems, Ltd. (NTSpace) is designing and testing the radars under the direction of JAXA and NICT.

DPR Instrument Details. The DPR is a spaceborne precipitation radar capable of making accurate rainfall measurements. The DPR is expected to be more sensitive than its TRMM predecessor especially in the measurement of light rainfall and snowfall in the high latitude regions. Rain/snow determination is expected to be accomplished by using the differential attenuation between the Ku-band and the Ka-band frequencies. The variable pulse repetition frequency (VPRF) technique is also expected to increase the number of samples at each IFOV to realize a 0.2 mm/h sensitivity.

The KuPR and KaPR, together with GMI, are the primary instruments on the GPM spacecraft. These Earth-pointing KuPR and KaPR instruments will provide rain sensing over both land and ocean, both day and night. Top-level general design specifications are listed in Table 1.

EARTH OBSERVING SYSTEM DATA AND INFORMATION SYSTEM (EOSDIS). The system that will manage a dataset of Earth science observations to be collected over a 15-year period. Existing data indicates that the Earth is changing, and that human activity increasingly contributes to this change. To monitor these changes, a baseline of "normal" performance characteristics must be obtained. For the Earth, these baseline characteristic must cover a global scale and a long enough period that the variation caused by seasonal changes and other cyclical or periodic events (e.g., El Niño and the solar cycle) may be included in the analyses. The baseline characteristics also must enable scientists to quantify processes that govern the Earth's system. Functionally, EOSDIS will provide computing and networking facilities supporting EOS research activities, including data interpretation and modeling; processing, distribution, and archiving of EOS data; and command and control of EOS observatories.

EARTH-ORBITING SATELLITES (DATA RECEIVING AND HANDLING FACILITIES). Ground support of spacecraft is often referred to as "TT&C," for tracking, telemetry and command. Tracking generally refers to measuring the position of a spacecraft, telemetry to information carried on the radio-frequency (RF) downlink signal, and command to information transmitted from the ground to a spacecraft. Increasingly, these terms are somewhat narrow to describe the action fully, as, for example, transmission of voice and video on the uplink. Though these functions were initially stand-alone elements of space operations, technological advances and economic pressures have blurred distinctions, both among them and with related operational activities. For example, computing power and reliability have advanced sufficiently that many functions can be economically accomplished at the point of ground receipt or of application, rather than at a centralized facility. For Apollo, the separate functions of command, telemetry, tracking, and voice communications were integrated into a single radio-frequency (RF) system. Readers should be aware that the boundaries of data receiving and handling functions are dynamic.

The genesis of data receiving and handling facilities was primarily in the military launch ranges. Differences and limitations necessitated changes as space activities developed. Geographically, coverage expanded globally. Operationally, mission durations became more continuous and ground activities increasingly interactive.

Early space flights were brief. Operations were simple, few, and far between. With no existing infrastructure, supporting systems, procedures, and operators had to be put in place for each mission — usually unique for each flight. Preplanning an entire mission has gradually been replaced by continual interaction by both flight controllers and mission scientists — resulting in far more productive missions. Led by the interplanetary designs, spacecraft have become much more autonomous — more robust and require less, and less critical, ground control. Some ground operations systems evolved from "specialized mission unique" to "general purpose multimission." Even as multimission applications shared hardware, they often retained unique software. Generally, RF systems became more standardized (strongly prompted by international spectrum allocations), as have terrestrial communications as these needs are increasingly met commercially. However, many data systems and operating procedures remained quite unique. Sharing multipurpose assets is itself quite expensive, and technology has reduced costs sufficiently that in many cases it now makes economic sense to consider dedicated systems again — though constructed of standardized components.

Although much of this discussion focuses on NASA, it is in a larger sense the history of most space operations and thus has broader

significance. In the Cold War environment the Soviet systems evolved independently, but most other agencies and countries followed NASA's lead, primarily to take advantage of existing designs, systems, and infrastructure. NASA originally had three separate networks of ground stations for controlling and tracking spacecraft. The Space Tracking And Data Network (STADAN) initially spanned the globe north and south across the Americas. It was used primarily for near-Earth scientific satellites. Telemetry and command systems were independent of each other, and tracking relied primarily on radio interferometery. The Deep Space Network (DSN) was used for interplanetary spacecraft; its notable characteristic was large antennae and very sensitive receivers. These stations were located around the world so that all directions in the celestial sphere were continuously in view of one of the stations. The Manned Space Flight Network (MSFN) was established just for "manned" missions. These stations were located primarily along the ground track of early orbits launched from Florida.

By the late 1960s, NASA had about 30 ground stations around the world. In Spain, Australia, and California, one station of each of the three networks was located within a few kilometers of the other two — each independently operated and often having incompatible systems. Responding to budget reductions after the Apollo program, the agency consolidated the STADAN and MSFN facilities into the Space Tracking and Data Network (STDN). This consolidation was primarily in name, and years passed before it evolved into an integrated network. Systems and RF spectrum differences accounted for much of this delay. The ground stations slowly became more standardized, but the control centers frequently preserved their individuality. With the advent of relay satellites (see TDRSS Relay Satellites section following), NASA closed most ground stations and colocated remaining STDN facilities with the three DSN stations. The Tidbinbilla station (Fig. 1) near Canberra, Australia, is typical; the other two stations are located in California's Mojave Desert and near Madrid, Spain. See also **Deep Space Network (DSN)**.

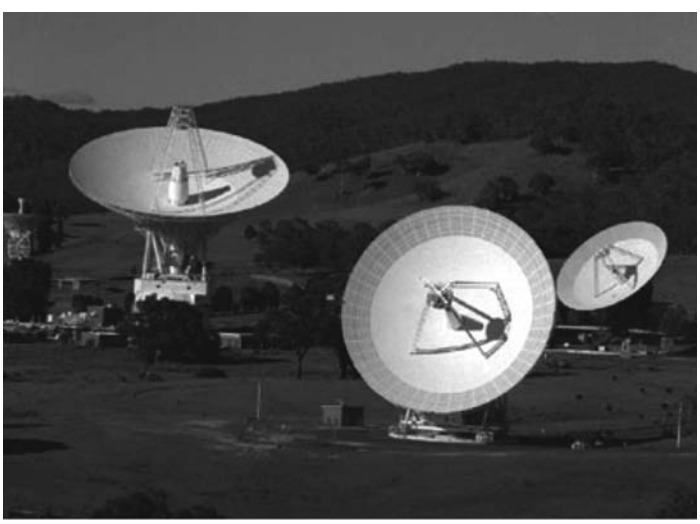

Fig. 1. NASA's Tidbinbilla, Australia, Tracking Station is one of three that provide communication with most NASA spacecraft beyond geosynchronous orbit. Antennae are (from left) a 26-meter (85 ft) (STDN dish built for Apollo at Honeysuckle Creek and relocated to Tidbinbilla; the 70-meter (230 ft) diameter DSN antenna (expanded from 64 meters (210 ft); the newest, a 34-meter (112 ft) beam waveguide DSN dish; and the original DSN antenna, a 26-meter dish expanded to 34 meters. (*image courtesy of NASA*)

These tracking stations were originally the focal points for executing space operations. Prepass planning was accomplished by the flight projects and the plan communicated — often via teletype messages on HF radio — to the stations. For the Mercury and Gemini missions, flight controllers were dispatched to the MSFN stations and interacted with the astronauts during the brief contact periods. As ground communications became sufficiently reliable, control was centralized in Houston for Apollo; the ground stations became remote communications and tracking terminals. The STADAN and DSN underwent similar evolution; control became real time and centralized at mission control centers as reliable communications became available.

The subsequent evolution of data receiving and handling methods was synergistically enabled by advances in technology, although arguably more influenced by competitive factors than by either technical performance or economics. As often happens early in the evolution of a technology, there was little reason to standardize, and various designers developed somewhat different approaches to the same basic tasks. In space operations, the spacecraft manufacturer usually determined the design of the telemetric system. Industrial participants, of course, sought competitive advantages by perpetuating proprietary concepts. Internecine battles both between and even within space agencies also inhibited standardization. Ground facilities were usually viewed as infrastructure and were funded separately from the spacecraft programs. Thus space–ground cost trades were seldom a major consideration. As a result, ground facilities must often accommodate a number of different approaches to command and telemetry. This has led to such situations as one NASA Center now using four different ways to transmit telemetric data to the ground: time division multiplex (TDM) and three different packet data formats — each requires singular ground data-handling systems.

The economic benefits of standardization are persistently apparent, and progress is slowly being made. The Consultative Committee for Space Data Systems (CCSDS) was established by the major space agencies in 1982 to promote international standardization of space data systems. In 1990, CCSDS entered into a cooperative arrangement with the International Standards Organization (ISO), and many CCSDS recommendations have now been adopted as ISO standards. The reader is referred to the CCSDS for the latest information. http://public.ccsds.org/default.aspx

Tracking

Initially, "tracking" was accomplished primarily by measuring the angle of the spacecraft's path as a function of time from ground observing stations. Both optical and RF observations were used. Optical was by tracking telescopes, and, of course, depended on favorable lighting conditions. RF tracking was passive — receiving a spacecraft beacon signal at fixed antennae on the ground and determining angles using interferometry. NASA's STADAN system was called the Minitrack. Radars were also used — transmitting signals from ground-based antennae and observing the reflections from the satellite. Radars provided another important parameter: range. Doppler information could also provide range rate data. Primarily due to weight and power limitations, few satellites carried transponders, and radars had to rely on skin tracking. The tracking data parameters measured by most of these methods were then transferred to central facilities with highly skilled specialists and usually the latest mainframe computer systems for processing and reduction. Except for a very few critical activities such as Apollo maneuvers, orbit determination was far from a real-time process. The tracking tasks included determining where the spacecraft had been when observations were made and also predicting its future orbital path. This propagation activity requires quite sophisticated modeling of such parameters as Earth's shape and mass distribution, solar pressures, and outgassing and venting from the spacecraft. The Apollo USB system measured range and range rate using a pseudorandom code carried on the uplink to the spacecraft, then turned around and retransmitted to the ground on the downlink. Some programs chose a simple tone rather than a pseudorandom code. Angles were also measured but were increasingly of secondary importance relative to the range–range rate data.

Spacecraft designers are beginning to incorporate GPS receivers onboard, permitting the spacecraft to determine its own orbit and transmit the data to the ground via telemetry. One of the more precise "tracking" examples to date has been the Topex-Posidon spacecraft, where GPS was used in the differential mode to measure the spacecraft orbit to about 2 centimeters (0.8 in). This precision was necessary because the spacecraft orbit was the reference from which changes in sea level were determined. Corner reflective mirrors are carried on some spacecraft, permitting range to be measured quite accurately by using ground-based lasers. Many of the applications of this technique were not to determine the spacecraft orbit, but rather to measure tectonic drifts on Earth — movement of the ground station.

Differences among various concepts include different protocols for time-tagging tracking parameters. Even within the same agency, some programs chose to read all parameters at the same instant, whereas others chose to read each parameter sequentially, each had its individual time tag.

Such differences were necessarily reflected in different systems for ground processing. Today much of the activity in orbit computations has been transformed from art to science, mostly executed in software. At the same time, the tools — computers — have become cheap and reliable. Commercial vendors now offer software packages that determine orbit functions using low-cost computer platforms. This, along with the use of GPS, has greatly simplified the tracking function. See also **Global Positioning System (GPS)**.

Telemetry

Telemetry — literally, measuring at a distance — is the transmission of data from a spacecraft to ground facilities. This often consists of measured parameters (either analog or digital) and could relate to either the status of the spacecraft or to observations made by the spacecraft scientific instruments (often referred to as "science data"). Occasionally this telemetry is simply relayed from another source via the spacecraft, for example, emergency locator beacons from downed aircraft and meteorological measurements collected from buoys. Voice communications from people onboard a spacecraft are often handled as "telemetry."

Telemetric systems have been used in aeronautical and space flight testing for more than 50 years. Early telemetric systems were based on analog signal transmission. These systems used frequency multiplexed/frequency modulation (FM/FM) techniques. In this technique, each sensor channel is transmitted by mixing the sensor output with a local oscillator using dual-sideband suppressed-carrier (DSBSC) amplitude modulation (AM). The outputs of each mixer are then summed and used as the input to a frequency modulator for transmission. In this technique, each of the local oscillators forming the frequency multiplexed signal need to be different and separated in frequency to keep the channel signals from overlapping in the frequency domain.

The FM/FM techniques were used in the Mercury manned spacecraft program as well as in the early, unmanned programs such as the Ranger and Lunar Orbiter spacecraft. The need for a large number of oscillators and the lack of flexibility gave way rapidly to digital techniques. For example, the Gemini program began using digital techniques after the Mercury program, and this continued on to Apollo and the Shuttle (the major exception was the real-time video data that has remained in their TV-compatible analog format). Deep space missions to the Moon and planets have also been using digital techniques for sensor data since the mid-1960s. These systems are based on pulse code modulation (PCM) for the data acquisition. The modulation techniques can be either analog frequency modulation (FM) or phase modulation (PM) or digital techniques based on phase shift keying (PSK) or frequency shift keying (FSK).

In the following sections, we will examine the basics of the data acquisition system and data encoding. Then we will look at the digital modulation techniques and finally at the error-correcting codes used in current space systems. The International Foundation for Telemetering is a nonprofit organization formed in 1964 to promote telemetry as a profession. Interested readers are referred to http://www.telemetry.org for further information.

Data Acquisition. Sensor data is collected within the spacecraft, and the sensor output is typically in an analog form such as a voltage or a current. The analog value is converted to a digital code word by an analog-to-digital circuit in a process called pulse code modulation. The code word takes on a value from 0 through $2^N - 1$ where N is the code word size. Typical values for N range from 8 to 16 depending upon the degree of resolution required. The sample rate is determined by the bandwidth of the underlying analog signal. By the Nyquist sampling theorem, the sensor needs to be sampled at a rate at least twice the signal bandwidth, although sample rates at least five times the signal bandwidth are often used to allow for higher quality signal reconstruction and additional signal processing. In PCM systems, one needs also to specify the data encoding method and the time multiplexing format. Data encoding determines the channel transmission characteristics, and the multiplexing format determines the signal sampling discipline.

Data Encoding. The data format for transmission represents a trade-off among occupied bandwidth, data clock recovery, and immunity to phase reversals. As part of the overall telemetric system specification, the data encoding methodology needs to be specified. Typical data formats used in space telemetry systems include

- NRZ-L: Different voltage levels are assigned for logic 0 and logic 1 values, and the voltage level does not change during the bit period.
- NRZ-M: The voltage level remains constant during the bit period, and a level change from the previous level occurs if the current data value is a logic 1; no change is made if the current data value is a logic 0.
- NRZ-S: The voltage level remains constant during the bit period, and a level change from the previous level occurs if the current data value is a logic 0; no change is made if the current data value is a logic 1.
- Bi-ϕ - L: The NRZ-L signal is modulo-2 added with the data clock to show the logic level during the first half of the bit period and its complement during the second half of the bit period.
- Bi-ϕ - M: A level change is made at the start of the bit period, and a second change is made for the second half of the bit period if the logic level is a 1.
- Bi-ϕ - S: A level change is made at the start of the bit period, and a second change is made for the second half of the bit period if the logic level is a 0.

The M and S representations are called differential waveforms and are generally considered immune to phase reversals for correct decoding. However, the NRZ-M and NRZ-S techniques suffer from a higher error rate because when a single bit error occurs during transmission, two bit errors occur upon detection. Despite this higher error rate, the phase reversal immunity is considered a greater advantage, and differential NRZ encoding is frequently used. The L representations require correct phase determination to recover the data correctly. The Bi-ϕ representations generally require twice the transmission bandwidth of the NRZ representations. However, they have better clocking capabilities. Because of this, typical space telemetry transponders will have specifications detailing the maximum number of consecutive 0 or 1 values and the minimum number of transitions in a block when NRZ coding is used.

Data Packaging. For transmission from the spacecraft to the ground station, the data needs to be packaged to allow for synchronization, error detection, and accounting of data sets. Additionally, data may need to be tagged for routing to specific analysis centers. To accomplish this, data are typically packaged into one of two formats: telemetric frames and telemetric packets.

Telemetric frames are based on time-division multiplexing of the spacecraft sensor data for transmission across the space channel. Each sensor is transmitted at least once per frame cycle; more critical data is transmitted at a higher rate. The telemetric frame is based on a highly structured format that has embedded synchronization codes and accounting information to allow quick synchronization and verification of the transmission of all data. Normally, the frames are sent continuously to keep the channel filled to maintain synchronization and detect link dropouts. If link dropouts occur, the repeating, structured pattern of the frames allows rapid receiver resynchronization once the signal returns. The IRIG-106 standard developed for missile and aeronautical telemetry is often used in the space channel as well. The frames are processed in software upon reception using a database that shows the location of each sensor value in the overall frame structure and applies any necessary calibration to convert the raw PCM code value back to a meaningful datum.

As link reliability increases, a different philosophy for data packaging can be considered. Computer networking technology developed for ground telecommunications networks has been used as the basis for developing packet telemetric systems. The advantage of the packet system over the frame-based system is that the transmission can be more easily customized to the needs of the data sources, not sending data merely to maintain a fixed sampling discipline. The packets also allow distributed data processing.

The Consultative Committee for Space Data Systems (CCSDS) packet format is based on a structure consisting of a header that contains data source and destination information and other related system information. The body of the packet contains the data. Following the data, error detection, correction codes, and other information can be added. This packet system has been successfully used on many spacecraft, and commercial vendors supply standard ground station hardware for processing CCSDS packet telemetry.

Modulation. Once the telemetric data are packaged in a frame or packet format, they are transmitted across the radio link using some form of modulation. There are a large number of permutations for radio modulation depending upon mission needs, power requirements, and data rates. In this section, we examine the basic technologies used in data transmission.

The PCM/FM and PCM/PM techniques are often used in missiles and sounding rockets even today. The technique first uses the PCM technique

to sample the data. The data are encoded using one of the data formats described and are placed in telemetric frames. Finally, the baseband data is routed to the input of either a frequency modulator (FM) or phase modulator (PM) for transmission. The advantage of using FM and PM is the constant envelope signal on the output.

The PCM/PSK/PM technique is an extension of the PCM/PM technique. The PCM output is used as the input to a phase shift keying (PSK) modulator. The PSK process used is binary PSK (BPSK) modulation which is a DSBSC AM process described by

$$s(t) = \sqrt{E}d(t)\cos(\omega t) \tag{1}$$

where ÖE is the normalized signal strength, $d(t)$ is the PCM output data as a function of time, and ω is the PSK subcarrier frequency. This technique has been used, for example, in the Voyager telemetric system. The additional PM modulation step provides two advantages. First, the technique allows mixing other subcarriers with the PSK data stream to provide a total composite signal. This technique also maintains a constant transmission envelope that can be important when transmitting through nonlinear amplifiers.

The use of the PM modulator does add a degree of system complexity, so that data transmission at the PSK modulator output level is frequently used. In the PSK system, many different combinations give different efficiencies (bandwidth and performance). These PSK techniques are supported in the standard TDRSS transponder hardware.

Binary-phase shift keying (BPSK) was described before. BPSK transmits one PCM bit per channel symbol and is the simplest of the PSK techniques. It also has the lowest transmission efficiency.

Quadrature-phase shift keying (QPSK) can be considered as two orthogonal BPSK channels transmitted at the same time. The transmitted signal takes two of the PCM bits at a time and forms a single channel symbol, where the channel symbol changes state every two bit periods. The two channels are called the "in phase" or I channel and the "quadrature phase" or Q channel. There is a total of four possible carrier phase states in QPSK, where the carrier is described by

$$s(t) = \sqrt{E_i}d(t)_i\cos(wt) + \sqrt{E_q}d_q(t)\sin(wt) \tag{2}$$

where ÖE_j are the normalized signal strengths, $d_i(t)$ and $d_q(t)$ are the PCM output data as a function of time, and ω is the PSK carrier frequency. In the TDRSS system, the relative I and Q channel signal strengths can be varied; typical values are 1:1 for equal strength and 1:4 for nonequal strength. These are defined by the user profile when using the TDRSS system.

The QPSK modulation technique allows the possibility that the channel symbol state can cause a 180° phase shift. This can cause undesired harmonic generation in nonlinear amplifiers. To mitigate against this, a delay is added to one of the two bits used to form the channel symbol that keeps phase changes to a maximum of 90°. This technique is called offset QPSK (OQPSK). It is also known as staggered QPSK (SQPSK). The transmitted signal is then described by

$$s(t) = \sqrt{E_i}d(t+T)_1\cos(wt) + \sqrt{E_q}d_q(t)\sin(wt) \tag{3}$$

and the variables are as described for QPSK. The delay of one bit period T is seen added to the in-phase data channel. Upon reception, a similar delay is added to the quadrature-phase channel to bring the two bits back into alignment.

In many payloads, there are two independent PCM data streams: one for health and welfare data and one for high-rate scientific data. The TDRSS system allows considering the I and Q channels as two independent data channels that have different data rates on each. This form of transmission is called unbalanced QPSK (UQPSK). This technique has the advantage that it does not send the low-rate channel at the higher data rates, thereby degrading performance. The system also has the advantage of OQPSK that it does not have frequent 180° phase shifts. The mathematical description for the carrier is the same as that given before for QPSK.

By applying waveform shaping to the I and Q data signals used in the QSPK modulation signal, a form of frequency shift keying is made. The Advanced Communications Technology Satellite used the minimum shift keying (MSK) technique. The carrier can be described by

$$s(t) = d(t)_i\cos\left(\frac{\pi}{t}2T_b\right)\cos(wt) + d_q(t)\sin\left(\frac{\pi}{t}2T_b\right)\sin(wt) \tag{4}$$

where T_b is the bit period. The data filtering functions are half-period sinusoids. This technique can be demodulated by using a coherent QPSK demodulator.

The wireless communications industry is using another form of filtered QPSK called Gaussian minimum shift keying (GMSK). Instead of sinusoidal filter functions, Gaussian-shaped filters are used to prefilter the data before mixing with the carrier. The MSK techniques are being examined because of their transmission bandwidth efficiency compared with QPSK. A related, patented form of filtered QPSK developed by Feher is currently being evaluated for telemetric systems. This FQPSK modulation system uses proprietary filter functions in a manner similar to GMSK. Preliminary results indicate that it has an improved spectral efficiency for data transmission. Tests are currently being conducted within NASA and the U.S. DoD to evaluate this technique for ground and space telemetric systems.

Data Transmission. Several techniques are used for transmitting this modulated RF signal from a spacecraft to the ground. The original, and still most common, method is direct transmission to receiving antennae on the ground. These transmissions may be initiated by ground command or instructions stored onboard or may be broadcast continuously. Signals are usually directed to specific TT&C stations, although transmission of some types of meteorological data, for example, is simply broadcast to all interested users. For weak signals, ground antennae are occasionally arrayed to provide increased gain. Another technique increasingly used is relay through another satellite, usually one in geosynchronous orbit (see TDRSS section following). This technique involves a space-to-space cross-link in addition to the relay-sat-to-ground link, but it offers several advantages. Communications with Earth-orbiting satellites are possible almost any time, any place. (Depending on specific geometry, some limitations may exist in polar regions.) This avoids the need for a large network of ground stations. Such ground networks are usually expensive to build and operate and are subject to disruption due to local political and environmental conditions. It also centralizes the point of data reception on the ground, avoiding the need for subsequent terrestrial relay. Although cross-links can present some technological challenges, they also offer freedom from interference and interception.

Like the evolution of tracking data handling described before — and for similar reasons — telemetric data is usually transferred from the ground receiving station to a central facility for processing. Even though the telemetric data rates of today are greatly increased, economical hardware exists to perform much of this processing in a "black box" in real time at the ground station. However, as will be discussed under Future Trends, other factors limit this evolution.

The characteristics of the transmission medium and path are different in the space-to-ground link and in the terrestrial link from the ground station back to the control and central data handling centers. Although the latter was sometimes HF radio in very early days, it is normally satellite or coax/fiber today. These differences reflect directly that the "best" protocols for the terrestrial link are different from those for the space-to-ground link. Thus, the ground receiving station is required either to reformat the data, or commonly, encapsulate the first protocol into the second, increasing overhead.

As the Internet has grown, considerable interest is developing in using standard Internet data protocols (Transmission Control Protocol/Internet Protocol, TCP/IP) in spacecraft. This is still a research area, but there is considerable interest among scientific investigators and systems designers in providing Internet-to-space support. The ground-based TCP/IP protocols have some recognized difficulties in the space environment. For example, the long link delays and relatively high channel error rates lower the throughput of these protocols. To mitigate against these effects, research is currently ongoing into modifications of TCP/IP for space. Progress is also being made within CCSDS to develop the Space Communications Protocol System (SCPS) that is based on the TCP/IP protocol stack but modified for use in the space channel environment.

As part of the long-term trend for space communications, system designers are investigating the application of commercial telecommunications technology to space communications. This emphasis comes from two drivers: the need to reduce system cost and the need to use system bandwidth better. By using commercial telecommunications satellites and associated ground networks, spacecraft operating costs can be reduced because infrastructure costs may be shared with commercial users. The need to use more efficient modulation techniques has led system designers to consider techniques used in the wireless industry. Modulation techniques

such as GMSK and FQPSK were designed for the commercial wireless communications industry. The FQPSK technique is currently being evaluated within the U.S. Department of Defense for use in missile and aeronautical telemetry. Their relatively higher bandwidth efficiency over PSK methods makes them good candidates for use in constrained-bandwidth environments for space as well.

Data Processing. Telemetry was originally processed in decommutators that were essentially giant patch panels, reconfigured for each spacecraft. As computing power grew, processing was accomplished using software in mainframe computers. (Like IBM, many space pioneers found it difficult to advance beyond this stage.) The next step was use of application-specific integrated circuit (ASIC) technology. As ASIC technologies became practical, they proved much more efficient for repetitive processes such as telemetric processing than general purpose machines controlled by software. Also, processing in chips rather than mainframes permitted substantial increases in throughput telemetric rates, avoiding the need for expensive buffering to reduce processing rates. (They also proved considerably more reliable because most operating failures were in the connections.) The current state of the art is to use programmable gate arrays — combining the speed of a hardware approach with the flexibility of a software solution. Numerous vendors now offer such products.

Processing of data is often broken down into four levels: Level 0 through Level 3. Though the Level 0 step is still common, it is primarily an artifact of reel type onboard data recorders. Data were recorded serially onboard onto a recorder for playback (dump) to a ground station when one was in view. This data was then usually dumped with a reverse playback — avoiding the need to rewind and cue the recorder. The Level 0 function is to remove the space-to-ground transmission protocols, restore the reversed data stream to its original direction, and separate the various multiplexed parameters into their original components. Level 1 data processing involves appending axillary data from other sources, such as orbit and attitude data. Levels 2 and 3 processing require active involvement and judgment of the scientists in analyzing and presenting the data. Levels 1 through 3 are normally considered part of scientific data processing rather than the ground data-handling function.

The solid-state recorders increasingly used on spacecraft today, of course, do not need to be dumped in the reverse direction. Second, data can be read out of the recorder in any desired sequence, obviating the need to demultiplex a serial data stream on the ground. Third, using economical hardware and relatively simple software, space-to-ground protocols can be stripped and data reformatted for terrestrial transmission in realtime, even at 100-Mbps rates. This effectively obviates the need for Level 0 processing. Using GPS for onboard orbit determination, as described earlier, similarly obviates this Level 1 step.

Error-Correction Coding

Error-correcting coding has been studied by theorists since Shannon's work in the late 1940s. Error-correcting coding techniques became widely used in space communications in the 1970s with the advent of good techniques by Viterbi and Fano for decoding convolutional codes. Current data services used with NASA's Deep Space Network and the TDRSS network permit the user to select from standard error-correction coding techniques.

Forward Error-Correcting Codes. Transmission over the space channel introduces errors into the data stream. The goal for space-to-ground transmission accuracy for most telemetric data has historically been a bit error rate (BER) of 10^{-5}, or no more than one error in 100,000 bits. (For comparison, coax and fiber generally deliver data at BERs better than 10^{-10}.) Two basic techniques are used for recovery: request a retransmission of the data, or add an error-correcting code to the data. On missions that have long propagative delays, requesting retransmissions often reduces the data throughput to unacceptably low levels. Thus the error-correction technique is usually preferred because it requires less memory and processing capabilities on the spacecraft.

Here, we discuss the two common error-correcting coding techniques used in space systems. They permit correction of the data upon reception, so they are called forward error-correcting (FEC) techniques. They accomplish this task by adding redundant information to the transmitted data. This implies that a higher transmission rate is needed and consequently more transmission bandwidth to achieve the same raw data throughput. This is considered acceptable when achieving a much higher data quality. The FEC can permit the system to operate as if it had a 3- to 6-dB higher received signal-to-noise ratio that it actually has — a significant benefit.

The FEC that has the longest history in space communications has been convolutional coding. This has been used on missions since the 1970s and even for deep space missions like Voyager. The convolutional encoder is built around a fixed-length shift register whose length is known as the constraint length K. Once each bit time, a new data bit enters the shift register, and multiple outputs are computed as a function of the current shift register contents. Typically two or three outputs are generated for each bit time, giving rise to a rate one-half or rate one-third coding. A Viterbi decoder is used to decode the data and correct for transmission errors. NASA requires that all S-band services on TDRSS use a rate one-half convolutional encoder. Typically the constraint length is $K = 7$. TDRSS also supports the rate one-third coding, but it is not part of the CCSDS recommendations.

The Reed–Solomon coding technique is a form of block coding where the data stream is partitioned into fixed-length blocks and redundant information is added to the end of the block to form the transmitted signal. Reed–Solomon block coding is characterized by the number of information symbols and the number of code symbols in a transmitted block. The CCSDS recommends Reed–Solomon encoding using transmitted blocks of 255 total symbols that have 223 information symbols in the block. This is written as a (255,223) R–S code.

The CCSDS standards recommend using Reed–Solomon codes either by themselves or in conjunction with convolutional codes, as discussed in the following section. The TDRSS does not support Reed–Solomon decoding as a basic service but will pass encoded data to the user for decoding. Reed–Solomon codes can be used without convolutional coding through TDRSS if Ku-band services are being used, but not in the S-band services.

Concatenated Coding. It is known that the output of the Viterbi decoder produces errors in a burst pattern. To compensate for this, missions can use a concatenated coding technique. First, a Reed–Solomon code is applied to the data stream to form what is known as the "outer code." These coded data are then encoded with a convolutional or "inner code." The convolutional code removes the bulk of the channel transmission errors, and the Reed–Solomon code removes the burst errors from the convolutional decoder. The CCSDS recommendation for concatenated coding is to use a (255,223) R–S outer code with a rate one-half, $K = 7$ convolutional inner code.

A recently discovered coding technique called turbo codes has begun to be seriously investigated for application in space communications, http://www331.jpl.nasa.gov/public/JPLtcodes.html. These codes were first published in 1993. They have the advantage of providing performance near the Shannon limit for channel performance, even at low signal-to-noise ratios. Recent experiments have shown cases with TDRSS where the ground station receivers could not lock onto the signal in low SNR environments even though the symbol decoding was still functioning. Turbo codes are based on convolutional codes on the encoding side and are decoded using iterative solution techniques in the receiver. Current research involves determining optimal code structures and decoding techniques for use in the space channel.

Command

Command is essentially the reverse of telemetry: digital data is modulated in one of several ways on the uplink carrier. Basic differences are that data rates are much lower, and transmission integrity is usually more critical because these data normally control the spacecraft. The command system generally can be thought of as providing instructions for the onboard spacecraft systems to initiate some action. Two classes of command strategies are commonly used in modern spacecraft: single command words and command files. Many early spacecraft command systems were basically tone response systems, that is, when a given tone of a specific frequency was received by the spacecraft, a specific action was undertaken. Tone commands are still often found in rocket command destruct systems.

CCSDS has published standards used by many programs. Differences are primarily in the intermediate transmission path between the originating control facility and actual transmission from the RF transmitter. Some concepts transmit the command message directly from the control center in "real time," whereas others stage it at intermediate points such at the remote ground station. In the latter case, it is error checked and stored at this intermediate location, awaiting a transmit instruction either as a function of time or on electronic or verbal instruction from the control center. A "command

echo" is frequently used for verification: a receiver at the ground antenna detects the command on the RF link, which is returned to the control center for comparison with the intended command structure. The term "command" is often used to describe all signals modulated on the uplink signal; however, such uplinks can include both analog and digital voice communications with astronauts, and video uses are planned in the future.

The command word will typically look like a binary computer instruction that has a system address, command instruction number, and command data value. Sometimes the command will use a simple check sum for error detection. Other error check strategies that have been used in spacecraft include repeating the command bits twice and then performing a bit-wise check for agreement before executing. In all cases, the command received word would be echoed in the telemetric data stream as a specific telemetric word, so that the operator could check for command validity. The spacecraft would be configured for two possible modes of command acceptance: execute the command upon passing the received error check, or wait until a ground operator sends an execute command after verifying that the operational command was correctly received. In operations, routine commands would be executed immediately upon passing error validation. Commands that could be dangerous for spacecraft operations, for example, firing a thruster or exploding pyrotechnic bolts, would have the operator in the loop. The operator would wait for the configuration command to be correctly echoed in telemetry and then would send the execute command to initiate the actual operation.

Command files are more appropriate for sequences of operations, especially those for a spacecraft beyond Earth orbit. For example, the Voyager planetary encounters would operate by loading a file of command sequences for camera settings and spacecraft attitude before the encounter where the communication times could be in excess of hours. The operators would verify that the file had been loaded into the spacecraft memory by playing back the memory through the telemetric stream. Any transmission errors could be corrected before the encounter, and then the spacecraft would operate in automatic mode, without immediate operator interaction, during the encounter. The structure of the commands within the files can resemble those found in the individual command mode. The file organizes the commands for bulk transmission.

All of the modulation and coding techniques used for telemetric transmission apply to command transmission as well. In general, very sophisticated FEC is not done because of onboard processing limitations. However, parity checks or check sums are often used to identify command errors. For low Earth orbit (LEO) operations, repeating commands that are found in error is often sufficient.

TDRSS Relay Satellite

In the mid 1970s, NASA began developing a communications and tracking network in space — the Tracking and Data Relay Satellite System (TDRSS). The basic concept was demonstrated during the Apollo Soyuz Test Project mission using the Applications Technology Satellite ATS-6. By using the relay satellite concept, communications with a fixed ground station for LEO satellites can be increased from 5 to 10 minutes per contact at a fixed ground station to more than 85% of the total orbit time. (The TDRSS concept used a single ground station that had two active relay satellites located above the horizon of this station. This resulted in a "zone of exclusion" on the opposite side of Earth that had no coverage. This ZOE region was later covered by another relay satellite, using a second ground station, to meet the needs of the CGRO satellite, and increased TDRSS coverage to 100%.)

TDRSS was first seen as just another station of the STDN, except that it was located in the sky. However, technical differences such as signal levels and Doppler rates made it clearly a very different kind of station. The primary motivation for building TDRSS was economic, more for cost avoidance than cost reduction. Costs of upgrading the STDN to meet Space Shuttle needs, it was estimated, would be more than the cost of developing and deploying a relay satellite system. A second consideration was political; operations at ground facilities on foreign territory were disrupted several times by political disputes. The first TDRSS satellite was launched in April 1983. It was stranded halfway to geosynchronous altitude by an explosion of its upper stage rocket, but by using its tiny maneuvering thrusters, eventually it reached its operational location over the Atlantic that summer. Launching the second satellite was the objective of the ill-fated Challenger mission in January 1986. Completing the TDRSS constellation was a high priority because so many new programs depended on it. Thus, the third satellite was aboard Discovery in September 1988 on the first Shuttle mission after Challenger. It was completely successful; four more spacecraft have since been successfully launched.

From technical and performance standpoints, TDRSS has proven outstanding. In addition to supporting users at standard S-band frequencies, TDRSS provides a high-frequency service in the Ku-band region and commercial service at C-band. (This commercial service was added by the spacecraft contractor to spread the costs of the satellites and thus reduce costs.) This complex system has demonstrated its ability to relay data at more than 400 megabits per second from user spacecraft virtually anyplace over Earth. Each relay satellite can communicate with two high-rate users simultaneously, and the system can handle an additional 20 low-rate users. This low-rate system — termed multiple access — was one of the first systems to successfully use code division multiple access (CDMA) techniques that permit multiple users to share the same radio spectrum and is now employed in some cellular phone systems. TDRSS provides more than six times the global coverage of the ground network it replaced, at data rates six times as high. It enables real-time contact virtually anytime, anyplace — an especially valuable feature of the relay satellite approach. It also has unanticipated applicability to small systems and has been successfully used with high-altitude balloons, with aircraft to relay real-time infrared images for forest fire fighting, and with handheld transmitters for voice and data.

A fixed price procurement approach was selected even though extensive development was needed, and NASA became directly responsible for launching the satellites. Thus, substantial government–industry cooperation was required in the face of a somewhat adversarial contractual relationship. Another significant challenge was that of dealing with two distinctly different cultures: a communications industry accustomed to a highly regulated environment and the engineering focused aerospace industry. The difficulties were more complex than can be summarized here; interested readers are referred to Aller, R.O. Issues in NASA Program and Project Management. From a program perspective, the TDRSS system was deployed late and cost more than original estimates. Even so, the cost of augmenting the STDN for the Shuttle was avoided, and closing most of the STDN in the 1980s and shifting to TDRSS actually reduced costs. Amortized development and launch costs plus operating expenses of the TDRSS are less than the operating costs alone would have been for the ground network it replaced.

NASA procured three follow-on TDRSS spacecraft in the mid-1990s. Hughes (now Boeing) won the competition with a design based on its HS-601 bus. An artist's rendition of this design is shown in Fig. 2. The first of this series was successfully launched in 2000. http://msl.jpl.nasa.gov/QuickLooks/tdrssQL.html

Radio-Frequency Spectrum Issues

By the nature of space operations, "wireless" communications links are necessary. Thus ground data-receiving facilities are strongly influenced by radio spectrum issues. The International Telecommunication Union (ITU) was established in 1865 (as the International Telegraph Union). The ITU is now under the United Nations and endeavors to coordinate radio spectrum use internationally. Radio waves have no respect for political boundaries, so this coordination has become critical. As transmitters and receivers moved from terrestrial locations into the air and then into space, signals radiate far more of Earth. As the private sector sought to capitalize on the economic potential of freedom from "wires" that technology subsequently enabled, extreme pressures have developed for spectrum allocations. This stage and the extremely rapid development of associated technologies presented an especially vital but difficult challenge to the somewhat cumbersome ITU processes. Not surprisingly, these pressures have focused on the lower frequencies. Technology is more proven in this region, and signal characteristics such as power, directionality, and interference favor this region for widespread commercial use. Because wave-lengths are longer, hardware manufacturing tolerances are also less critical and costs are reduced.

For largely these same reasons, space activities initially operated in the lower frequency regions, primarily the VHF region. However, factors such as interference from other RF users in this region and the need for greater bandwidth slowly drove space programs to vacate this region in favor of higher frequencies. NASA chose the S-band region, transmitting uplinks near 2100 MHz using downlinks above 2200 MHz. Some other U.S. agencies elected to downlink at these same frequencies, but to transmit

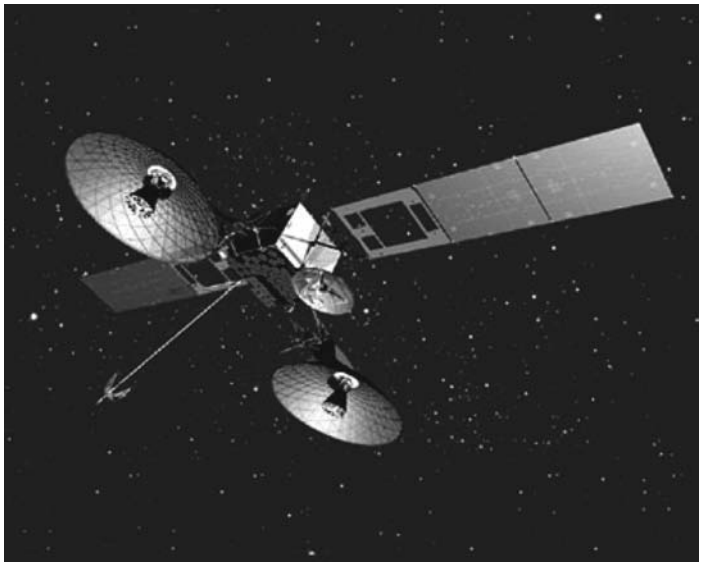

Fig. 2. Second generation of NASA's TDRSS spacecraft, used for tracking and communications with most near-Earth-orbiting spacecraft. From geosynchronous orbit, the two large movable antennae each provide communication at high data rates with spacecraft far below. A phased array antenna on the Earth-facing panel permits simultaneous communications with 20 users at lower data rates. The small dish antenna relays signals to/from the ground control station in New Mexico. (*NASA*)

at lower frequencies (L-band, near 1700 MHz). This S-band spectrum was originally allocated internationally for space use in a footnote to the allocations table, specifically noting that such use was permitted on a secondary basis. This secondary allocation meant that use must not interfere with the use of this spectrum by those holding primary allocations and that conversely, holders of secondary allocations had no recourse if primary users interfered with them. Interestingly, this applied to programs such as NASA's Apollo and Space Shuttle programs: their primary operating frequency was authorized only as a secondary allocation, legally subject to these previously stated constraints. (Note that deployment of the TDRSS relay satellite had an interesting effect on this situation because TDRSS transmits downward to low Earth-orbiting satellites at the normal uplink frequency and conversely, receives signals transmitted upward at the downlink frequency.)

This intense competition for spectrum, together with need for additional bandwidth and desire for primary allocations, is driving space programs to adopt higher frequencies — mostly in the Ku and Ka-band regions. Initial use of optical frequencies is also being considered. Technologies for these higher frequencies is not as mature as those for lower frequencies, but they do offer advantages in bandwidth and in the power and weight of communications terminals in space. Disadvantages, in addition to less mature technologies, include the need for high pointing precision of antennae and susceptibility to atmospheric interference, especially rain and clouds. Certainly, costs of necessary modifications to the ground infrastructure inhibit these moves to higher frequencies.

Future Trends

As has been said, predictions are difficult, especially about the future! Tempting as it is to focus on the evolution of relevant technologies as the indicator of future trends, history suggests that sociological factors soon dominate technology and economics. Recall that for years after technology replaced the steam locomotive with diesel power, railroads retained firemen even though they no longer had boilers to stoke! Early TT&C facilities had the characteristics of "infrastructure," and infrastructures are especially adept at self-preservation, aided by the detachment from their customers. We will attempt to place data-receiving and data-handling facilities in the context of the historical evolution of technology and from this perspective identify factors determining trends. Finally, we will hazard some guesses about near-term trends.

Typically a technology evolves from an era of a few specialists proficient in using it, through one where the process becomes increasingly understood, standardized, and automated, so that necessary expertise and skill levels drop. Eventually tools become available that those unskilled in this particular technology can readily use to meet their needs. Entrepreneurs see market potential and derive new, more efficient products and processes by employing the technology. However, progress is frequently intermittent as other factors come into play. Those finding careers, organizations, and profits threatened summon political and industrial support to resist change, and efforts at standardization are soon caught up in competitive battlegrounds. Note that much of the early effort necessarily involved "inventing" the needed data-receiving and data-handling facilities. The entities formed for this purpose specialized in designing, rather than using, solutions. Once created, these entities usually strive to reinvent custom solutions for each application, rather than using or adapting existing alternatives.

Technologies that existed early in the space age determined the technical approaches for meeting satellite communications and data-handling requirements, and more importantly, they also determined the structure of the organizations and processes for meeting these requirements. Yet, technology seldom conveniently evolves within the boundaries of established management and fiscal structures. Matters that should be simple engineering issues whose solutions are submerged in silicone, for example, instead become contentious interorganizational issues. Few comprehend the technical implications as technology expands across borders, and interpersonal relationships — influenced by individual, provincial, and fiscal interests — dominate resolution.

The result of this confluence of technological, sociological, and political realities is that future trends are dominated by the heritage of the particular organization. New players usually adopt the latest economical technology and employ commercially available solutions when they enter the arena; thereafter they become increasingly bound by their own heritage. The pace and direction of technology limit advancement, but they are only two factors determining future directions. Implicit in this hypothesis is the view that few of the concepts and facilities commonly used today for receiving and handling space data from satellites are state of the art. Prudent conservatism is certainly warranted. Challenges of adopting state-of-the-art technologies are that performance risks are often increased due to immature development, costs are usually relatively high in the early stages, and amortization of changeover costs is difficult to justify. However, if a truly competitive marketplace develops using a given technology, this usually stimulates the private sector to evaluate objectively the economics of advances in that technology.

Although the expanding technologies of communications and computing are often said to be converging, semantics must be understood. Many of the recent advances in communications result from computing advances: the ability, effectively and economically, to digitize, package, route, and unpack material being moved. Transmitter and receiver advances, especially at higher RF frequencies as well as optical, contribute directly to space operations. (Other communications technology advances such as fiber are very significant, of course, but are not directly applicable to space-to-ground communications.) Considering the computing aspect, approaches that combine the speed of a hardware approach with the flexibility of a software solution, as now offered by programmable gate arrays, will become dominant. Chip technology offers tremendous increases in processing speed over the old mainframe approach, due in part to the small dimensions.

Other prognostications: space programs will rely increasingly on navigation satellites (GPS, Glonass, Galileosat) to determine orbit onboard. A TCP/IP-like transmission protocol such as SCPS, adapting to the space channel environment, will probably become popular. Use of embedded chips at the points of application greatly streamline data processing, allowing eliminating some previously required no-value added steps such as transport to centralized facilities. Techniques such as turbo codes that promise to perform near the Shannon limit, even under low signal-to-noise ratio conditions, will be pursued. Constraints on spectrum and bandwidth will focus attention on more efficient modulation techniques, such as FQPSK. Spectrum competition and the need for additional bandwidth are also driving space programs to higher frequencies — mostly in the Ku- and Ka-band regions. Optical transmission will become a serious contender for the space-to-ground channel — circumventing RF spectrum restrictions, avoiding RF interference, and permitting increased security. Technology is improving the power limitations of light transmitting diodes, and spatial diversity (multiple receiving sites) will avoid cloud cover. Adoption of customized commercial hardware and software solutions in preference to unique solutions will greatly increase, especially among new users. Even

noncommercial users will gravitate in this direction. Numerous, mostly small, vendors now offer space operations products commercially and competitively.

EARTH POINT. The point where the forward straight-line projection of a meteor trajectory intersects the surface of the Earth.

EARTH RADIATION BUDGET (ERB). See **Nimbus Satellite Program**.

EARTH RADIATION BUDGET EXPERIMENT (ERBE). An experiment to obtain data to study the average radiation budget of the Earth and determine the energy transport gradient from the equator to the poles. Three satellites were flown in different orbits to obtain the data: the Earth Radiation Budget Satellite, ERBS (launched in October 1984), NOAA-9 (launched in December 1984), and NOAA-10 (launched in September 1986).

See also **Television and Infrared Observation (TIROS)**.

EARTH RADIATION BUDGET SATELLITE (ERBS). See **Space Science Missions: Earth**.

EARTH-RATE UNIT (ERU). A unit of angular drift, as of a gyro, equal to the rate of angular movement of the Earth with respect to the stars, 15° per hour.

EARTH SCIENCE ENTERPRISE (ESE). International research program to understand earth's environment as a system. A major challenge of ESE is to observe, understand, model, assess, and eventually predict global change. Meeting this challenge will help to evaluate the impact that human activity (e.g., clearing forests and burning fossil fuels) has on our environment, and to distinguish human-induced changes from the effects of natural events (e.g. volcanic eruptions, erosion).

NASA's ESE uses space-, aircraft-, and ground-based measurements to provide the scientific basis for understanding global change. The program will produce long-term global maps of clouds, land and ocean vegetation, atmospheric ozone, sea-surface temperature, and other global processes necessary to understand the state of the Earth and to detect any patterns of change. This information will be available to scientists and policy makers through the Earth Observing System Data and Information System (EOSDIS).

The centerpiece of NASA's ESE will be the Earth Observing System (EOS), a series of satellites planned for launch beginning in 1999. Measurements from EOS will be complemented by the Earth Probes, a series of discipline-specific satellites and instruments designed to observe Earth processes where smaller platforms and/or different orbits from EOS are required. Planned Earth Probes will measure tropical rainfall, ocean productivity, ozone, and ocean surface winds.

In addition, ESE includes current NASA Earth science missions collecting important data on the global environment, such as the Upper Atmosphere Research Satellite (UARS) and the Ocean Topography Experiment (TOPEX/POSEIDON), Space Shuttle experiments such as ATLAS, and aircraft campaigns. See also **Earth Observing System (EOS)**; **Earth Observing System Data and Information System (EOSDIS)**; and **Satellites (Scientific and Reconnaissance)**.

EARTH'S RATE CORRECTION. A command rate applied to a gyro to compensate for the apparent precession of the gyro spin axis with respect to its base caused by the rotation of the Earth.

EARTH SYSTEM SCIENCE PATHFINDER (ESSP) PROGRAM. The Earth System Science Pathfinder (ESSP) Program addresses unique, specific, highly-focused mission requirements in Earth science research. The ESSP program is an innovative approach for addressing Global Change Research by providing periodic "Windows of Opportunity" to accommodate new scientific priorities.

The ESSP missions are the cornerstones of a dynamic and versatile program consisting of multiple Earth system science space flights which include *The Gravity Recovery and Climate Experiment (GRACE); Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO); CloudSat; Orbiting Carbon Observatory (OCO)* and *Aquarius*. The ESSP program is characterized by relatively low to moderate cost, small to medium sized missions that are capable of being built, tested and launched in a short time interval. These missions are capable of supporting a variety of scientific objectives related to earth science, including the atmosphere, oceans, land surface, polar ice regions and solid earth. Investigations include development and operation of remote sensing instruments and the conduct of investigations utilizing data from these instruments.

The ESSP Program is responsible for the management, direction and implementation of these science investigations. These ESSP missions encompass the entire project life-cycle from definition, through design, development, integration and test, launch, operations, science data analysis and distribution.

ESSP missions are peer-reviewed science investigations selected from proposals submitted in response to biennial Announcements of Opportunity (AO's) released by the Office of Earth Science. They consist of a series of small, quick turnaround, frequent (launch rate of one or more per year), low-cost missions lead by a Principal Investigator (PI). At least two ESSP missions are selected from each AO. The PI is responsible for science integrity, for assembling the team for complete mission implementation, and is accountable for mission success. The team may include university, industry, government, Federally Funded Research and Development Centers (FFRDC) and international partners as desired by the PI. ESSP missions are spaceborne Earth science investigations which encompass the total life cycle from concept definition, through operations, data product generation, distribution and archiving. NASA mission costs for each ESSP mission are capped. The project management for ESSP missions follows a streamlined approach, (e.g., standard industry practices and procedures) to the maximum extent possible.

ESSP Missions

Gravity Recovery and Climate Experiment (GRACE). The primary goal of the GRACE mission is to accurately map variations in the Earth's gravity field over its 5-year lifetime. The GRACE mission has two identical spacecrafts flying about 220 kilometers (137 miles) apart in a polar orbit 500 kilometers (311 miles) above the earth. See Fig. 1. The GRACE twin

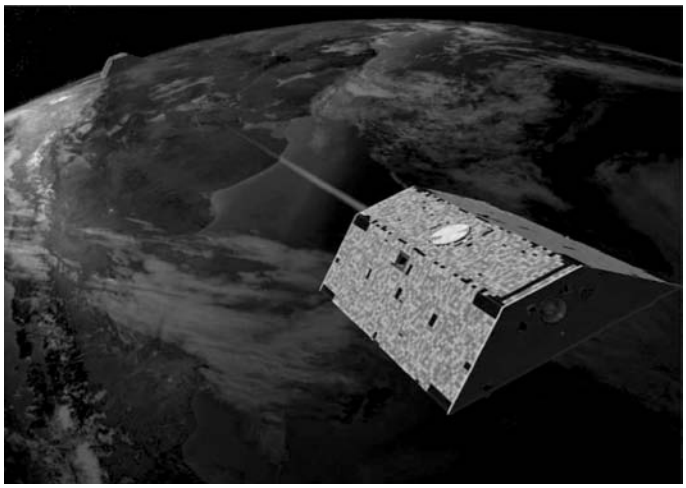

Fig. 1. Orbiting Twins –The GRACE Satellites.

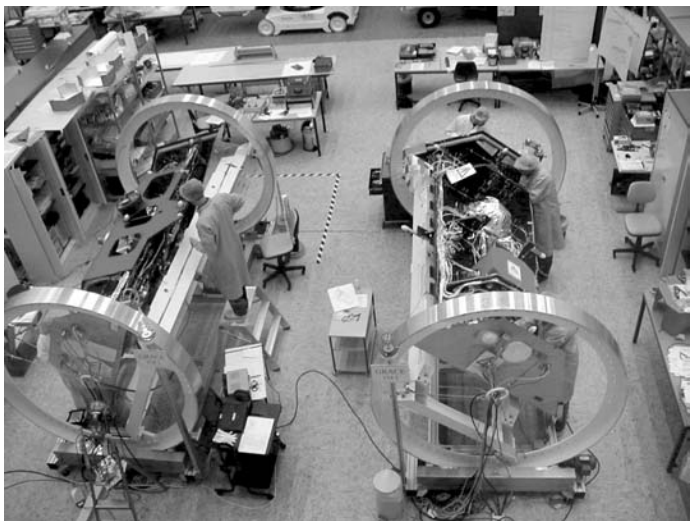

Fig. 2. GRACE Satellites during the assembly phase.

satellite mission was launched on March 17, 2002 aboard the ROCKOT launch vehicle from Plesetsk Cosmodrome, Russia.

They will map the Earth's gravity fields by making accurate measurements of the distance between the two satellites, using geodetic quality Global Positioning System (GPS) receivers and a microwave ranging system. This will provide scientists from all over the world with an efficient and cost-effective way to map the Earth's gravity fields with unprecedented accuracy. The results from this mission will yield crucial information about the distribution and flow of mass within the Earth and its surroundings.

The gravity variations that GRACE will study include: changes due to surface and deep currents in the ocean; runoff and ground water storage on land masses; exchanges between ice sheets or glaciers and the oceans; and variations of mass within the earth. Another goal of the mission is to create a better profile of the Earth's atmosphere. The results from GRACE will make a huge contribution to NASA's Earth science goals, Earth Observation System (EOS) and global climate change studies.

GRACE is different form most Earth observing satellite missions — Terra and Aqua for example — because it doesn't carry a suite of independent scientific instruments on board. It does not make measurements of the electromagnetic energy reflected back to it from the Earth's surface. Instead, the two GRACE satellites themselves act in unison as the primary instrument. Changes in the distance between the twin satellites are used to make gravitational field measurements.

The two identical satellites orbit one behind the other in the same orbital plane at an approximate distance of 220 kilometers (137 miles). As the pair circles the Earth, areas of slightly stronger gravity (greater mass concentration) will affect the lead satellite first, pulling it away from the trailing satellite, then as the satellites continue along their orbital path, the trailing satellite is pulled toward the lead satellite as it passes over the gravity anomaly. The change in distance would certainly be imperceptible to our eyes, but an extremely precise microwave ranging system on GRACE is able to detect these minuscule changes in the distance between satellites. A highly accurate measuring device known as an accelerometer, located at each satellite mass center, will be used to measure the non-gravitational accelerations (such as those due to atmospheric drag) so that only accelerations caused by gravity are considered. Satellite Global Positioning System (GPS) receivers will be used to determine the exact position of the satellite over the Earth to within a centimeter (1/4 inch) or less. Members of the GRACE science team can download all this information from the satellites, and use it to construct monthly maps of the Earth's average gravity field during the mission. See Fig. 2.

The key spacecraft components include: *K-band Ranging System (KBR)* which provides precise (within 10 μM) measurements of the distance change between the two satellites needed to measure fluctuations in gravity; *Ultra Stable Oscillator (USO)* which provides frequency generation for the K-band ranging system; *SuperStar Accelorometers (ACC)* which precisely measures the non-gravitational accelerations acting on the satellite; *Star Camera Assembly (SCA)* which precisely determines the two satellites' orientation by tracking them relative to the position of the stars; *Coarse Earth and Sun Sensor (CES)* which provides omnidirectional, reliable, and robust, but fairly coarse, Earth and Sun tracking. Used during initial acquisition and whenever GRACE operates in safe mode; *Center of Mass Trim Assembly (MTA)* which precisely measures the offset between the satellite's center of mass and the "acceleration-proof" mass and adjusts center of mass as needed during the flight; *Black-Jack GPS Receiver and Instrument Processing Unit (GPS)* which provides digital signal processing; measures the distance change relative to the GPS satellite constellation; and *Globalstar Silicon Solar Cell Arrays (GSA)* which covers the outer shell of the spacecraft and generates power.

GRACE is a joint partnership between the NASA in the United States and Deutsche Forschungsanstalt fur Luft und Raumfahrt (DLR) in Germany. Dr. Byron Tapley of The University of Texas Center for Space Research (UTCSR) is the Principal Investigator (PI), and Dr. Christoph Reigber of the GeoForschungsZentrum (GFZ) Potsdam is the Co-Principal Investigator (Co-PI). Project management and systems engineering activities are carried out by the Jet Propulsion Laboratory.

Management of the GRACE Project is further delegated among the following five systems.

Satellite System (SAT). JPL led the development of the Satellite System in partnership with Space Systems/Loral (SS/L) and Astrium GmbH (AGmbH). Engineers at JPL developed the GPS receiver and laser retroreflective assembly. AGmbH provided major elements of two flight satellites based on an existing small satellite designed for the CHAMP mission. SS/L provides the attitude control system, microwave instrument electronics and system and environmental testing.

Science Instrument System (SIS). The SIS is managed by JPL and includes all elements of the inter-satellite ranging system, the GPS receivers required for precision orbit determination and occultation experiments, and associated sensors such as the Star Cameras. This System also coordinates the integration activities of all sensors, assuring their compatibility with each other and the satellite.

Launch Vehicle System (LVS). The LVS was managed by the Launch Vehicle System Manager DLR and supported by JPL and its contractors. The LVS includes the ROCKOT launch vehicle, multi-satellite dispenser, and the personnel, test equipment and facilities for preparation, integration and launch of the satellites. See also **ROCKOT Launch Vehicle**.

Mission Operations System (MOS). The MOS consists of facilities and resources of the German Space Operations Center (GSOC), tracking antennas at Weilheim and Neustrelitz, and other stations and facilities needed for supporting launch and early orbit procedures (LEOP) and contingency operations. These facilities are used to monitor and control the satellite, perform initial processing of the telemetry data, and deliver all data to the SDS for further processing and generating science products. In addition to real-time operations, the MOS function provides the Central Checkout System for ground testing using command and data interfaces. The operations team also monitors satellite performance and health throughout the duration of the mission. Mission operations are conducted at the GSOC control center in Oberpaffenhofen, Germany.

Science Data System (SDS). The SDS functions include science data processing, distribution, archiving and product verification. The SDS is

a distributed entity and managed in a cooperative approach by JPL and UTCSR in the US and GFZ in Germany. The cooperative approach includes sharing of processing tasks, harmonization of product archives and validation/comparison of products. Data and products to be processed and archived by the SDS include corrected inter-satellite range and accelerometer measurements, GPS orbit and occultation data, orbit, gravity field and GPS occultation products. The SDS also receives, processes and archives ancillary data (e.g. meteorological fields) necessary for data processing and verification.

Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO). The Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) was launched on April 28, 2006 aboard a Delta II Launch Vehicle from Space Launch Complex 2, Vandenberg Air Force Base, California, to study the impact of clouds and aerosols on the Earth's radiation budget and climate. CALIPSO is flying in formation with five other satellites in NASA's "A-Train". See also **Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO)**.

CloudSat. CloudSat is an experimental satellite designed to measure the vertical structure of clouds from space. The instrument on the satellite will produce detailed, three-dimensional images of cloud structures which will contribute to better predictions of clouds. See also **CloudSat**.

Orbiting Carbon Observatory (OCO). After launch in 2008, the OCO mission will collect precise global measurements of carbon dioxide (CO_2) in the Earth's atmosphere. Scientists will analyze OCO data to improve our understanding of the natural processes and human activities that regulate the abundance and distribution of this important greenhouse gas. This improved understanding will enable more reliable forecasts of future changes in the abundance and distribution of CO_2 in the atmosphere and the effect that these changes may have on the Earth's climate.

The Jet Propulsion Laboratory, http://www.jpl.nasa.gov/ will lead the OCO effort. Orbital Sciences Corporation, http://www.orbital.com/ and Hamilton Sundstrand Sensor Systems will partner with JPL to realize this vital mission.

See also **Orbiting Carbon Observatory(OCO)**.

Aquarius. Aquarius is a focused satellite mission to measure global Sea Surface Salinity (SSS). Its instruments will measure changes in SSS equivalent to about a "pinch" (i.e., 1/6 of a teaspoon) of salt in 1 gallon of water. By measuring SSS over the globe with such unprecedented precision, Aquarius will answer long-standing questions about how our oceans respond to climate change and the water cycle. For example, monthly SSS maps will give clues about changes in freshwater input and output to the ocean associated with precipitation, evaporation, ice melting, and river runoff. Aquarius data will also be used to track the formation and movement of huge water masses that regulate ocean circulation and Earth's climate.

The mission will be led by principal investigator Dr. Gary Lagerloef of Earth & Space Research, http://aquarius.gsfc.nasa.gov/science.php. Goddard Space Flight Center (GSFC) will build and calibrate the highly accurate radiometers that are crucial for the detection of ocean salinity. Jet Propulsion Laboratory (JPL) will design and build the scatterometer that helps to minimize measurement errors due to sea surface roughness. JPL will manage the mission until launch when GSFC assumes this duty. Data processing, dissemination, and archiving tasks will be shared between GSFC and JPL.

NASA will partner with the Argentine space program CONAE on the Aquarius mission, building on a successful long- standing relationship between NASA and Argentina. Multiple universities and corporate and international partners will be involved in the Aquarius mission.

Aquarius is named after the Water Bearer constellation because of its objective to explore the role of the water cycle in ocean circulation and climate. Aquarius is scheduled to launch in 2009 and will orbit the earth for at least three years, repeating its global pattern every 7 days. Within two months, Aquarius will collect as many sea surface salinity measurements as the entire 125-year historical record from ships and buoys, and provide measurements over the 25 percent of the ocean where no previous observations have been made.

EARTH TECTONICS AND EARTHQUAKES. The Earth is an energetic, dynamic planet that is continuously, if ever so slowly, changing. Profound and extremely important changes have occurred since the planet was formed an estimated $4\frac{1}{2}$ billion years ago. Paleomagnetic and paleoseismic evidence, dating back only some one-half billion years, reveal how the shapes and juxtaposition of the continents and oceans have changed during the most recent 10% of the Earth's total life span to date.

Because these changes take place at such a *slow* rate, the human inhabitants of the Earth tend to develop the mistaken impression that, as they admire the magnificent landscape and seascape, the familiar features are forever, so to speak. The life span of a human is essentially *infinitesimal* on the time scale of the planet's changing events. Were it not for an occasional major earthquake or volcanic eruption, most persons would be oblivious of the gigantic forces and physicochemical processes at work under the Earth's crust.

The 1994 Northridge, California earthquake of magnitude 6.6+ (Richter scale) occurred in southern California in the San Fernando Valley, south of the San Gabriel Mountains and north of the city of Los Angeles. Thousands of aftershocks, some strong, occurred over a period of several days after the initial shock. Casualties were fewer than 100. Property damage was estimated in the billions of dollars. Great inconvenience, and interruption of normal living and the economy, of Greater Los Angeles resulted mainly from the creation of thousands of homeless citizens and extensive damage to the region's freeways. Although scientists did not regard the Northridge event as the "Big One," predicted for so many years, some seismologists turned their attention to the possibility of a number of previously undetected faults located directly under the downtown and outlying regions of Greater Los Angeles — sources of weakness unrelated to activity along the much-studied San Andreas Fault.

Studies of the Earth's early history fall within the broad province of *geochronology*, but are assisted in major ways by other applied sciences, such as seismology, radioactivity analysis, geomagnetics, probability and statistical analysis, volcanology, and orogeny, among many other technical disciplines.

Modern earthquake science and volcanology are largely guided by a relatively recent concept (1960s) known as *plate tectonics*. With this concept, scientists now have a basic physicochemical mechanism/process against which prior concepts can be tested and new hypotheses, working within the framework of plate tectonics, can be proposed. This is precisely what has been transpiring over the recent past — namely, that some aspects of the earlier assumptions of plate tectonics are being revised and refined with the help of new observational data. This research is being enhanced continuously through greatly improved field sensors, transmission systems, computer-assisted simulations, and laboratory techniques for determining the ultimate physical properties, such as the use of the diamond anvil high pressure cell, and also by the high temperatures achieved with laser beams.

Plate Tectonics

Although the theory of plate tectonics is a comparatively recent development, it followed a slow but logical development, in essence, since the early mapmakers of the Earth, dating back to the 1400s and 1500s (Period of the Great Explorers).

Concept of Continental Drift. Obviously, early mapmakers were persons of keen curiosity and advanced intellect for their time. As maps of the Earth were developed, particularly those involving most of the oceans and continents, questions arose as to why the boundaries of the continents and oceans essentially had matching images (i.e., the eastern borders of a continent tended to match (in jigsaw puzzle fashion) the western borders of another continent). This would have been particularly noticeable in the matching of the eastern edge of South America with the western edge of Africa. Such matching could not be ascribed simply to coincidence or chance. However, years went by and it was not until Francis Bacon, in 1620, made formal mention of the provocative geographical correspondences, but he did not theorize on a possible cause. A few other curious scholars, however, introduced some very generalized scenarios, including the case of sinking *Atlantis*.[1] Long before the full development of the plate tectonic theory, a visionary meteorologist, Alfred Wegener of Berlin, in 1912 proposed the hypothesis of *continental drift*. At that time,

[1] A fabled island in the Atlantic that, according to legend, was submerged beneath the sea.

Wegener's concept was not amenable to the then-prevailing theory of the structure and maturing of the Earth. The model[2] then popular claimed that, after the Earth was formed from a molten state, it cooled, becoming solid inside — with heavy elements, such as iron, sinking to form a solid core and lighter elements rising to form a surface crust upon cooling. Essentially accurate regarding some aspects, the model did not explain the mechanism of continent and ocean formation, nor how the joining of or the drifting apart of continents affected the ultimate tectonic nature of the Earth's surface. Wegener did find considerable evidence for his hypothesis in the form of "matching" fossils, animals, and geological features. See Fig. 1.

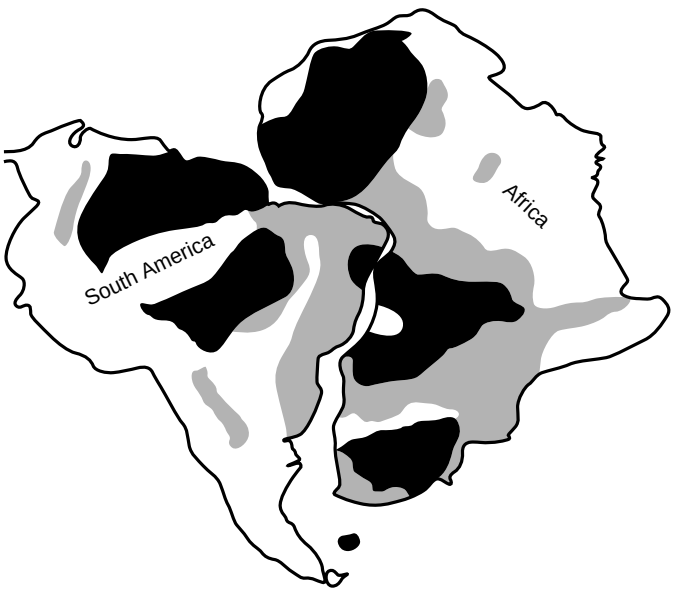

Fig. 1. Very approximate depiction of how Wegener believed Africa and South America were nestled prior to slowly drifting apart. Black areas represent regions of continental structure that ultimately broke during the separation of the continents. Similarly, regions of crust (shown in gray), most of which also indicate as being part of essentially a continuous land mass prior to drifting away from each other. Wegener demonstrated quite well his premise of continental drift, but did not explain the mechanism behind the movement of continents. Thus, his theory did not embrace the full concept of plate tectonics. [*Diagram is patterned after A. Hallam. (See reference)*.]

Some contemporary researchers feel that Wegener came pretty close to developing the plate theory, but was limited by a lack of precise instruments, inadequate surveying techniques, and to a degree, he was just a few decades ahead of his peers. In the excellent A. Hallam article (see reference), there is a review of Wegener's lifetime contribution to geophysical science.

Distribution of the continents over many millennia of time has been suggested by a number of researchers. One concept suggested by Wegener was that, at one time in the Earth's development, land masses comprised a supercontinent, which he referred to as *Pangea*. See Fig. 2.

Plate Tectonics Simplified. The Earth model based on the concept of plate tectonics describes the surface of the planet (biosphere, ecosphere, etc.) as supported by underlying large, broad, and thick plates that are composed of continental and oceanic crust and materials from the upper mantle. Because, in essence, these plates "float" on an underlying viscous material of the mantle, they have the ability to move, much as a ship may move on the ocean. Thus, unlike a soundly engineered structure, such as a building or bridge, which is supported by a strong, reliable foundation upon which the structural integrity of the building depends, the foundation supporting the Earth's surface layer is not so rigid and dependable. To carry the analogy one further step, one may visualize a large building, one side of which rests on a movable platform and the other side of which rests on another movable platform. The platforms may move in the same general direction at different rates; or they move in opposing directions.

[2] Developed by G.K. Gilbert (United States Geological Survey) and H. Reed (Johns Hopkins Univ.), 1906.

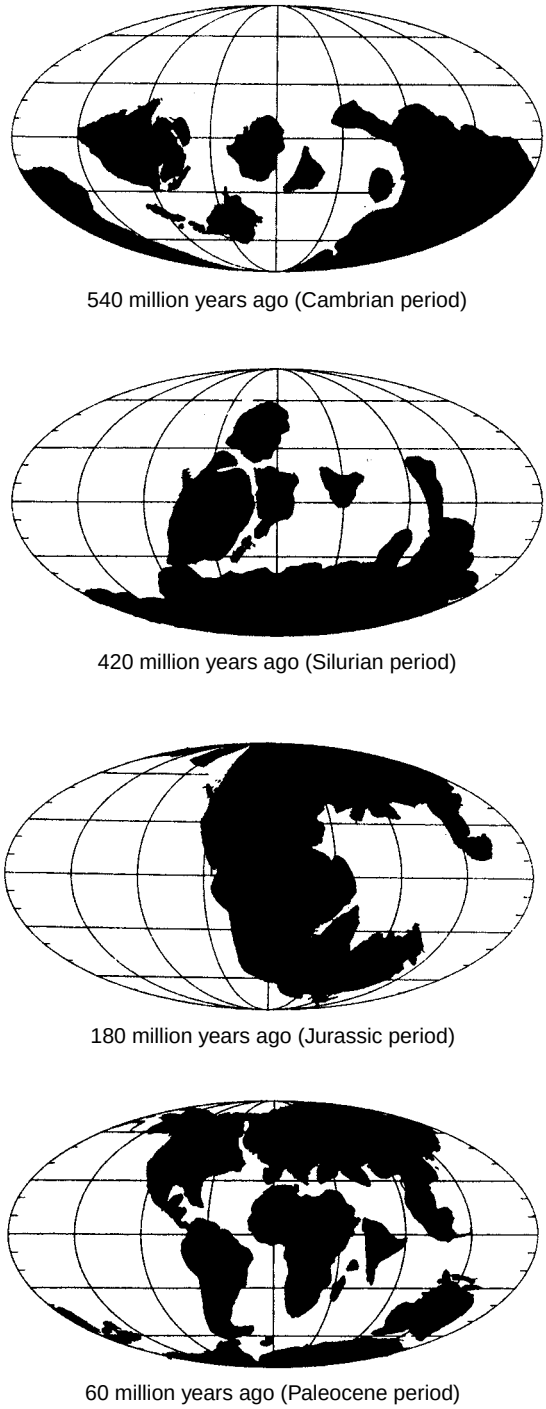

Fig. 2. Abridged and simplified facsimiles of the distribution of continents and oceans on Earth based upon paleomagnetic evidence dating back 540 million years. A series of more detailed, computer-generated maps was prepared by researchers in connection with the University of Chicago Paleographic Atlas Project. (*See also Siever (1983) reference*.)

In any case, if the platforms do not move in complete synchronism (a condition not found in plate tectonics), the building will either move in on itself, devastatingly crushing one portion against the next; or parts of the building will move away from each other, causing equal damage.

Continents in total or in part are supported by separate plates, as indicated by the detailed map of Fig. 3. The plates move more or less independently and at rates measured in terms of a few centimeters per year. Like ships, the plates tend to bump one another, one plate rising over or subducting below an adjacent plate. They may grind away at each other like ice floes in a river. They are driven by energy coming from the phenomenon known as *seafloor spreading*. This is the hypothesis that the oceanic crust is increasing by convective, upwelling of magma along

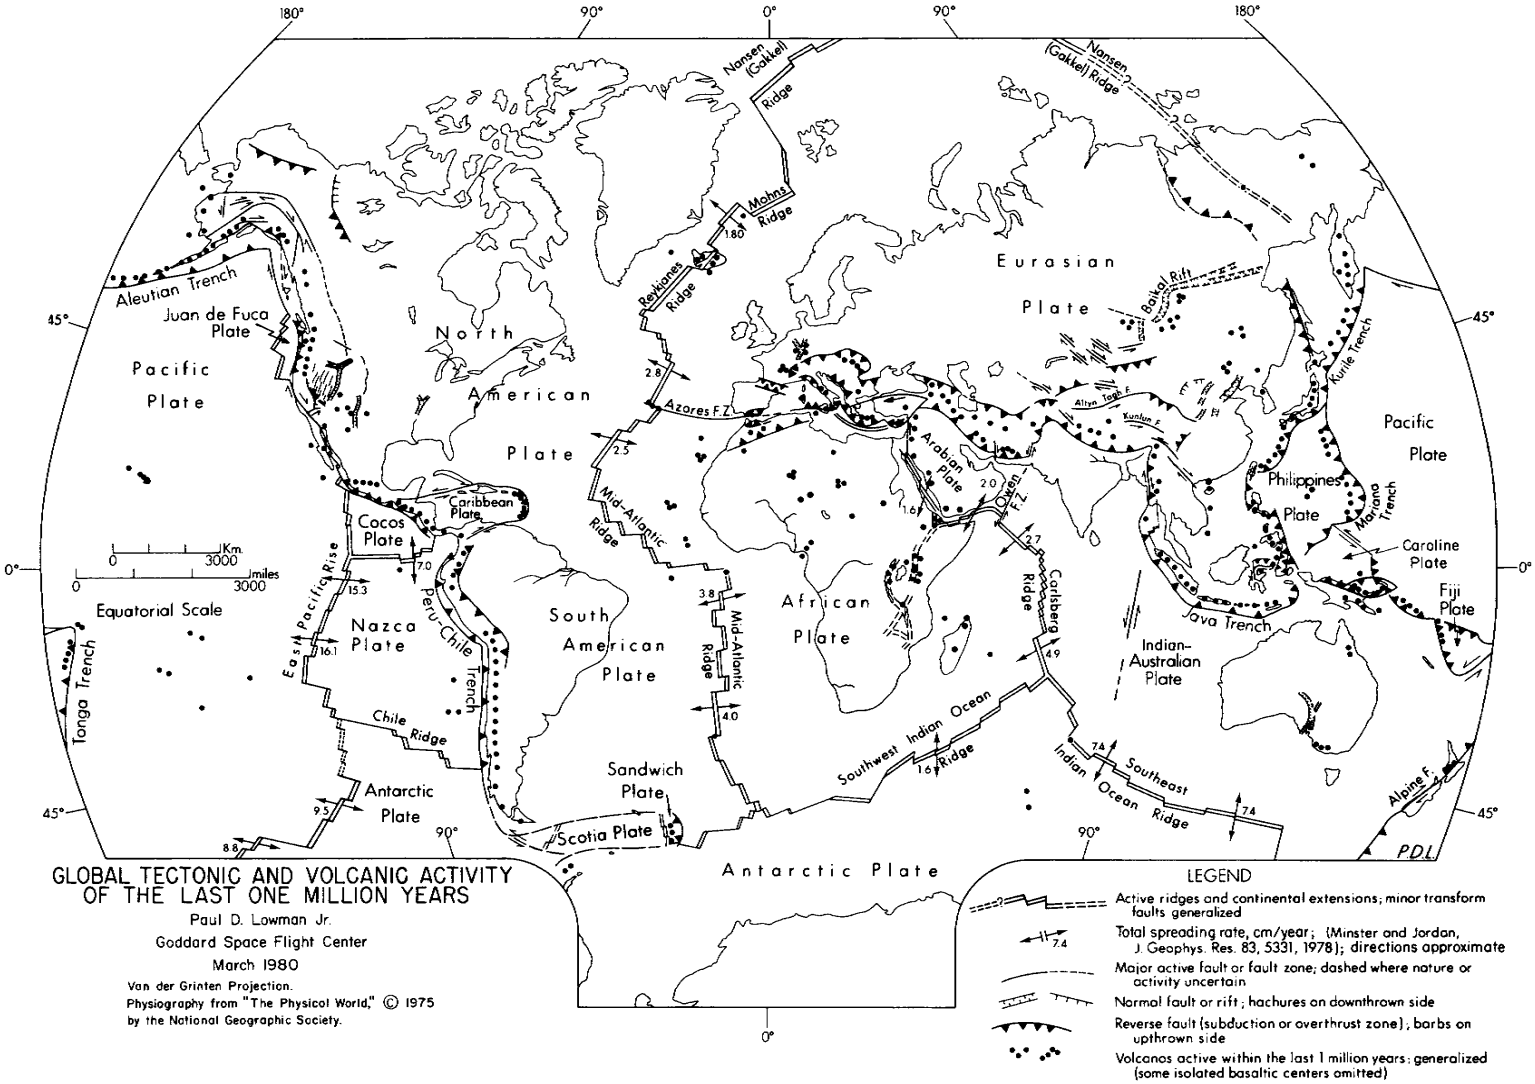

Fig. 3. Principal plates, ridges, and trenches according to the theory of global plate tectonics. The outer surface of the earth, just under the crust and known as the lithosphere, supports a number of rigid plates. These plates may be about 100 kilometers (62 miles) or more in thickness. The continents (about 40 kilometers; 24 miles thick) essentially rest on the larger lithospheric plates. In the case of the western United States, southern California is part of the Pacific Plate, whereas the rest of North America is on the North American Plate. The three main forms of plate boundaries are (1) mid-oceanic ridges, (2) transform faults, and (3) subduction zones. New crust is created along the mid-oceanic ridges by the rise of basaltic magma. This cools and is carried away by sea-floor spreading. The mechanism of seafloor spreading was conceived as the result of two important discoveries: (1) the mid-oceanic ridge system, and (2) the zebra-stripe pattern of magnetic anomalies which symmetrically flank these ridges. Studies of ocean floor rocks support a presumption that the sea floors are moving away from the mid-oceanic ridges.

Transform faults, along which the mid-oceanic ridges are offset, provide areas where the lithospheric plates can slide past one another. Subduction zones are the sites of destruction of the lithospheric plates. There are places in the ocean trenches where one oceanic plate descends beneath another. Should a second plate have a continental crust, then mountains would be inclined to develop along the continental margin, as exemplified by the Andes. Where two continental crustal plates collide, even greater mountain-building activity is created. Movement of plates so affects the crust that earthquakes, mountain building, and volcano formation become an intimate part of the system. A majority of volcanoes occur in arcs which are parallel to the oceanic trenches and are believed to result from one ocean crustal plate being subducted beneath another plate. Partial melting of the oceanic crust on the descending plate may occur as it passes onto the high-temperature athenosphere. Thus, magma ascends to the surface and forms volcanoes and underlying granitic batholiths. Volcanoes are also situated along the mid-oceanic ridges and, less frequently, over isolated “hot spots” in the athenosphere, exemplified by the Hawaiian volcanoes. See **Volcano**.

the mid-oceanic ridges or world rift system and moving away the newly created material at a rate of from 1 to 10 centimeters per year. See also **Oceanography**.

The forces moving the plates, although acting slowly, are relentless and where plates push together or pull apart, the strains set up in the materials so contacted build up steadily and slowly to very high values. Periodically, the time is reached when so much energy no longer can be stored (as strain) in the materials and fractures thus occur. Sudden bursts of released energy cause earthquakes. The manner in which plates interact to form volcanoes is similar and is described in the article on **Volcano**.

As indicated by Fig. 3, most of the Earth's seismic activity occurs at the boundaries of plates. The greatest seismic activity, the largest shocks, and the deepest shocks, occur at places where plates converge (the arcs such as Japan and Tonga), where one plate is thrust beneath another to depths at least as great as the depths of the deepest earthquakes. Where plates diverge (as along the Mid-Atlantic Ridge), or slide past one another (as along the San Andreas Fault in California), seismic activity is shallow, and although substantial, is usually not as great as that of the arcs. The global patterns of the focal mechanisms of earthquakes also fit, in general, the patterns of plate motion. Seismological evidence played an important role in the development of the concept of plate tectonics. See Fig. 4.

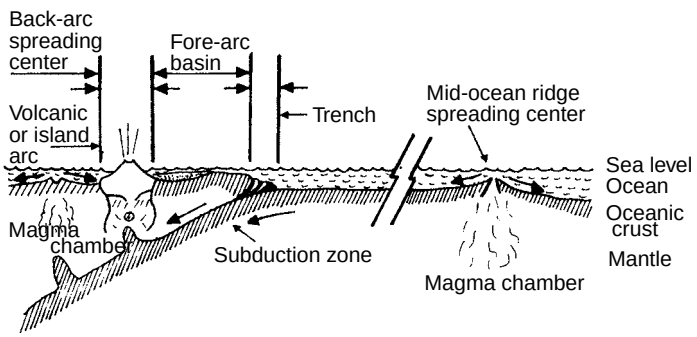

Fig. 4. Important features of plate tectonics. Examples are taken from the Mariana island-arc system. At depths of 90–100 kilometers (56–62 miles), the descending slab commences to melt and magma rises toward the surface, forming volcanic island arcs. The depressed area between the volcanic arc and trench gradually fills with sediments forming the *fore-arc basin*. Other magmas rise to the surface along the Mariana *back-arc basins*, creating a *spreading center* along which new crustal material forms at the surface. *Island arc* : Also known as a volcanic arc, an island arc is usually a chain of islands, e.g., the Aleutians, rising from the deep sea floor and near to the continents. *Trench* : A narrow, elongated depression of the deep-sea floor, with steep sides and oriented parallel to the trend of the continent and between the continental margin and the abyssal hills. Such a trench may be 2 or more kilometers (1.2 miles) or deeper than the surrounding ocean floor, and may be thousands of kilometers long. See also **Earth**; and **Ocean**. (*Sketch suggested by Davin and Gross, 1980.*)

It has been observed that most strong-motion earthquake data have been accumulated from events in California and Japan. California and Japan represent two different tectonic regions. The West Coast of the United States is not typical of continental margins. The primary seismic feature is the well-known San Andreas Fault, with its right lateral strike-slip movement (known as a transform fault). This is usually associated with mid-oceanic spreading ridges where it is of much shorter length and a consequence of the actual three-dimensional nature of the plates moving on the surface of the earth. The San Andreas Fault joins the spreading East Pacific Rise and the spreading zones of the Gorda and Juan de Fuca ridges to the north. The realization that the fault was of a transform type was first made by J. Tuzo Wilson (University of Toronto). Wilson recognized that a fault displacement of up to 1000 kilometers (620 miles) required some mechanism that allowed the displacements to occur while satisfying the laws for the conservation of matter. Because of the special nature of the relative movements between the Pacific Plate and the North American Plate, the San Andreas fault may be considered as an extension and a very large example of a mid-oceanic feature.

The majority of continental margin seismic activity stems from direct plate collisions, as exemplified by the activity along the Chilean coast. The focal depths, which are shallow off the coast, become progressively deeper as activity occurs further inland on the eastern side of the Peru-Chile trench.

The mechanism of seafloor spreading, considered to be the source of energy for moving the tectonic plates, is under continuous scrutiny by numerous geoscientists. Oceanographic investigations are revealing much new information on spreading and the formation of ocean ridges and trenches. Such research is exemplified by the current understanding of the nature and mechanics of the Cayman's Zigzag Rift. See Fig. 5. The actual mechanics of crustal formation are poorly understood. Early acoustic sound methods revealed very large zones of deep fracturing, fractures that stretch almost the width of an ocean. These form perpendicular to a ridge wherever one section of the ridge crest is offset horizontally from another. Fracturing also occurs on a very small scale. Such fracturing has been revealed by new instruments, such as side-scanning sonar. Small-scale cracking seems to result from thermal stresses during cooling. Johnson (University of Texas at Dallas) counted the cracks in a DSDP core recovered from 110-million-year-old crust in the Atlantic near Bermuda. It was found that the typical crack in the core was about 2 millimeters wide and 150 millimeters long, and that such cracks occurred about every 2 centimeters. Zones of intense cracking were found to occur through a 247-meter (810 foot) core. The end result of all this fracturing appears to be that the crust on and near the ridge crest is very permeable to water, possibly on the order of 20–25%.

Earthquakes

An earthquake may be defined as a sudden motion or trembling in the earth caused by the abrupt release of slowly accumulated strain. In certain locations of the world, earthquakes are to be expected — they are the rule, not the exception, as natural consequences of plate tectonics. Numerous variables affect the timing, the extent (magnitude) and exact location of an earthquake — hence they are difficult to predict. However, progress is being made. Synonyms for earthquake include: *Temblor* (sometimes spelled tremblor), *seism*, *macroseism* (as opposed to microseism), and *shock*.

Characteristics of Earthquakes

Aftershock. An earthquake that follows a larger earthquake, or main shock, and originates at or near the focus of the larger earthquake. Generally, major earthquakes are followed by a larger number of aftershocks, decreasing in frequency with increasing time. A series of aftershocks may last many days after small earthquakes; even months after large earthquakes.

Amplitude. This varies from a fraction of a centimeter to several centimeters. The destructive phase of an earthquake varies from one minute to but a few seconds. It is estimated that over the Earth there are over a million earthquakes each year, the majority of them occurring in regions of recent mountain building. The majority are quite weak. It is estimated that a major earthquake occurs on the earth about once per week. Tremors of the ocean bottom cause seismic sea waves (tsunamis). These sea waves have been known to rise 30 meters (100 feet) or more. When such waves break upon a densely inhabited coast, there is great loss of life and destruction of property. A list of major earthquakes in terms of lives lost is given in Table 7 under **Earth**.

Excluding certain near-surface regions, the velocities of dilative seismic waves range from about 5 kilometers per second in parts of the crust to a maximum of 13.5 kilometers per second at the base of the mantle; corresponding shear wave velocities range from 3 to 8 kilometers per second. The shortest periods of interest in the study of waves from distant earthquakes are of the order of $\frac{1}{3}$ second frequency (frequency = 3 Hz); the longest periods are about 53 minutes (frequency = $\sim$1 cycle per hour), and they correspond to a free oscillation of the earth in the fundamental spheroid mode.

Free oscillations of measurable amplitudes are generated only by the largest earthquakes. The largest earthquakes probably release between 10^{24} and 10^{25} ergs in the form of seismic waves, and the few largest shocks account for most of the energy released in this form. Mean annual release is estimated at 9×10^{24} ergs.

Deep Earthquake. In most earthquakes, the Earth's crust cracks like porcelain. Stress builds up until a fracture forms at a depth of a few kilometers and *slip* rock structure relieves the stress. A deep earthquake occurs hundreds of kilometers below the Earth's surface, i.e., down into the mantle where high pressure is believed to prevent rocks from cracking. Since 1989, more than 60,000 earthquakes at depths greater than 70 km (22% of all earthquakes) have been recorded. The subduction zone is the

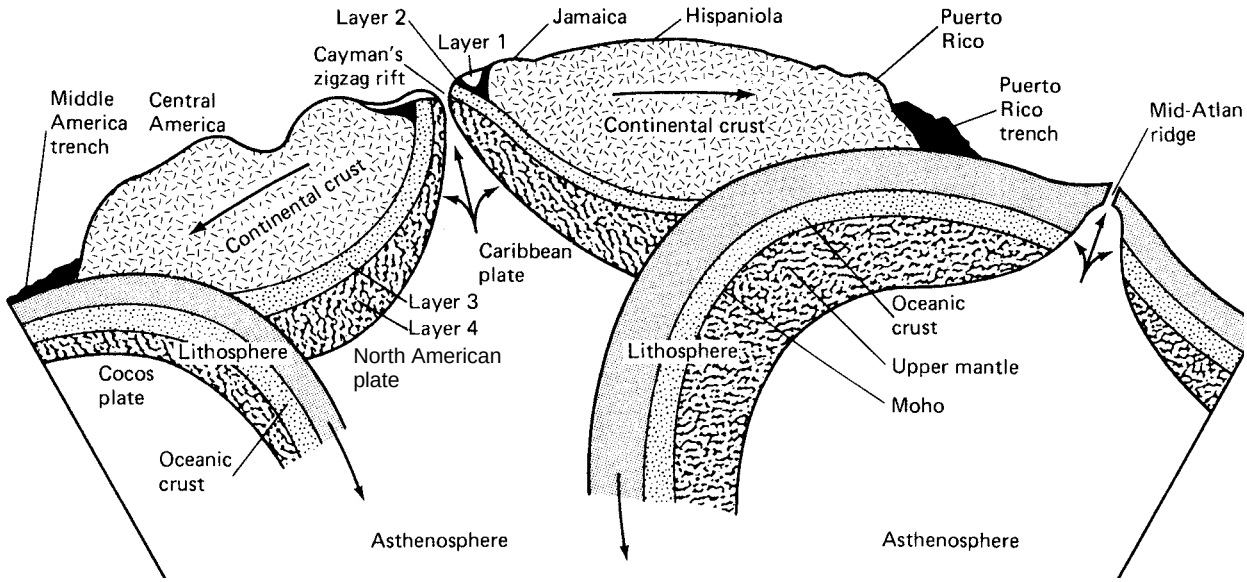

Fig. 5. The Cayman Trough off eastern Central America represents a great tear or shear in the ocean's crust. The trough is some 1500 kilometers (3052 miles) long and about 4 times the depth of the Grand Canyon. It is growing as two plates of the earth's crust (North American Plate and Caribbean Plate) slide past each other, but at a very slow pace. This tectonic action has created very large seismic events, including the February 1976 Guatemalan earthquake that killed some 23,000 people. As the plates separate, magma from the interior slowly rises into the rift valleys, thus continuously building oceanic crust. When plates collide, one edge plunges beneath the other, to be reabsorbed in the interior. Often volcanoes will be found along the overriding edge. Not to scale.

setting for nearly all deep earthquakes. There are numerous hypotheses pertaining to where and how the shock is created. One concept is based upon a sudden change of state, as temperature and pressure change with depth, from a plastic medium (loaded with energy) to a crystalline material capable of fracturing. Research in this area is in a comparatively early stage, and advantage is being taken of observing materials change under great pressures, as accomplished by the diamond anvil, and at very high temperatures, as effected by laser beams.

Earthquake Swarm. A series of minor earthquakes, none of which may be identified as the main shock, occurring in a limited area and time, frequently in the vicinity of a volcano.

Epicenter. That point on the Earth's surface directly above the focus of an earthquake.

Fault. A surface or zone of rock fracture along which there has been displacement from a few centimeters to a few kilometers in scale.

Foreshock. A tremor that commonly precedes a larger earthquake or main shock by seconds to weeks (possibly years) and that originates at or near the focus of the larger earthquake.

Focal Sphere. An arbitrary reference sphere drawn about the focus of an earthquake, to which body waves recorded at the Earth's surface are projected for studies of earthquake mechanisms.

Focus. That point within the Earth that is the center of an earthquake and the origin of its elastic waves. Sometimes called hypocenter.

Hidden Earthquake. A seismic event that occurs on a blind fault under folded terrain.

Isostasy. The state of equilibrium within the Earth's crust that is buoyantly supported by the plastic materials in the mantle.

Magnitude/Energy. See later paragraphs in this article.

Seismic. A term used to describe anything pertaining to an earthquake or earth vibration.

Seismograph. An instrument for recording vibrations of the Earth, particularly of earthquakes or artificially induced energy for the exploration of underlying rock formations and the interior of the Earth. The record produced by a seismograph is a *seismogram*.

Seismography. The study of the theory of seismographs.

Seismology. The study of earthquakes and, by extension, the investigation of the depths of the Earth (as in the case of oil and gas exploration) by way of measuring and analyzing natural or artificially generated seismic signals.

Strike-slip. Movement parallel with the strike of a fault, Subduction Zone.

Strike-slip Fault. A fault showing predominantly horizontal movement parallel to the strike; an absence of vertical displacement.

Subduction Zone. Area of crustal plate collision where one crustal block descends beneath another, marked by a deep ocean trench caused by the bend in the submerging plate. Downward movement of the subducting plate results in earthquakes, volcanoes, and intrusions on the far side of the trench.

Tremor. A minor earthquake, specially a foreshock or an aftershock.

Tsunami. A gravitational sea wave produced by any large-scale, short-duration disturbance of the ocean floor, principally by a shallow submarine earthquake, but also by submarine earth movement, subsidence, or volcanic eruption, It is characterized by great speed of proportion (up to 950 km/hr), long wavelength (up to 200 km), long period (varying from 5 minutes to a few hours), generally 10 to 60 minutes, and low, observable amplitude on the open sea, although it may pile up to great heights (30 meters or more) and cause considerable damage on entering shallow water along an exposed coast thousands of kilometers from the source. Also known as a seismic sea wave.

Faults. Generally considered to be a great fracture of the earth along which movement has taken place, with the result that the crustal blocks are displaced relative to one another. This movement, in most cases, appears to be intermittent and the actual individual displacements may be very small, but by accumulation may reach tens, hundreds, or rarely thousands of feet (meters). The fractures themselves may often be traced for many miles. The San Andreas fault, horizontal movement along a portion of which caused the earthquake that so severely damaged San Francisco, California, in 1906, has been traced for about 600 miles (965 kilometers).

In describing faults (See Fig. 6), certain terms have been adopted. Those in most common use are given herewith: the *fault plane* is the plane of the fracture and may be vertical or at some other angle; the angle between the fault plane and the horizontal is called the *angle of dip of the fault plane*. The angle between the vertical and the fault plane is spoken of as the angle of hade or simply as the hade of the fault. The surfaces of the fault plane are called the *walls of the fault*. If the fault plane dips, the uppermost wall is called the *hanging wall,* the lower wall the *foot wall*. These terms are applied irrespective of whether the fault is normal, with the hanging wall slipping down the dip of the fault plane, or whether it is a reverse fault with the hanging wall apparently pushed up the dip of the fault plane. A normal fault is sometimes spoken of as a *gravity fault*. The displacement measured along the fault plane is designated as the *slip*; the displacement measured vertically is called the *throw*; the displacement measured at right angles to the plane of the involved stratum is called the

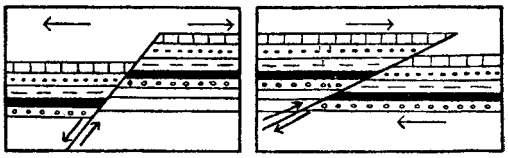

Fig. 6. Structure sections of a single normal fault (left); and simple thrust fault (right).

stratigraphic throw. The amount of horizontal displacement between the ends of a broken stratum measured at right angles to the direction of strike of the fault plane, is called the *heave*. The visible evidence of the trace of a fault plane at the earth's surface is called the *fault trace*. The block of the earth's crust that has moved downward, relatively speaking, to the other is called the *downthrown block* or referred to as the *downthrow side* of the fault. The other block is called the *upthrown block* or the *upthrow side* of the fault. If the strike of the fault plane is essentially at right angles to that of the bedding it is called a *dip fault*. A *strike fault* is one in which the movement has been parallel to the strike of the strata involved. A *compound fault* involving several parallel displacements dipping in the same direction, resulting in a step-like arrangement, is referred to as a *step fault*. The term *graben* or *trough fault* refers to a downthrown area bounded on each side by two or perhaps more faults. A *horst* is an uplifted area bounded by two or more faults. See Fig. 7.

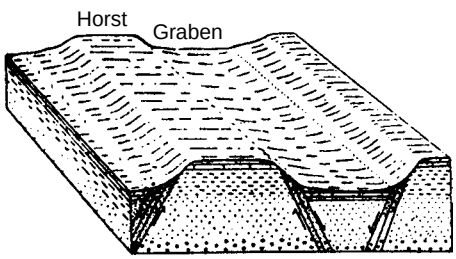

Fig. 7. Block diagram of one type of scenery produced by "normal" or block faulting. It may also be assumed that the graben has been pushed down, and the horst has been pushed up. Neither structure is necessarily entirely the result of tension. Note that the stratigraphic (vertical) order of the formations has not been duplicated or reversed.

Considerably more information on the characteristics of faults in various regions of Earth is given later in this article.

Public Reactions to Earthquakes

The majority of earthquakes that occur on the Earth are not detectable by people. In relating Richter Scale magnitudes to the size and energy of an earthquake, the following figures apply:

4.5	Detectable within 20 miles of epicenter. Possible slight damage within a small area.
6	Moderately destructive.
7	A major earthquake.
8	A great earthquake.

The frequency of occurrence of earthquakes increases by about a factor of 8 or 10 per unit of magnitude as *the magnitude decreases*. On the average, only about 25 shocks with a magnitude of 7 or more occur each year, but it has been estimated that there are at least one million earthquakes per year, most of them quite small. About 5,000 to 10,000 of these are routinely located and studied.

Quite understandably, earthquakes that cause major losses of life and property provoke the greatest attention. However, earthquakes of even greater magnitude may occur in relatively isolated areas; these are principally of concern to seismologists.

Three parameters are important in assessing an earthquake: (1) Duration of the earthquake; (2) velocity of the surface movement; and (3) the rate of change of this velocity. In their potential for damage, these three factors are closely related. Some of these relationships are immediately obvious. A very short earthquake of high velocity — only one or two cycles of ground motion — is less damaging than an earthquake causing similar motion for many cycles. An earthquake with high acceleration but low velocity is less damaging than one causing higher velocities. As part of an effort to develop seismic design standards for buildings and structures, these factors have been combined in a map, which tentatively characterizes potential earthquake risk in terms of acceleration and velocity throughout the United States. Participants in this development were the American Society of Civil Engineers, the University of California (Seismographic Station, Berkeley), and the Massachusetts Institute of Technology (Department of Civil Engineering). Efforts are sponsored by the National Science Foundation and the U.S. National Bureau of Standards. See Fig. 8.

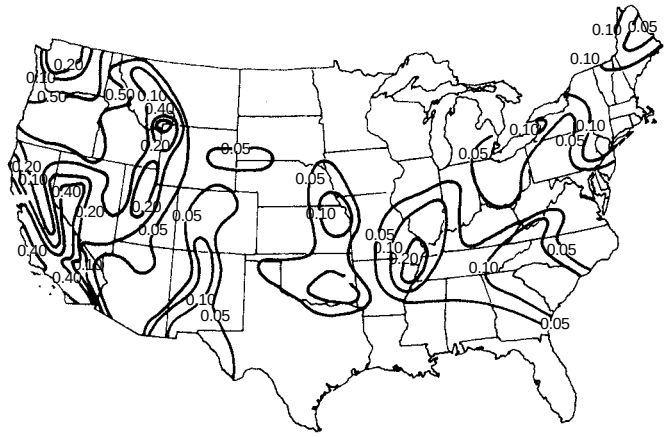

Fig. 8. Effective peak acceleration (EPA) for the lower contiguous United States. Contours represent EPA levels with a nonexceedance probability of between 80 and 95% during a 50-year period. Contours are for values of EPA in units of gravity. EPA is a modification of the peak-recorded instrumental acceleration designed to represent the energy content in the ground motion to which buildings respond. Although the estimate is somewhat more complex, it can be likened to the filtering out of high-frequency spikes of acceleration which structures do not react to because of their considerable inertia. (*America Society of Civil Engineers*.)

As early as 1883, the Italian geologist M.S. De Rossi and the Swiss naturalist F.A. Forel developed a scale of one to ten for expressing the intensity of an earthquake. Earthquake intensity may be defined as a measure of the *effects* of an earthquake, notably the effects in terms of people and structures. Earthquake intensity not only will be dependent upon the strength (or magnitude) of the earthquake, but also upon the distance from the epicenter. Intensity also will be markedly affected by local geology, by the numbers and kinds of structures in a given area, as well as the concentration of people within the affected area. Even the time of day may have a large bearing upon the effects, with large numbers of people assembled in factories, schools, offices, etc., during daytime hours. From a scientific standpoint, the *effects* may be of less value than measurements of *magnitude*. However, from an engineering and technological viewpoint, great knowledge has been learned from studying the aftermath of earthquakes, particularly in terms of structures of all types.

The De Rossi-Forel one-to-ten scale was ultimately replaced by the Mercalli scale, devised by Giuseppi Mercalli, an Italian geologist, in 1902. Again, this was an arbitrary scale of earthquake intensity, ranging from I (detectable only instrumentally) to XII (causing almost complete destruction). This scale was later adapted to North American conditions and became known as the *modified Mercalli scale*. This modified scale (MM) was prepared in 1931 by American seismologists, H.O. Wood and F. Neumann and takes into consideration such features as tall buildings, motor cars and trucks, and underground pipes, not included in the earlier, unmodified scale.

Although not purely based on scientific data, the modified Mercalli Scale is an excellent summary, not only of the human reactions to an earthquake but also of important structural events that usually take place with the increasing magnitude of an earthquake. It is also a good guide for architects and planners when designing new structures and modifying old structures, as well as for organizations that provide emergency services. See Table 1.

TABLE 1. AN ORGANIZED SUMMARY OF HOW PEOPLE AND STRUCTURES RESPOND TO EARTHQUAKES OF INCREASING MAGNITUDE
(Based on the Modified Mercalli Scale and given in order of increasing intensity)

1. *Not felt by persons, except under particularly favorable circumstances, Dizziness or nausea, however, may be experienced.*
Birds and animals may appear uneasy, disturbed. Trees, structures, liquids, bodies of water may sway gently: doors may swing slowly.

2. *Detected indoors by a few persons, particularly on upper floors of a multistory building; and by sensitive or nervous persons.*
Same manifestations as I, plus hanging objects will swing if delicately suspended.

3. *Detected indoors by several persons, usually as a rapid vibration, but which may not be recognized as an earthquake immediately. Vibration is similar to that from a passing, lightly loaded truck, or of a heavily loaded truck from some distance. In some instances, duration is sufficient to be estimated.*
Manifestation of II, plus appreciable movements on upper levels of tall structures. A standing motor car may rock slightly.

4. *Detected indoors by many persons and outdoors by a few persons. Awakens a few individuals, particularly light sleepers, but experience is not frightening except by persons who have had prior experience with earthquakes. Vibration similar to that from the passing of a heavily loaded truck. Sensation is like that of a heavy body striking the structure, or the falling of heavy objects inside the structure.*
Dishes, windows, and doors rattle: glassware and crockery clink and may crash. Walls and structure frame (particularly of a wooden house) creak, especially if intensity is in the upper range of this class. Hanging objects swing. Liquids in open vessels are disturbed. Parked automobiles rock noticeably.

5. *Detected indoors by practically everyone: and outdoors by most everyone. Slight excitement; some persons may run outdoors. Awakens most sleepers. Frightens a few persons.*
Buildings tremble throughout. Dishes and glassware break to some extent. Windows crack in some cases, but not generally. Vases and small or unstable objects frequently overturn. Hanging objects and doors swing generally or considerably. Pictures knock against walls or swing out of position. Doors and shutters open or close abruptly. Pendulum clocks stop or run fast or slow. Small objects move, and furnishings may shift to a slight extent. Small amounts of liquids spill from well-filled open containers. Trees and bushes shake slightly.

6. *Detected by everyone, indoors and outdoors. Awakens all sleepers. Frightens many people; general excitement, and some persons run outdoors.*
Persons move unsteadily. Trees and bushes shake slightly to moderately. Liquids are set in strong motion. Small bells in churches and schools ring. Poorly built buildings may be damaged. Plaster falls in small amounts. Other plaster cracks somewhat. Many dishes and glasses break, and a few windows break. Knick-knacks, books and pictures fall. Furniture overturns in many instances. Heavy furnishings move.

7. *Frightens everyone. General alarm, and everyone runs outdoors.*
People find it difficult to stand. Persons driving cars notice shaking. Trees and bushes shake moderately to strongly. Waves form on ponds, lakes, and streams. Water is muddied. Gravel or sand stream banks cave in. Large church bells ring. Suspended objects quiver. Damage is negligible in buildings of good design and construction; slight to moderate in well-built ordinary buildings; considerable in poorly built or badly designed buildings, adobe houses, old walls (especially where laid up without mortar), spires, etc. Plaster and some stucco fall. Many windows and some furniture break. Loosened brickwork and tiles shake down. Weak chimneys break at the roofline. Cornices fall from towers and high buildings. Bricks and stones are dislodged. Heavy furniture overturns. Concrete irrigation ditches are considerably damaged.

8. *General fright and alarm approaches panic.*
Persons driving cars are disturbed. Trees shake strongly, and branches and trunks break off (especially palm trees). Sand and mud erupts in small amounts. Flow of springs and wells is temporarily and sometimes permanently changed. Dry wells may renew flow. Damage slight in brick structures built especially to withstand earthquakes; considerable in ordinary substantial buildings, with some partial collapse; heavy in some wooden houses with some tumbling down. Panel walls break away in frame structures. Decayed pilings break off. Walls fall. Solid stone walls crack and break seriously. Wet ground and steep slopes crack to some extent. Chimneys, columns, monuments, and factory stacks and towers twist and fall. Very heavy furniture moves conspicuously or overturns.

9. *Panic is general.*
Ground cracks conspicuously. Damage is considerable in masonry structures built especially to withstand earthquakes; great in other masonry buildings — some collapse in large part. Some wood frame houses built especially to withstand earthquakes are thrown out of plumb; others are shifted wholly off foundations. Reservoirs are seriously damaged, and underground pipes sometimes break.

10. *Panic is general.*
Ground, especially when loose and wet, cracks up to widths of several inches; fissures up to a yard in width run parallel to canal and stream banks. Landsliding is considerable from river banks and steep coasts. Sand and mud shifts horizontally on beaches and flat land. Water level changes in wells. Water is thrown on banks of canals, lakes, rivers, etc. Dams, dikes, embankments are seriously damaged. Well-built wooden structures and bridges are severely damaged, and some collapse. Dangerous cracks develop in excellent brick walls. Most masonry and frame structures, and their foundations, are destroyed. Railroad rails bend slightly. Pipelines buried in earth tear apart or are crushed endwise. Open cracks and broad wavy folds open in cement pavements and asphalt road surfaces.

11. *Panic is general.*
Disturbances in ground are many and widespread, varying with the ground material. Broad fissures, earth slumps, and land slips develop in soft, wet ground. Water charged with sand and mud is ejected in large amounts. Sea waves of significant magnitude may develop. Damage is severe to wood frame structures, especially near shock centers; great to dams, dikes and embankments, even at long distances. Few if any masonry structures remain standing. Supporting piers or pillars of large, well-built bridges are wrecked. Wooden bridges that "give" are less affected. Railroad rails bend greatly, and some thrust endwise. Pipelines buried in earth are put completely out of service.

12. *Panic is general.*
Damage is total, and practically all works of construction are damaged greatly or destroyed. Disturbances in the ground are great and varied, and numerous shearing cracks develop. Landslides, rock falls, and slumps in river banks are numerous and extensive. Large rock masses are wrenched loose and torn off. Fault slips develop in firm rock, and horizontal and vertical offset displacements are noticeable. Water channels, both surface and underground, are disturbed and modified greatly. Lakes are dammed, new waterfalls are produced, rivers are deflected, etc. Surface waves are seen on ground surfaces. Lines of sight and level are distorted. Objects are thrown upward into the air.

Seismology

Many seismographs are of the inertial type, depending upon measurement of the relative displacement between a point fixed to the Earth and a mass loosely coupled to the Earth. Other instruments measure relative displacement between two points on the Earth. Seismographs installed throughout the world now number in the several thousands. Seismic instrumentation also includes accelerometers. See also **Accelerometer**.

During the past few decades, there has been a marked increase toward improving seismic measurements, including the research instrumentation used when studying the ocean floor and submerged mountains and valleys. Although it was about a quarter of a century ago, it is interesting to note that, during the Apollo Program, seismographs were placed on the moon for study of that satellite.

There are governmental and private organizations which exchange seismographic information on a worldwide basis. These include: the World Wide Seismic Network (WWSN), established in the early 1960s; the Lamont-Doherty Geological Observatory at Columbia University; the Coordinating Committee for Earthquake Prediction (CCEP); the U.S. Geological Survey (Menlo Park, California); the California Institute of Technology; the American Institute of Civil Engineers; the Woods Hole Oceanographic Institution (Woods Hole, Massachusetts); the Scripps Institution of Oceanography (La Jolla, California); and the Japan Meteorological Agency, among others.

The operating principle of a seismograph is shown in Fig. 9. When the ground shakes, the suspended weight, because of its inertia, scarcely moves, but the shaking motion is transmitted to the marker, which leaves a record on the drum. There are, of course, several configurations that utilize

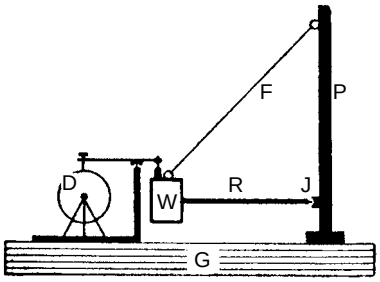

Fig. 9. Principle of a seismograph. *G*, ground; *P*, post set in the ground; *W*, weight; *R*, rigid support contacting the post with a free-moving sharp point at *J*; *F*, flexible wire; *D*, recording drum. Marker extends from *W* to *D*. An improved seismograph will employ an electrical pickup of pendulum movements. The instrument is placed on a concrete base which, in turn, is thoroughly anchored into bedrock so that when the instrument base moves it truly reflects earth movement and not extraneous vibrations.

this basic operating principle. A representative seismogram is shown in Fig. 10. This is the record of an earthquake of magnitude 6.5 (Aleutian Islands). The record was made at a station some 4,000 kilometers from the epicenter.

The basis of seismology is the observation and analysis of elastic energy as it propagates itself through the earth. When mechanical energy is released in a homogeneous earth, it is propagated outward in waves whose fronts are spherical and whose mechanism is alternating compression and rarefaction of the material through which they pass. These waves, called *P* waves, are physically analogous to the sound waves that spread outward from an explosion in air or water. The *P* wave travels at a rate of about 5.6 kilometers per second. It is the first wave to reach the surface. A longitudinal wave, the *P* wave tends to create a "push-pull" effect on rock particles as it passes.

The earth is not generally homogeneous, and though imperfectly elastic, it has rigidity or shear strength absent in air or water. This results in a second kind of wave action, in which the material through which the wave passes moves transversely to the direction of wave motion. These shear or *S* waves travel through solid material at a velocity a little more than half that of the *P* waves. The *S* wave causes the earth to move at a right angle to the direction of the wave.

In addition to the *P* and *S* types of waves (called body waves), there is also energy propagation along surfaces or interfaces. At the earth-air interface, waves similar to surface waves in water are propagated. These are called Rayleigh waves and cause, as in water, circular vertical motion of the material through which they pass, in the plane containing their direction of propagation. In solid material, surface waves like *S* waves also occur, the material moving horizontally in a plane transverse to the direction of motion of the wave. These waves are called Love waves (*L* waves). These waves usually are distinguishable only at great distances. *L* waves can cause the swaying of tall buildings as well as slight wave motions in bodies of water at great distances from the epicenter.

If the velocities of the different modes of wave propagation are known, deduction can be made, for example, of the distance between the earthquake and the observation station by measuring the time interval between the arrival of the faster and slower waves.

When earthquake waves move across an interface between earth materials with different elastic properties, their velocity, direction, and phase may be changed, and they will generally give rise to waves of other modes. For example, a *P* wave encountering an interface may give rise to a refracted and reflected *P* wave and a refracted and a reflected *S* wave. A wave may also be refracted even if it does not cross an interface, because of the change in pressure and density of the earth material as the wave penetrates more deeply into the earth.

Richter Scale. Earthquake size as determined by instruments is measured on a logarithmic scale called the Richter *magnitude* scale. In one variation of this scale, the very largest shocks have magnitudes slightly greater than 8.5. Energy in ergs is given empirically by $\log E = 11.4 + 1.5M$, where M is the magnitude. The measurements are based on records made on a standard type of seismograph a distance of 100 kilometers (62 miles) from the epicenter. Usually, seismograms from several different stations contribute to computing the magnitude of an earthquake. In most instances, of course, a station will not be the standard 100 kilometers from the epicenter. Thus, many records must be compared and complex conversion tables help to estimate the final figure. Fortunately, an experienced seismologist, within a few minutes, usually can estimate magnitude with reasonable accuracy from a record made at only one seismographic station. The logarithmic character of the Richter scale is often overlooked by lay people and news reporters. Obviously, an earthquake of 8.0 magnitude is not twice as powerful as one of 4.0 magnitude, but rather it is $10 \times 10 \times 10 \times 10$ times as powerful.

Modified Scales. In an attempt to provide a more meaningful and precise measure of earthquake energy, some seismologists are using a quantity called the *seismic moment*. This represents the product of the change in volumetric strain energy (the change in stress or stress drop multiplied by rigidity), the size of the fault rupture surface, and the actual displacement or throw of the fault. The seismic moment expressed in fundamental physical units becomes an incomprehensibly large number. For example, the seismic moment of the 1971 San Fernando earthquake ($M_L = 6.5$) was 1.4×10^{26} ergs. Research using a magnitude scale based upon seismic moment, developed by Kanamori (California Institute of Technology), has suggested revisions in the relative sizes of some historic earthquakes. The 1906 San Francisco earthquake would be reduced, while the 1960 Chilean earthquake, which may have been the largest event in this century, would be increased. Although seismic moment is more useful for the study of earthquakes, the complications brought about by the need to estimate three parameters have delayed acceptance of this value in the development of standards for earthquake-resistant structures.

In comparing earthquakes, Kanamori first compared the estimated energy release with the magnitude of moderate-sized events. The extrapolation was then made to large events by taking the Gutenberg-Richter relationship between magnitude and energy, and using the energy release computed from the seismic moment. It should be noted that while the new scale provides a better measure of the relative size of events, the recorded magnitudes of events using the Richter scales remains unchanged.

Seismology in Petroleum and Minerals Exploration. Mineral explorers, notably in the oil and gas field, have found in recent years that the former, traditional two-dimensional seismic prospecting methods were inadequate for solving the three-dimensional problems encountered in petroleum exploration. In three-dimensional seismic methodology, the reflected wave field must be adequately sampled spatially to ensure proper imaging of the subsurface by means of a three-dimensional wave equation. The development of petroleum resources led to the use of seismic exploration techniques. The first field work in the United States began in the mid-1920s. After surface and less expensive means of exploration for gas or oil, seismographic methods may be used. Charges of explosives may be used, or large hydraulic vibrators, mounted on trucks, may be used to induce a shock wave series into the earth. Seismographs measure the reflected or refracted shock waves at carefully spaced locations. Interpretations of data from rock strata more than 6 km below the surface often provide accurate results. Offshore seismic searches are conducted by creating sharp sound wave pulses in the water, which travel through the water and deeply into the rock formations below. Unfortunately, seismic

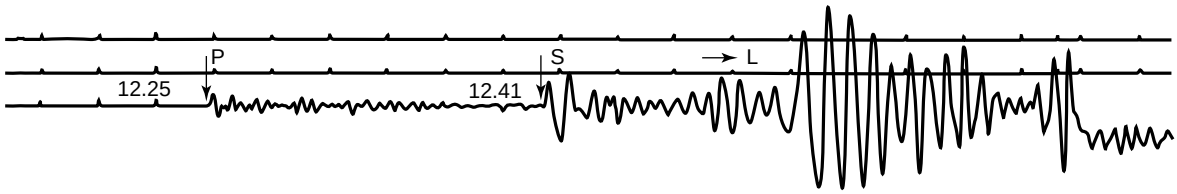

Fig. 10. Representative seismographic record (seismogram) of an earthquake. *P*, *S*, and *L* waves are described in text. (*University of California*.)

information can only indicate subsurface conditions normally favorable to the generation and accumulation of gas or oil — not positively identify their presence. See Table 2.

TABLE 2. REPRESENTATIVE LONGITUDINAL SEISMIC WAVE VELOCITIES

Material	Velocity	
	Feet per Second	Meters per Second
Weathered surface material	500–2,000	152–610
Gravel, rubble, sand (dry)	1,500–3,000	457–914
Sand (wet)	2,000–6,000	610–1829
Clay	3,000–9,000	914–2743
Sandstone	6,000–13,000	1829–3962
Shale	7,000–14,000	2134–4267
Limestone	7,000–20,000	2134–6096
Granite	15,000–19,000	4572–5791
Metamorphic rocks	10,000–23,000	3048–7010
Glacial till (Saskatchewan)	5,000–7,000	1524–2134
Ice	12,500	3810
Fresh water	4,700–4,900	1433–1494
Seawater	4,800–5,000	1463–1524

Data compiled from Jakosky and the Saskatchewan Research Council.

Earthquake Forecasting and Precursors

In the 1980s and 1990s, the study of tectonic data for use in forecasting earthquake events became more intensive. Some of the forecasting techniques, notably in the case of California, are discussed later in this article. In essence, historical information, combined with current seismic measurements, constitutes the basis for long- and short-range projections. These methodologies encompass the concepts of seismic gaps, dilatancy, groupings of small earthquakes, and history of foreshocks. Paleoseismology has become an important part of investigative techniques. Less scientifically accredited are shorter-term precursors, such as the presence of radon gas in groundwater, presence of helium in fault outgas, the electrical conductivity/resistivity of rocks, meteorological data and soil tilt, gravitational pull of the sun and moon, and animal behavior just prior to tectonic events.

Paleoseismology. Related to finding seismic gaps, a number of specialists have gone back into earthquake history, not in terms of years or decades, but in terms of centuries to arrive at long-term patterns. Paleoseismology embraces the detailed study of landforms across fault zones, analysis of deformed layers of sediment in the walls of trenches excavated across active faults and the determination of the age of carbonaceous material found in the sediments, using radiometric techniques. K.E. Sieh (California Institute of Technology) and colleagues have been conducting surveys of this nature along the San Andreas Fault, notably in the Pallet Creek area, since the mid-1970s. An initial analysis indicated a history of at least twelve large earthquakes in the last 1400 years, with an average recurrence interval between 140 and 150 years.

Tree rings also can be indicative of past tectonic action in a fault area because during such events some trees may be seriously affected. Roots growing across a fault may be severed, and vibration may shake off a tree's crown, actions that seriously affect tree growth. One group of scientists demonstrated by observing prior tree injuries, as obtained by analyzing tree rings, that a previously undetermined major earthquake occurred on the fault in 1812, thus shortening the seismic gap by about 44 years, instead of a previously assumed gap at that location of about 130 years. Such information can seriously alter the basis for models constructed to reflect assumed seismic gaps.

Historical Records — Seismic Gaps. Akin to Mendeleev's search for missing elements to fill out spaces in the Periodic Table of the Elements, seismologists today are making mid- and long-term predictions of earthquakes by identifying regions in which earthquakes have not occurred for a long period, but where theoretically they should have occurred. In other words, seismologists are selecting regions that are "overdue" for seismic action. The Tumaco, Colombia earthquake (December 12, 1979) of magnitude 8, the largest quake in northwestern South America since 1942, was predicted by Kelleher as early as 1972. This event filled a gap in the shallow seismic zone of northern Ecuador and southwestern Colombia, where no sizable earthquake had occurred since a quake of magnitude 8.7 happened in 1906. By carefully studying the region, Kelleher concluded that the direction of region during each prior significant earthquake in the general region was proceeding in a north to northeastern direction toward Tumaco.

The San Andreas Fault in southern California presents a major seismic gap. The fault is not uniform. As reported by scientists of the U.S. Geological Survey, on one section of the fault in central California, fault creep (slow slippage) characterizes the displacement. In other places, the fault releases its stored elastic strain in characteristic steps no longer than a few centimeters. In other places, the characteristic slip increment is from 7 to 10 meters. Episodes of slippage of the latter type were responsible for the great earthquakes of 1857 and 1906.

It has been suggested that, if averaged over a sufficiently long period of time, the sum of the various slippages or displacements along the fault should equal the displacement between the two underlying plates. Thus, the possibility for long-term predictions based upon what might be called "slip budget." By applying this method in conjunction with Reid's elastic-rebound theory, scientists have formulated long-range predictions of earthquake potential, namely, that large earthquakes will occur somewhere along the fault at intervals of from 50 to 200 years.

In their excellent report of the Tumaco earthquake, Herd et al. (1981) observe that history suggests that another series of large, shallow-focus earthquakes along the Ecuador-Colombia coastline may begin in this century near Esmeraldas. The 1942 Esmeraldas earthquake (magnitude, 7.9), the first of the latest series of northward-progressing earthquakes in the Ecuador-Colombia seismic gap, followed the 1906 earthquake by only 36 years. In the years since 1942, there have been no large-magnitude earthquakes near Esmeraldas. Another shallow-focus earthquake could recur in this new seismic gap at Esmeraldas before the balance of the 1906 seismic gap is filled near Buenaventura.

Another example of the "seismic gap" forecasting technique is the Alaskan earthquake of February 1979, which occurred in a sparsely populated part of the Alaskan coast, some 400 kilometers (248 miles) east of Anchorage. As shown by Fig. 11, the earthquake filled one of at least two seismic gaps, as forecasted as early as 1971. Another large quake in the remainder of the gap, which extends almost to Valdez, is expected within the next decade or so.

The earthquake forecast diagram shown in Fig. 12, based largely on the seismic gap theory, illustrates how well the USGS forecasted the 1989 Loma Prieta earthquake.

Groupings of Smaller Earthquakes — Foreshocks. Since the early 1990s, the search for correlations between the groupings of smaller earthquakes and foreshocks and larger subsequent earthquakes has received much attention. The theory is that nondestructive earthquakes and foreshocks indicate a build-up of stress that must eventually be released in the form of a main shock of considerable magnitude. However, in some earthquake-prone regions, such as California, scientists have been frustrated for the last few years by the absence of small quakes from which to obtain data. This area of interest has currently displaced the attention which scientists gave a few years ago to dilatancy-related effects.

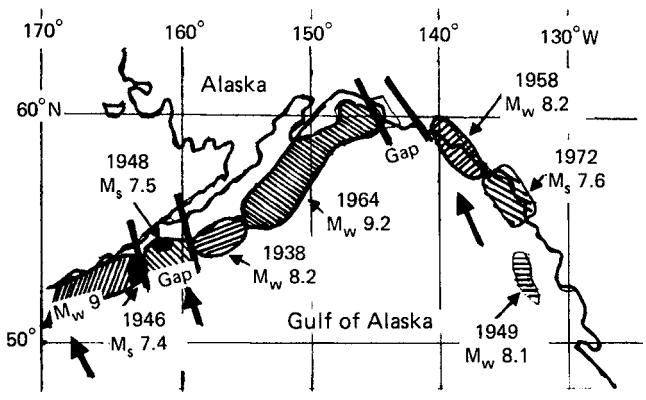

Fig. 11. Two gaps in the Alaska-Aleutian seismic zone. Top gap was noted in 1971. The 1979 earthquake ruptured only the eastern half of the gap. (*After McCann, Lamont-Doherty Geological Observatory*.)

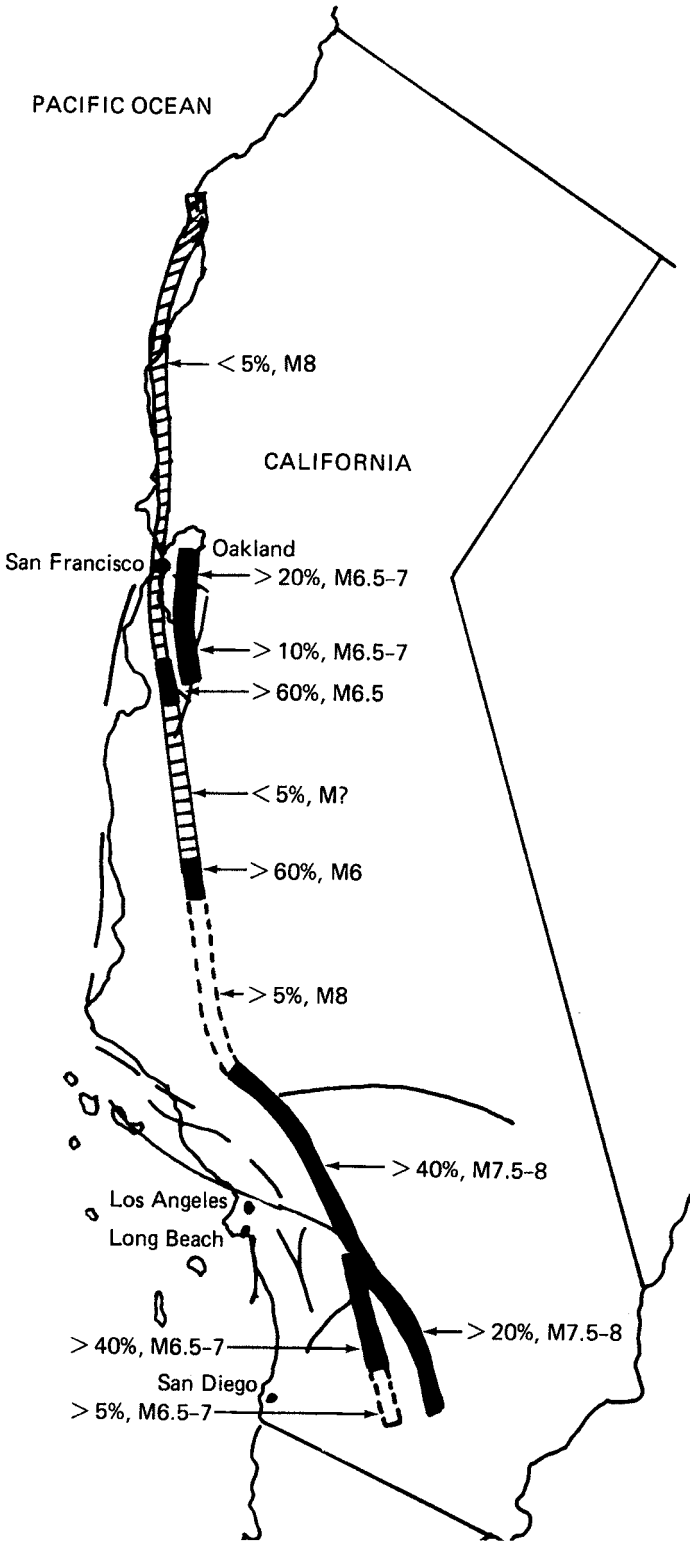

Fig. 12. The San Andreas Fault, which runs nearly the full length of California. Probability of a great earthquake occurring between the present time and the year 2015 is expressed as a greater than (>), or less than (<) percentage. If earthquake occurs along designated portions of the fault, the expected magnitude (*M*) is given after the percentage probability figure. Other single black lines show locations of additional principal faults in the state. (*Source: U.S. Geological Survey.*)

Although both events exhibited foreshocks, neither the Izu-Oshima-kinkai earthquake in Japan of 1978 nor the Adak event in the Aleutians could be interpreted with sufficient reliability to warrant a short-term prediction. In retrospect, however, pre-main event data could be used to forecast similar events should precipitating steps be similar, a broad assumption.

Not all earthquakes have foreshocks of at least moderate magnitude. Of 160 earthquakes of magnitude 7 or greater included in a survey by the California Institute of Technology, only half exhibited foreshocks of magnitude 4 or greater. Thus, it is obvious that lesser earthquakes must be included in possible foreshock groupings in an effort to expand the database and yet remain above the random earth noise level. Clusters of events of magnitude 3 and 4 are now included by some investigators. Also, foreshocks useful to forecasting purposes may be separated by much greater time spans than previously considered. For example, it appears that there was a subtle pattern of seismicity over a ten-year period in the case of the San Fernando, California earthquake of 1971.

Investigators at several institutes have proposed the concept of a "slow earthquake," for which the crustal movement is about one hundred times slower than that of a normal quake. Such a slow quake would not produce higher frequency seismic signals recorded by standard seismographs and thus would go undetected. Nevertheless, such an earthquake could transmit stress from one place to another. In the opinion of one investigator, slow earthquakes may be responsible for a sudden increase of stress to critical levels within only a few days or weeks prior to a final failure. If indeed slow earthquakes do occur, this would greatly complicate the problem of making long-term predictions.

Seismic amplitude measurements made by the U.S. Geological Survey in 1978 suggest that foreshocks sometimes may have different focal mechanisms than aftershocks. The ratio of the amplitudes of *P* and *S* waves from the foreshocks and aftershocks of three California earthquakes (Oroville, Galway Lake, and Briones Hills) during the 1975–1977 period showed a characteristic change at the time of the main events. As this ratio is extremely sensitive to small changes in the orientation of the fault plane, a small systematic change in stress or fault configuration in the source region may be inferred. The success of the Chinese in predicting the Haicheng earthquake (February 1975) was based upon the use of long-, intermediate- and short-term precursors. As pointed out by Lindh et al. (1978), the imminent prediction was based partly on the recognition of a swarm of small-to-moderate earthquakes near Haicheng as a potential foreshock sequence. However, foreshocks do not always occur; estimates of their frequency vary widely and they are usually recognizable as foreshocks only in hindsight. To use foreshocks in a predictive mode, one must distinguish them from background seismicity and earthquake swarms.

Dilatancy Theory. H.R. Reid (Johns Hopkins University) a number of years ago proposed that earthquakes are generated by the sudden slip and elastic rebound of crustal blocks bordering a fault. The crust could bend under strain, then snap and straighten out, thus releasing the energy of the strain. A model of this theory involves many microscopic events preceding an earthquake and many observations over a considerable time span are needed to fill out the dilatancy model. The application of the theory has now been combined with the concept of plate tectonics.

A precursor that is directly implied by dilatancy is *crustal uplift*. Such uplift may be detected by geodetic or tilt measurements. Where a dilatant zone is sufficiently large as well as shallow, dilatancy could produce a crustal uplift of several centimeters. In the case of an earthquake of magnitude 6 (Odaigahara, Japan, 1960), five tiltmeters at different localities up to 100 kilometers from the epicenter detected precursory movements. Six months prior to the earthquake, rapid tilting in the direction away from the epicenter began to be recorded at two stations, 40 and 100 kilometers from the epicenter. Simultaneously a strainmeter at one of the sites began to show anomalously high rates of extension. These activities continued for 3 months, after which they stopped. However, a station farther to the south began tilting. One month prior to the earthquake, all three stations began tilting in the opposite direction and two additional stations began to tilt rapidly. The data indicate that different stages of dilatancy occurred at different times at different localities. Both the magnitude and the duration of the tilts are explicable on the basis of the dilatancy model. The reverse of tilt just prior to the earthquake indicates some type of short-term precursor, perhaps due to a slight compaction of the dilatant volume.

Presence of Radon Gas. As early as 1966, the year of the Tashkent earthquake, analysis of waters from a deep well in the hypocentral region indicated a variation in the radon content prior to the earthquake. Radon has a half-life of only 3.8 days, and its lifetime diffusion distance is only several centimeters. Thus, its increased concentration in the Tashkent well prior to the earthquake and its larger aftershocks could have been caused by two means: (1) an increase in the surface area of rock in the epicentral

region due to cracking, or (2) by an increase in the flow rate of pore water. Both of these effects are predicted by the dilatancy model. In the case of the Izu-Oshima-kinkai, Japan earthquake of 1978, precursory changes in the radon concentration of groundwater were observed. The distance from the epicenter to a continuous radon monitoring station at Nakaizu was about 25 kilometers (15.5 miles). A sudden drop and a subsequent increase in the radon concentration recorded 5 days prior to the earthquake were significant. The size of the spike-like change was about 15%. After the earthquake, a remarkable increase in the radon concentration occurred.

In a 1980 paper, five Japanese scientists made the following observations: "Although our understanding of the whole mechanism of radon emission remains unclear, the observed precursory changes must somehow reflect the deformation or damage, or both, to the artesian layer caused by the action of stress release or stress accumulation. Even though we did not predict the occurrence of the Izu-Oshima-Kinkai earthquake, our efforts were directed toward obtaining data on reliable premonitory changes through observation, a first step toward earthquake prediction. We conclude that the measurement of the radon concentration in groundwater at carefully chosen wells should offer definitive information on the likelihood of an earthquake."

In California, in 1979, radon gas concentration was measured in two wells along the San Jacinto Fault, on the northern margin of the Los Angeles basin. A marked increase in concentration was noted during the period of minor seismic activity. More data are needed to make a judgment, according to some West Coast geophysicists.

Helium "Spots". Japanese scientists have found that measurements of variations in the degassing rate from a fault can be a good way of inferring the most recent time of displacement along a fault, including displacements, such as creep and stick slippage. Helium is believed to be one of the most ideal elements to measure for this purpose because of its mobility, chemical inertness, and low abundance in the atmosphere. Using helium as a geochemical tracer, the investigators aimed at a qualitative assessment of an active fault related to the occurrence of an earthquake. It should be pointed out that helium surveys already have been attempted for prospecting for natural gases, ores, and active geothermal areas. Application of a similar technique to active fault zones may provide useful information for earthquake prediction.

Electrical Conductivity. A measurement associated with the concept of dilatancy is a significant reduction of the electrical resistivity of rock and soil prior to an earthquake as a result of the influx of water into the dilatant region. In the Garm region of Russia, strong correlations were shown some years ago between minima in electrical resistivity and the occurrence of earthquakes. These findings were supported by studies of the electrical resistivity of rocks in the laboratory.

Meteorological Data and Soil Tilt. A popular instrumentation strategy for earthquake prediction is to deploy large numbers of relatively inexpensive tiltmeters, strainmeters, creepmeters, and other geophysical instruments. Most of these instruments are implanted at shallow depths in soil regimes near active faults. In some cases, the sites are within the fault zone. Scientists at the U.S. Geological Survey (Menlo Park, California), over a two-year period, studied the numerical relation between earthquake activity, temperature, and rainfall, as well as tiltmeter response. Their conclusions were that, if the data contain premonitory earthquake signals, they are buried in local meteorological noise. Separating an earthquake anomaly from the response to surface phenomena becomes more difficult as the earthquake anomaly lead time approaches the rise time of the soil to weather and seasonal variations.

Animal Behavior. The reports of animal behavior as a precursor of an imminent earthquake are taken seriously by some researchers and not really ruled out by any investigators. The following excerpt from the Haicheng Earthquake Study Delegation (China, 1979) is of interest: "Some instances noted at this time (before the earthquake) were of snakes being found frozen on the road... geese flying, chickens refusing to enter their coops, pigs rooting at their fence, cows breaking their halters and escaping, and goats as well as cows being unusually restless. Rats appeared to behave as though drunk. Three well-trained police dogs howled, refused to obey commands, and kept their noses close to the ground as though sniffing." In China, numerous nonscientifically trained persons serve as observers along with scientific coordinators. The content of the foregoing excerpt may be better understood after perusing the Shapley (1976) reference listed.

Most investigations have shown that peculiar animal behavior occurs during or after, rather than before an earthquake. If animal precursors are to be considered seriously, there must be some scientific explanation of the sensing mechanisms possessed by birds, farm animals, pets, etc., that make them more perceptive than humans, or even of scientific instruments. One possible explanation is the superior sensitivity of some animals to perceive very low, negligible (from a human standpoint) vibrations of earthquakes of magnitude 2 and under. These may arrive as very gentle foreshocks of a large quake. Only a very nearby seismometer would pick up such vibrations. If felt by only one instrument in California's dense network of seismometers, for example, the data would not be considered valid. There is also the possibility that animals will detect very low, rumbling booms with a frequency of 50−70 Hz, similar to faint thunder. Humans can detect such noises, but some species, such as pigeons, are far more sensitive to frequencies below 50 Hz. Again, such mild vibrations could arrive ahead of a large shock.

Seismologists have noticed the barking of dogs during the gentle foreshocks of weak quakes as well as the mild aftershocks. Some of these effects were observed during the Willits, California earthquake of 1977. However, an extensive monitoring activity, from which several reports were received, failed to provide convincing documentation of peculiar animal behavior prior to the Coyote Lake, California quake of November 1979. At that time, there were over 1200 volunteer observers in the region.

To date, no details have been worked out (except possibly in China) to include animals in a detection network for providing earthquake warnings sufficiently in advance to be of practical value.

Peculiar Earthquake Phenomena. Rumbling noises are definitely associated with some earthquakes and are not a figment of the imagination. At least since the time of Benjamin Franklin, there have been reports of a peculiar light "which illuminated the night sky" during an earthquake. Somewhat parallel to the animal behavior reports, the matter of an earthquake light persists. Thompson (1978) reports that mysterious phenomena, including earthquake light, have been chronicled since ancient times. Geologists noted a brightening of the sky the night before a major earthquake in Turkey (1975). In Japan, sightings and photographs have documented bright night skies before an earthquake. In one modern theory, it is proposed that hydrocarbons convert to methane, which is capable of surviving the high pressures and temperatures deep within the earth. It is further proposed that methane escaping through faults in the land surface catches up small grains of dust or dirt that collide, creating sparks that could ignite the methane and cause the flames and explosions sometimes reported prior to and during earthquakes. It has also been suggested that methane, combining with sulfur to form hydrogen sulfide may also be responsible for the observed uneasiness of animals.

A troubling aspect of the 1989 Loma Prieta earthquake was the absence of premonitory tremors. However, a serendipitous finding of radio signals discovered by Stanford University electrical engineers may prove important. Their monitoring of signals was not whatsoever related to an interest in earthquakes. For a number of years the group has been interested in very low frequency (VLF) radio waves in connection with the development of a communications medium for use with submarines. Thus, during the time frame of the Loma Prieta event, the scientists had been monitoring VLF waves. A few years prior, the Stanford engineers had moved their antenna from the Stanford campus to a location that would not be affected by background radiation. This location happened to be Corralitos, located only $6\frac{1}{2}$ km from the epicenter of the Loma Prieta quake. After cleaning up debris from the quakes, the investigators found that VLF waves had increased dramatically about 3 hours prior to the quake. They noted that the effect, involving ultralow (ULF) waves, definitely was associated with the Loma Prieta event. The researchers offer the hypothesis that: increased stress on rocks along the fault line generated a surge of piezoelectricity, or pressure-induced current, that in turn produced the radio waves. The fact that only the lowest-frequency (.01 Hz) waves were detected may imply that the prequake activity occurred well beneath the earth's surface. However, not all geophysicists agree with this concept.

Hydrothermal Precursors. Some researchers at The Carnegie Institution, Department of Terrestrial Magnetism, Washington, DC, (see Silver and Valette-Silver reference) summarized the finding of a recent study. "During the period 1973 to 1991, the interval between eruptions from a periodic geyser in northern California exhibited precursory variations 1 to 3 days before the largest earthquakes within a 250-km radius of the

geyser. These include the magnitude 7.1 Loma Prieta earthquake for which a similar pre-seismic signal was recorded by a strainmeter located halfway between the geyser and the earthquake. These data show that at least some earthquakes possess the observable precursors, one of the prerequisites for successful earthquake prediction. All three earthquakes were further than 130 km from the geyser, suggesting that precursors might be more easily found around rather than within the ultimate rupture zone of large California earthquakes." Hydrothermal data currently are used as part of earthquake forecasting in the United States, China, and Russia. In addition to Loma Prieta, the other two earthquakes mentioned were the Oroville earthquake of 1975 and the Morgan Hill event of 1984, both located in California.

Regional Tectonics and Paleotectonics

Because the interface between the earth's crust and the mantle is not consistently uniform under the continents and oceans, surface and near-surface phenomena (mainly earthquakes and volcanism) exhibit different characteristics from one geographic location to the next. There are parts of the earth's surface that are relatively quiet — that is, where major earthquakes have not occurred during the recent past and where volcanoes are not present. One must appreciate, of course, that the geologic time scale is measured in terms of millions of years. By contrast, there are very active, sometimes called hot areas where the present and recent past tectonic activity has been great. In fact, a large portion of the earth's tectonic activity presently is occurring in a region sometimes called the "Ring of Fire," which geographically includes the continental borders on either side of the Pacific Ocean. See also **Volcano** in this encyclopedia.

South and Central Western United States. The earth's crust is actively deforming in several regions. Because the San Francisco earthquake of 1906 occurred along the San Andreas Fault, it has been the focus of attention by geophysicists for several decades.

San Andreas Fault. This fault, which lies along the border defined by the Pacific plate and the North American plate, is located along the California coastline, commencing under the Pacific Ocean some distance north and west of San Francisco, with landfall several miles north of San Francisco. Because horizontal slip of this fault under the San Francisco Bay area was determined as the cause of the San Francisco earthquake of 1906, much geophysical research has been conducted pertaining to the San Andreas Fault, which is comprised of numerous segments that occur over a distance of some 600 miles (960 km), thus affecting southern California as well as further north.

Coachella Valley Segment of the San Andreas Fault. As recently as June 1992, the Landers earthquake (M = 7.4) occurred in California's Mojave Desert, 240 km east of Los Angeles. This further alerted scientists to the probability of a potential large-magnitude earthquake in the Los Angeles area. The Landers event emphasized the clustering of earthquakes very near to the Coachella Valley segment of the San Andreas fault. These included prior events at Big Bear, Palm Springs, and Joshua Tree. Geophysicists are becoming increasingly concerned with so many quakes occurring so close together on the northern end of the segment. One investigator has observed that an M = 7.5 earthquake on the Coachella segment alone would not cause the "Big One," but if the rupture broke into the next segment north and west, it could trigger an earthquake of M = 7.8 just at the edge of heavily populated San Bernardino. Rupture of this segment in line would continue past Los Angeles proper and could produce a quake of M = 8.

This view conflicts with the observations of the next paragraph and demonstrates the complexity and difficulty of predicting earthquakes based mainly on statistical evidence.

Recent studies have shown that the San Andreas Fault is not necessarily suspect in all major earthquakes in California that may occur in the future. Some scientists, for example, have observed that the next large quake (the so-called "Big One") may not be attributed to the San Andreas Fault, particularly if it occurs in southern California.

A model constructed in the 1960s indicated that the Pacific and North American plates have been moving relative to each other at a rate of 60 mm per year over the past 2 to 3 million years. During the 1970s, researchers, assisted by much improved instrumentation, indicated that movement along the San Andreas fault did not account in full for the relative movements of the two plates. Three causes were suggested to explain the discrepancy:

1. The early plate-movement rate was too high;
2. The missing motion may have included spreading of the Great Basin[3] and the Range Province of Utah and Nevada; or
3. Deformation in coastal California.

Scientists essentially concur that there is a combination of the three aforementioned factors. This, in essence, removes some of the onus from the San Andreas Fault and some of the ancillary faults located near it.

These findings have been confirmed through the study of horst and graben structures and scarps, which are common to areas that have been compressed or stretched as the result of distant plate activity. In other words, plate interactions are not confined just to plate boundary interactions, but may spread for long distances along the breadth and length of a plate. Thus, in addition to faults, large areas of crust can be deformed and contribute to the total absorption of energy from underlying plate action. These energy-absorbing areas, so to speak, can reduce the total energy borne by surface fractures and thus contribute to area stability. On the other hand, these absorbing areas can become saturated and, like fractures, can become focal points for earthquakes. Such events may be variously referred to as fold, deep, or hidden earthquakes.

By way of perspective, one must appreciate that the theory of plate tectonics was not generally accepted by most geophysicists until the 1960s. Consequently, new hypotheses pertaining to details frequently are proposed.

As observed by Segall and Lisowski (see reference), "the horizontal displacements accompanying the 1906 San Francisco earthquake and the 1989 Loma Prieta earthquake are computed from geodetic survey measurements."[4] The 1906 earthquake displacement field is entirely consistent with the right-lateral strike slip on the San Andreas fault. In contrast, the 1989 Loma Prieta earthquake exhibited subequal components of strike slip and reverse faulting. These results, together with other seismic and geological data, may indicate that the two earthquakes occurred on two different fault planes.

Loma Prieta Earthquake, 1989. Much of the information that follows is a condensation of a report by the U.S. Geological Survey staff, released in January 1990.

The first major earthquake on the San Andreas fault since 1906 fulfilled a long-term forecast for its rupture in the southern Santa Cruz Mountains. Severe damage occurred at distances of up to 100 km from the epicenter in areas over ground known to be hazardous in strong earthquakes. Stronger earthquakes will someday strike closer to the urban centers in the United States, most of which also contain hazardous ground. The Loma Prieta earthquake demonstrated that meaningful predictions can be made of potential damage patterns and that, at least in well-studied areas, long-term forecasts can be made of future earthquake locations and magnitudes. Such forecasts can serve as a basis for action to reduce the threat that major earthquakes pose to the United States.

The surface wave magnitude, M, of the earthquake was 7.1. The quake was felt as far away as Los Angeles to the south and Reno, Nevada, to the east. Confirmed fatalities numbered 62 persons, injuries were 3757, with 12,000 persons left homeless. Property losses were estimated at $6 billion. Even though a few other major earthquakes have occurred in the United States since the Great San Francisco Earthquake in 1906, Loma Prieta produced dramatic nationwide reactions and concern, these resulting from excellent and extensive television coverage. Prior major U.S. earthquakes since 1906 included the Kern County, California, earthquake (July 1952, M = 7.5) and the Great Alaskan Earthquake (March 1964, M = 9.2).

[3] A region of the western United States located between the Sierra Nevada and the Wasatch mountains, including parts of Nevada, California, Idaho, Utah, Wyoming, and Oregon.

[4] Horizontal displacement during the 1989 Loma Prieta earthquake have been measured with a variety of techniques. Most information has come from laser electronic distance measurements (EDM). Changes in distance constrain horizontal displacement up to rigid body translations and rotations of the network. Global positioning system (GPS) measurements between Loma Prieta and several other locations, including Eagle, Mount Hamilton, and Ford Ord, constrain the relative displacement vectors these sites and thus the rotational component of the displacement field. Displacement of the Ford Ord site relative to stations remote from the epicentral region have been determined by very long baseline interferometry (VLBI), constraining the transitional components of the displacement field.

The Loma Prieta earthquake ruptured a segment of the San Andreas Fault in the Santa Cruz Mountains that had been recognized as early as 1983 as having a high probability of rupture within the following few decades. In a USGS study of 1988, this segment was assigned the highest probability for producing an M 6.5 to 7 earthquake of any California fault segment north of the Los Angeles metropolitan area.

Some Unfortunate Parallels with 1985 Mexico City Earthquake. Just as much damage and as many casualties were caused by the Michoacan earthquake (official name) in Mexico City, some 350 km distant, as by the Loma Prieta quake, which reached parts of San Francisco and Oakland, much of its damage caused by effects on ground fills and the phenomenon of *liquefaction*. Inadequate freeway design was a cause of severe damage. Damage assessment of Loma Prieta revealed unreinforced brick masonry and structures having soft, open-ground floors that have inadequate resistance to shear deformation induced by strong earthquake shaking. It is interesting to note that modern buildings in nearby San Jose generally held up well during the earthquake. In the central San Francisco Bay Area, structures known to be of earthquake vulnerability were damaged. San Francisco's marina district was built over landfill and hence suffered from liquefaction; gas lines and water lines were broken, thus furnishing the fuel for a disastrous fire in that district and delaying ample water supplies to put the fires out. The Loma Prieta earthquake reinforced the observations of experts to the effect, "The amount of damage produced by an earthquake depends chiefly on the geological character of the ground. Where the surface is of solid rock, the shock usually produces little damage, whereas in structures on landfills, great violence is manifested."

The Loma Prieta earthquake generated landslides throughout a region of about 14,000 square kilometers. Away from the zone of surface fractures, landslides were most numerous in the Santa Cruz Mountains and consisted of rock falls, rock slides, and debris slides.

Short, Sharp Shock. The strong shaking associated with the Loma Prieta earthquake persisted only for some 6 to 10 seconds, as contrasted with the Armenia earthquake, 1988, when shaking went on for a period of 30 seconds. At an Earthquake Engineering Research Institute (Univ. of California, Berkeley) meeting held a few months after the Loma Prieta earthquake, one scientist observed that the 40–50-km rupture of the fault segment that caused the earthquake began at a central point, traveling outward in two directions at once. Had the fault ruptured unidirectionally, strong shaking could have persisted for 20 to 30 seconds. Experts observe that a number of borderline structures that survived had been stressed nearly to their limits and, had the shaking continued for just a little longer, many large buildings would have collapsed. In several instances, large diagonal cracks developed in some of the taller buildings, suggesting that just a little more pounding would have brought them down. Some structural engineers, in analyzing the damage rendered to the Oakland Bay Bridge, also express some good fortune in the manner in which both the earthquake forces and the bridge performed. Two short stretches of roadway in the eastern third of the bridge collapsed, with the loss of only one life. The roadway segments that fell were the upper and lower roadways at pier E9 of the bridge, midway across the eastern stretch of the bridge. Subsequent damage assessment of the bridge indicated that inertial forces within the bridge pulled the trusses and roadway east of pier E9 toward Oakland by about 7 inches (18 cm) relative to the main portions of the bridge. Each of the numerous piers supporting the bridge use forty 1-inch diameter bolts to secure the roadways with each pier. Fortunately, in the opinion of a structural engineer, if the initial shocks of the earthquake had not ruptured these particular bolts, the forces would have been transferred to pier E9 per se, with much greater damage being done to the bridge. In retrospect, it appears that the failed bolts on one pier served as a protective energy-relief device, much as a safety valve on a boiler. Several hundred more cars and their passengers could have been thrown into the bay had the bolts not sheared. A map and more detail can be found in the Barinaga reference listed.

Liquefaction. This phenomenon occurred in the 1987 Superstition Hills, California earthquake and in the Loma Prieta earthquake, notably in the San Francisco marina area built upon landfill. As defined by Holzer, Youd, and Hanks, "Seismically induced liquefaction involves the loss of static shearing resistance of saturated, relatively loose, sandy deposits due to a tendency to closer packing of the constituent grains dynamically driven by seismic shear waves. If pore fluid in the liquefying layer cannot escape, this reduction in pore volume causes porewater pressure to increase. Liquefaction is generally thought to occur when pore pressure approaches lithostatic. Common surface manifestations of liquefaction include fountains of water laden with sediment and ground failure.

Fold Earthquakes in California. Some California earthquakes identified as *fold earthquakes* include:

1. Coalinga earthquake, 1983, M = 6.3, causing no deaths, but demolishing 75% of unreinforced structures.
2. Kettleman Hills earthquake, 1985, M = 6.1, located in a remote area, but felt over a wide area.
3. Whittier Narrows earthquake, 1987, M = 6.0. This event struck within the populous Los Angeles basin and, as pointed out by Stein and Yeats, "The Whittier Narrows quake was only one-tenth the size of the Coalinga event, but it caused 10 times the damage, that is, $150 million and taking 8 lives."

In none of these earthquakes did underlying faults slip-cut the surface of the earth. The earthquakes occurred on young anticlines less than several million years old. In each case, the fold heightened measurably during the earthquake. From this pattern of performance, it can be reasoned that not only can young anticlines be sites of earthquakes, but also that the folds actually are created by tectonic activity — that is, by a series of earthquakes over time, but with little if any evidence at the surface. It was determined that the Coalinga earthquake differed from surface-fault quakes in its pattern of aftershocks. Unlike surface-fault earthquakes, in which the aftershocks tend to be aligned along the plane of the fault, in the Coalinga event the aftershocks were distributed more diffusely, above and below the fault plane. This could suggest that the Coalinga anticline involves a number of faults. See also **Anticline**.

The Whittier Narrows earthquake lifted its associated anticline, the Santa Monica Mountains fold. Some geologists suggest that the Whittier Narrows event has been but one of many similar events that have taken place along a blind fault that runs for 150 km underneath the California coastline. Also, it is suggested that the Point Magu earthquake, 1973, M = 5.6, also may have been a fold earthquake. Another anticline, known as the Ventura Avenue anticline, is located on the southern California coast. Although no major earthquake has been registered along this anticline, paleotectonics records indicate that it may be related to other California anticlines previously described.

Geophysicists have noted that anticline fold earthquakes rupture comparatively slowly. Rupture time for the Kettleman Hills earthquake was estimated at 16 seconds — that is, about four times longer than a typical surface-faulting earthquake. The rupture time at Coalinga compared with most surface quakes, but it was observed that the seismic activity took much longer to die out. Some investigators note that these characteristics may be related to the slower release of pressure from fluids contained in the rocks. These observations may reflect a scenario of slow, more prolonged earthquakes. Questions still unanswered: Do anticline faults undergo steady and continuous slip, or do they grow intermittently through earthquakes equal to or larger than the Whittier Narrows event? Stein and Yeats have observed, "It is incumbent on seismologists to distinguish between the two competing explanations; their consequences are dramatically different. If earthquakes larger than the 1987 event are possible beneath the Santa Monica mountains fold, then Los Angeles' greatest earthquake threat may not come from a future M8 shock on the San Andreas fault, 50 km to the north, but from a smaller earthquake originating under downtown Los Angeles." Investigators are probing this possibility.

Some clues may be derived from further studies of fold, deep, and hidden earthquakes that have occurred in other parts of the world. Earthquakes between M7 and M7.8 have occurred on blind faults in Argentina, Canada, northern India, Japan, and New Zealand, with a high potential for such earthquakes in the Balkans, Chile, Iran, Italy, Pakistan, and Taiwan.

Brief mention should be made of the El Asnam, Algeria 1980 M7.3 shock, which killed 3,500 people in three North African cities, and the Armenian 1988 (M = 6.4) earthquake, which claimed a minimum of 25,000 lives. The aftershock pattern of the latter earthquake was diffuse. The area of the Armenian event had been mapped previously by the former USSR Academy of Science. After the event, observations were made by a *Landsat* satellite.

The Armenian earthquake has been described as a "worst-case scenario." The city of Spitak is less than 5 km from the fault. Just 4 minutes after the main shock of M = 6.8, a major aftershock of M = 5.8 collapsed most of the buildings that had been weakened by the main shock. The majority

of people were killed by the collapse of old, weakened buildings that incorporated no shock-resistant structural design. Even some of the more recent high-rise buildings were severely damaged.

Some so-called very deep focus earthquakes (focal depths of 50–1200 km) occur from causes not previously described and poorly understood. Subduction zones appear to be the setting for such events. The most destructive earthquake of this type to occur within recent times occurred in Bucharest, Rumania, 1977 (M = 7.2). The focal depth was estimated at 150 km. Another deep-focus earthquake occurred 650 km under Colombia, M = 7.6. A number of investigators, notably Wadati and Benioff, have developed hypotheses as to the active physics and mechanism of such quakes. These concepts are summarized by Frohlich (see reference).

Very Short-Term Alerting Systems in California. Most earthquake prediction systems, as previously described, are geared to the long term — that is, expectations at best are expressed in terms of years. Such predictions are useful toward increasing the public's awareness of how necessary it is to support preparative measures, such as reinforcing structures, setting up agencies for coordinating earthquake emergencies, and providing practical safety precautions to individuals, much as is done in connection with the threats of tornadoes and hurricanes. Conventional earthquake prediction procedures obviously do not serve those immediate actions that can be taken if warning can be given in just a few minutes or even seconds prior to a shock.

During the past decade, considerable research has been directed toward *very short-term* warnings, even though initially this may seem scientifically implausible. However, by way of sophisticated and strategically placed earthquake instrumentation systems, warnings essentially in terms of "real time" may be possible. Applications, however, appear to be applicable only to tectonically limited areas. Nevertheless, a combination of such measurement systems could serve wider warning areas. In 1993, considerable research along these lines is under way.

Seismic versus Radio Waves. Radio waves travel considerably faster than seismic waves; thus, over a distance, site instrumentation data can telegraph ahead seismic information from a given site. For example, most damaging seismic waves propagate out from a fault rupture at a rate of about 3 km per second, obviously slow in comparison with the radio transmission of instrumentation data measured at a given site. Within a distance of some 32 km (20 mi), there is a 10-second time difference of arrival time. Over a distance of 320 km (300 mi), there would be a time differential of about 200 seconds (3 minutes). By integrating such segments of an active fault, however, the warning or alerting time span could be increased.

The Parkfield Experiment. Locations along the San Andreas fault and the Parkfield segment in particular have produced reasonably uniform seismic patterns over a period of years. But, of course, there always have been fairly wide margins of error in terms of predicting exact times of occurrence. At Parkfield, past earthquakes have displayed very similar characteristics (seismic patterns). These are typical of a so-called *periodic quake*, based upon the seismic gap theory. Thus, geophysicists regard the Parkfield fault as a "model."

Since the late 1880s, magnitude 6 quakes have occurred at Parkfield on an average of one every 22 years. Quakes occurred in 1881, 1901, 1922, 1934, and 1966. These data have been confirmed even from far-distant seismic centers, such as one in the Netherlands, in addition to centers in the United States. Parkfield, a sparsely populated community (less than 50 people), was not selected because of possible local damage or loss of life, but because of its past reliable quake record. A quick calculation shows that another quake should have occurred in 1988 and thus, as of early 1992, is overdue, but so was the one in 1966. To the geophysicist, similarity of seismic data is far more important than exact timing.

The Parkfield experiment was established in 1985 and since then many millions of dollars have been invested by the USGS, the state of California, and universities worldwide. The overall aim is to develop a warning system in terms of weeks, days, hours, or even seconds of a magnitude 6 earthquake.

A "real-time" warning system has been established that provides four levels of alert:

Level D. This is the lowest level and indicates that some *unusual* seismic or slip activity has occurred on the fault segment, but that there is less than 1% chance of a magnitude 6 earthquake within 72 hours. Approximately 50 Level D alerts had been issued as of early 1990.

Level C. This occurs when (a) numerous arrays of instruments located along the fault segment record low levels of activity, or (b) one array of instruments records a high level of activity. This indicates that there is less than a 5% change of a magnitude 6 earthquake. About 20 Level C alerts were issued between 1987 and early 1990.

Level B. This represents an 11–37% probability of a magnitude 6 quake occurring within the next 72 hours.

Level A. This represents that the probability of an earthquake occurring within a very short time span is 1 in 2.

No Level B or A alerts have been issued since the system was established.

Arguments that favor a real-time warning system, even if the warning period is very short, include: turning off gas supplies and thus preventing quake-started fires, putting emergency agencies on highest alert, warning hospitals, alerting vehicular traffic, securing radioactive materials, and, depending upon the time interval available, interrupting public radio and television programs to warn the public. As one scientist stated, a person can crawl under a desk in just a few seconds.

A similar system in Japan alerts high-speed rail trains to come to a stop as quickly as possible without causing injury to passengers.

Parkfield, unfortunately, was too far from the October 1989 Loma Prieta earthquake to participate. If a short warning could have been issued from another station along the San Andreas Fault, perhaps gas could have been turned off and thus rendered not available to fuel the fire that occurred in the marina area of San Francisco.

Seismic Instrumentation at Parkfield. Some sets of state-of-the-art and more sophisticated instrumentation installed along the Parkfield segment include a strong-motion array, a distributed strong-motion array, a differential strong-motion array, a surface geology effects array, a dense strong-motion array, a liquefaction array, and a pipeline experiment, among other systems.

As reported by Allen Lindh (USGS), strain measurements make up the backbone of monitoring instrumentation. These sensors determine the deformation of rock at a single point. This requires a precision of about 1 part per billion. This precision is impossible to achieve at the surface, and thus the strain gages are installed about 300 meters (1000 feet) down into the earth. A device referred to as a "two-color laser geodimeter" is used to detect any distance changes between hilltops up to 10 km (+6 mi) apart with a precision of 1 mm. Such measurements indicate any movement of crustal blocks on the earth's surface. Any change of "slip" pattern is indicative of a forthcoming quake. Different arrays of seismometers are used to measure almost infinitesimal motions of the earth's surface and record acoustics and other kinds of energy radiated by an earthquake. Such data are computer analyzed to estimate locations and magnitudes of small quakes within 3 to 5 minutes. These data are helpful for determining possible foreshocks, which could signal an imminent large quake.

Additional instrumentation at Parkfield includes magnetometers, which detect changes in the earth's magnetic field, and creep meters, which measure surface slip on the fault. Deep-water wells also are monitored to determine possible rock deformation. Under test is a telluric current monitoring array, which senses changes in resistivity to electrical currents in the earth.

Communication and Computer System. Data from the aforementioned instruments are transmitted by microwave or satellite to a center at Menlo Park, California. For this experimental system, USGS scientists are available around the clock to analyze data whenever the computer finds a situation corresponding with the previously mentioned levels of alert.

Generally based upon the assumption that the Parkfield experiment will perform well, planning for a much more ambitious and sophisticated warning system involving all important segments of the San Andreas fault is well underway. Already, of course, there are scores of fault measuring systems installed along the fault. These are to be upgraded to include the most sophisticated instrumentation. The basis of an integrated system, of course, would be extensive analysis of past performance of many of the segments of the San Andreas Fault. Added to the integrated system at the start would be data gathering stations along an essentially connected fault running from north of San Francisco to considerably southeastward of Los Angeles. Somewhat further into the future, other major faults, such as Hayward to mention only one, could be added to the system.

The overall technology, under development at Massachusetts Institute of Technology, essentially would be based on an artificial intelligence (AI) program in a computer linked to accelerometers and other instrumentation

along the fault line. In an "if this, then" fashion, the computer, operating at a very high data processing rate, would determine the magnitude of a quake and the areas most likely to sustain damage. Warnings then would be sent automatically by radio or telephone directly to regions at risk, at which time warning sirens and other emergency operations would commence. The program is being written in LISP artificial intelligence language and will run on a standard 386 chip-based personal computer.

Instrumentation that will feed data to the master center will be located approximately 5.6 km (0.6 mi) apart. The accelerometers to be used will be about .03 cubic meters (1 cubic foot) in size and mounted on concrete pads, ideally set in bedrock to provide the most precise information.

Northwestern United States. Exercises in paleoseismology have revealed that a large earthquake occurred during the eighth or ninth century A.D. almost directly under present-day Seattle, Washington. Investigators describe the Juan de Fuca plate as being subducted beneath the North American plate, moving in an east-northeast direction. Geodetic data concerning deformations in northeastern Washington reveal that strain is accumulating. The average rate of strain accumulation in the Olympic network has been estimated through the use of triangulation surveys.

Moderate earthquakes occurred under Puget Sound in 1949 and 1965, the latter causing an estimated $12 million in damage. Since that quake, a tight code on building construction has been implemented. Radioactive carbon dating and tree ring counting (dendrochronology) currently are underway, out of which models of past tectonic activity in the area will be constructed. This research is underway by the U.S. Geological Survey staff and the University of Washington. There had been insufficient time, as of the mid-1990s, to assess the hazard posed by the Seattle fault. Officials also are concerned that an earthquake in the area could create tsunamis in Puget Sound.

Central and Eastern North America. By normal tectonic standards, those regions of America east of the Rocky Mountains are considered "quiet." However, a few of the greatest earthquakes in terms of magnitude throughout the world have occurred in continental crust — not near the boundary of two plates, but at distances well within the length and breadth of a given plate. Such events sometimes are referred to as "interplate" earthquakes. Their focal points generally are deep; their frequency of occurrence usually is in terms of scores of years or centuries, in contrast with the comparatively short terms of repetition as experienced in plate-boundary regions.[5]

Of the 15 recorded intraplate earthquakes occurring on stable crust that has been stretched and thinned over the past 250 million years, 6 occurred on part of the North American plate (eastern North America): New Madrid Seismic Zone (3 times); Charleston, South Carolina; Grand Banks, Newfoundland, 1929 (M = 7.4); and Baffin Bay, West Greenland, 1933 (M = 7.7).

All of these earthquakes occurred well within the boundaries of the North American plate, recalling that the eastern boundary of this plate extends well eastward, to the Mid-Atlantic ridge.

The events occurred where crust has been stretched and thinned over the past 250 million years.[6]

New Madrid Seismic Zone. The New Madrid Fault is centrally located in this zone. This fault lies in a slightly northeasterly direction, extending from Memphis, Tennessee, on the south, and nearly reaching Paducah, Kentucky, at its northern terminus. Historically affected seismic areas have included western Tennessee and Kentucky, eastern Missouri and Arkansas, southern Indiana and Illinois, and northern Mississippi.

Newspapers of the day described the 1812 event in impressive, but unconfirmed terms: "It toppled chimneys in distant Cincinnati, Ohio, rang church bells in far-off Boston, Massachusetts, awakened President James Madison at the White House, and Thomas Jefferson at Monticello in Virginia."

As reported by Liu, Zeback, and Segall (see reference), first- and second-order triangulation networks were established in the area as early as 1929. In the 1950s, a much wider area was surveyed with the use of second-order triangulation. Although crustal deformation can be measured with repeated angle measurements from triangulation data alone, the aforementioned investigators, associated with Stanford University and the USGS concluded that there were insufficient repeated angles in the region to compute strain. Consequently, a new survey of many of the triangulation stations with the global positioning system (GPS) was implemented in 1991. "This made it possible to determine whether detectable crustal strain had accumulated during the past 35 to 40 years." Rapid crustal strain accumulation since the 1950s was detected. A tentative conclusion was drawn to the effect that the observed strain rates were due to postseismic, lower-crustal flow in response to the 1811–1812 events, rather than strain accumulation associated with impending earthquakes.

Mistaken Warning of a December 1990 Event. In the fall of 1990, Dr. Iben Browning, described as a self-taught climatologist and who previously had made outstanding forecasts of a few prior seismic events and thus had established a form of track record,[7] but one that ranged from skepticism and luck to some degree of recognition among a few professionals and notably in the nonscientific community, declared that a large earthquake would occur along the New Madrid fault on December 3, 1990. The event *did not* occur and, as of early 1993, no such event has occurred. However, at least one school district in the area closed schools on December 3 and 4. Missouri and Arkansas National Guards also were put on alert. The entire affair became a major media event. Although very interesting, more detail cannot be given here. The reader is referred to the Kerr, August 9, 1991, reference listed.

Charleston, South Carolina Earthquake. The largest earthquake recorded in the eastern coastal areas of the United States occurred near Charleston, South Carolina, in August 1886. Because this event (M = 7.0+) affected a populous area, it is generally considered to have been the most destructive of earthquakes occurring in the United States during the nineteenth century. It has been estimated that a similar event in the same location today would result in several thousand fatalities and property damage of $400 million or more.

Amick and Gelinas (Ebasco Services Incorporated, West Meadows, North Carolina) have conducted research to assess the probability of future earthquakes in the region. Because Charleston is quite distant from an active plate boundary and there is an absence of any convincing paleoseismic evidence of faulting or other characteristic physical phenomena normally associated with such tectonic events, such an assessment indeed is difficult and carries an aura of mystery to be solved.

In their excellent report (see reference), Amick and Gelinas summarize their observations to date, "The special distribution of seismically induced liquefaction features discovered along the Atlantic seaboard suggests that during the last 2000 to 5000 years, large earthquakes (body magnitude, $m_b \geq 5.8 + 0.4$) in this region may have been restricted exclusively to South Carolina. Paleoliquefaction evidence for six large prehistoric earthquakes was discovered there. At least five of these past events originated in the Charleston, South Carolina, area, the locale of a magnitude 7+, including the 1886 event. During the past two millennia, large events have occurred about every 500 to 600 years."

[5] An exception to this generalization was the occurrence of three events in the New Madrid seismic zone. One event occurred in 1811 (M = 8.2), and two events occurred in 1812 (M = 8.1 and M = 8.2)

[6] The remaining (worldwide) recorded intraplate events on stable crust (See Johnson/Kasten reference) were:

EURASIAN PLATE:

Basel, Switzerland, 1356 (M = 7.4); Taiwan Straits, 1604 (M = 7.7); Haiman Island, 1605 (M = 7.7); Portugal, 1858 (M = 7.1); Nanai, China, 1918 (M = 7.4).

INDIAN-AUSTRALIAN PLATE:

Kutch, India, 1819 (M = 7.8); Exmouth Plateau, Australia, 1906 (M = 7.6); South Tasman Rise, 1951 (M = 7.0).

AFRICAN PLATE:

Libya, 1936 (M = 7.1).

[7] Dr. Browning, who apparently considered the gravitational pull of the sun and moon for his forecasts, previously had close-coupled forecasts in connection with the eruption of Mount St. Helens in 1980, the Mexico City quake event of 1985, and the Novado del Ruiz eruption in Colombia in 1985.

EARTH TIDE. (1) The response of the solid Earth to the forces that produce the tides of the sea; semidaily earth tides have a fluctuation of between 7 and 15 centimeters (2.7 and 5.9 inches).

(2) A periodic movement of the Earth's crust caused by the tide-producing forces of the moon and sun.

EARTHWORK. This term denotes work, the object of which is to alter the surface of the earth to serve some useful constructional purpose. In addition to excavation, building of embankments and trimming of slopes, earthwork also includes the clearing and grubbing of rough land, grading, etc. Excavation of rock and loose rock is usually considered earthwork.

Among the most common forms of earthwork are preparation of subgrade for railways and highways, buildings of embankments for hydraulic work and construction of open drainage systems. In the preparation of a roadbed, the original surface of the ground is altered to the required degree by cuts and fills. As far as possible, cut should equal fill, so that the material excavated may be hauled a short distance and used to fill depressions in the proposed roadway. Where the amount of cut is insufficient for filling, the deficiency must be made up by hauling from borrow pits. An excess of cut is deposited on spoil banks.

The vertical dimension of the cut or fill at any station is found by leveling. An engineer's level is set up near the station. The height of the instrument, which is the vertical distance between the line of sight of the level and a reference plane called the datum, is obtained by taking a rod reading on a bench mark or other point of known elevation above the datum. After the height of instrument is determined a rod reading is taken on the ground at the station. This is the ground rod. The difference between the height of instrument and the known grade elevation at the station is the grade rod. The cut or fill is the algebraic difference between the grade rod and the ground rod. The point where the side slope of a cut or fill will intersect the ground surface is marked by a stake called a slope stake. Slope stakes are set before construction is begun.

To measure the amount of cut or fill in earthwork, transverse cross-sections of the cut or fill are measured at regular intervals. These sections are then plotted on paper, and the area computed. Sections are taken close enough so that the volume of earthwork between them is considered that of a prism of length equal to the distance between stations, and area equal to the average of the two sections. This is known as the end area method. A more accurate result is obtained by the use of the prismoidal formula, which states that the volume of the earth equals $\frac{1}{6}(a_1 + 4a_m + a_2)D$, where a_1 and a_2 are the end areas, a_m is the mid-section area, D is the length of the section being measured. Earthwork is usually done on a contract basis and paid for on the basis of volume excavated, or volume of fill. A fill of earth usually shrinks 10–20% upon compacting. Rock may be expected to occupy 15–30% greater volume after excavation than before.

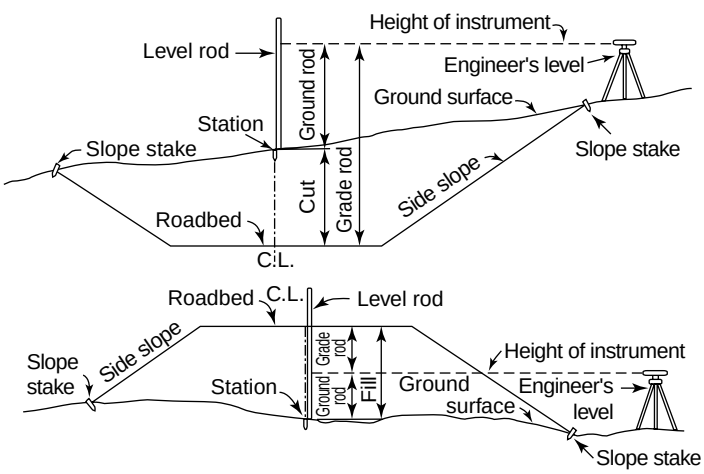

Fig. 1. (*Top*) Cross section of a highway in cut. (*Bottom*) Cross section of a highway in fill.

If the volume of cut or fill between any two successive stations is given an algebraic sign (+ for cut and − for fill), the algebraic sum of the volumes starting at an initial station may be represented by a continuous curve called a mass diagram. The abscissa for any point on the curve is its horizontal distance (in units of 100 feet) measured from the initial station; the ordinate is the algebraic sum (in cubic yards) of the volumes up to the point. Plus-ordinates (cut) or plotted above the x-axis, and minus-ordinates (fill), below. See Fig. 1.

EARTHWORM *(Annelida, Oligochaeta).* Terrestrial segmented worms of many species. They burrow in earth containing organic matter on which they live, coming to the surface only in damp cloudy weather and at night. Their activity in loosening and mixing the soil in fields is estimated to be valuable in crop production.

EAST AUCKLAND CURRENT. See **Ocean Currents**.

EAST AUSTRALIAN CURRENT. See **Ocean Currents**.

EASTERLIES. See **Winds and Air Movement**.

EASTERLY WAVE. A migratory wavelike disturbance of the tropical easterlies. It is a wave within the broad easterly current and moves from east to west, generally more slowly than the current in which it is embedded. Although best described in terms of its wavelike characteristics in the wind field, it also consists of a weak trough of low pressure. Easterly waves do not extend across the equatorial trough. To the west of the trough line in an easterly wave over the ocean, there is generally found divergence, a shallow moist layer, and exceptionally fine weather. The moist layer rises rapidly near the trough line; in and to the east of the trough line intense convergence, much cloudiness, and heavy rain showers prevail. This asymmetric weather pattern may be greatly distorted by orographic and diurnal influences if the wave passes over land areas. Easterly waves occasionally intensify into tropical cyclones.

EASTERN EQUINE ENCEPHALITIS VIRUS (EEEV). See **Arthropod-borne Viruses**.

EASTERN TENT CATERPILLAR *(Insecta, Lepidoptera).* Also known as the apple-tree tent caterpillar (*Malacosoma americanum*, Fabricius), this insect eats the foliage of trees and disfigures them with its nests. The insect is most widespread in the northeastern United States, although it is found throughout the country east of the Rocky Mountains, and in parts of California. Similar species are found in the Rocky Mountains and farther west. See Fig. 1.

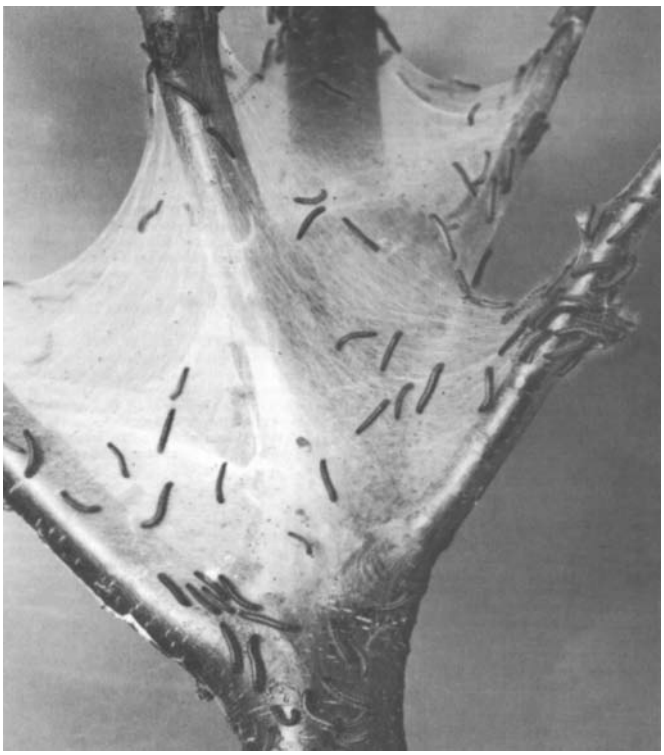

Fig. 1. Nests of the eastern tent caterpillar. Note the layers of silk.

Wild cherry trees and apple trees are most often attacked. Peach, pear, plum, rose, hawthorn, and various shade and forest trees are occasionally infested. In spring, their unsightly nests or "tents" are conspicuous on susceptible trees. They are more active in some years than others. They may eat nearly all the leaves of a tree, which weakens the tree, but seldom

kills it. Once the caterpillars mature in early summer, they cause no further feeding damage.

One generation of the insect develops in a year. The larvae, or caterpillars, hatch in spring from egg masses, about the time the first leaves are opening. The young caterpillars keep together and spin threads of silken web. After feeding for about two days, they begin to weave their tent in a nearby tree crotch, sometimes joining with caterpillars from other egg masses. As the caterpillars grow, they enlarge the tent until it consists of several layers. In good weather, the caterpillars leave the tent several times per day in search of food, stringing silk after them. In bad weather, they remain between the layers of the tent.

When fully grown, about 6 weeks after hatching, the caterpillar is nearly 2 inches (5 centimeters) long and sparsely hairy. It is black, has a white stripe along the middle of its back, and other white and blue markings. When they are mature, the caterpillars spin cocoons on tree bark, fences, brush, etc. The cocoon is about 1 inch (2.5 centimeters) long and white to yellowish white, depending upon age and presence of caterpillars. Inside the cocoon, the larvae transform to pupae, the resting stage. In early summer, reddish brown moths emerge and the females deposit masses of eggs in bands around twigs. The eggs are covered with a foamy secretion, which dries to a firm, brown covering that looks like an enlargement of the twig. An egg mass usually contains about 200 eggs. The larvae develop inside the eggs, but they do not hatch until spring.

These caterpillar larvae are prey for other insects, toads, and birds. The small wasps (chalcid wasps. etc.) develop as parasites in the eggs, larvae, or pupae. Control chemicals applied to the nests and about one foot (0.3 meter) of surrounding area is effective. The spray should be applied before nests are 3 inches (7.5 centimeters) in diameter. The insects are easy to control by hand removal and burning if only a few trees are infested. Wherever possible, wild cherry trees growing near orchards should be removed.

A similar species, the *forest tent caterpillar* (*Malacosoma disstria*), and the *fall webworm* (*Hyphantria cunea*) are sometimes mistaken for the eastern tent caterpillar. The forest species attacks mostly forest trees and seldom fruit trees. The web of the fall webworm can be distinguished from that of the tent caterpillars by the fact that the webworm's nest is made at the tip of a branch instead of at the crotch.

EAST GREENLAND CURRENT. An ocean current flowing south along the east coast of Greenland, carrying water of low salinity and low temperature. The east Greenland current is joined by most of the water of the Irminger current. The greater part of the current continues through Denmark Strait between Iceland and Greenland, but one branch turns to the east and forms a portion of the counterclockwise circulation in the southern part of the Norwegian Sea. Some of the east Greenland current curves to the right around the tip of Greenland, flowing northward into Davis Strait as the west Greenland current. See also **Ocean Currents**.

EAST KOREA WARM CURRENT. See **Ocean Currents**.

EAST MADAGASCAR CURRENT. See **Ocean Currents**.

EATING DISORDERS. The term 'eating disorder' refers to a persistent and severe disturbance of eating habits that results in impaired physical health or psychosocial functioning. This disturbance should not be secondary to any recognized general medical disorder or other psychiatric condition. **Anorexia nervosa** and **bulimia nervosa** are the best characterized of the eating disorders. Anorexia nervosa has been recognized for many years, with physicians in the last century providing particularly good accounts of the disorder. In contrast, bulimia nervosa was first described in 1979. The two disorders are closely related in that they have many features in common and some patients move from one disorder to the other (generally from anorexia nervosa to bulimia nervosa). Other eating disorders are encountered, most of which appear to be variants of anorexia nervosa or bulimia nervosa. These disorders are referred to as 'atypical eating disorders'.

Eating disorders should not be confused with obesity, which is a general medical condition in which there is excess body fat (a proxy being excess body weight). Eating disorders and obesity may coexist, although in clinical practice most people with an eating disorder have normal or low body weight. See also **Obesity**.

Anorexia Nervosa

Two features need to be present to make the diagnosis of anorexia nervosa. The first comprises a characteristic set of attitudes to shape and weight in which self-worth is judged largely, or even exclusively, in terms of shape and weight. Whereas most people evaluate themselves on the basis of their perceived performance in a variety of domains (such as interpersonal relationships, work, sport, artistic ability, etc.), in anorexia nervosa shape and weight dominate self-evaluation. This over evaluation of shape and weight (sometimes described as the 'core psychopathology') is seen in these people's intense interest in their shape and weight, their pursuit of weight loss, and their fear of weight gain.

The second core feature is the active maintenance of an unduly low body weight. This is the behavioral expression of the abnormal attitudes to shape and weight. For formal diagnostic purposes an 'unduly low body weight' may be defined as a body mass index (BMI) below 17.5. (The BMI is weight in kilograms (pounds) divided by height in meters (feet) squared.) This low weight is achieved and maintained by a variety of means, including intense dietary restriction, excessive exercising and, in some, self-induced vomiting. See also **Anorexia**.

Bulimia Nervosa

Three features need to be present to make the diagnosis of bulimia nervosa. The first comprises the same core psychopathology as in anorexia nervosa, with self-worth being judged in terms of shape and weight. The second is the practice of extreme weight-control behavior of the type that leads to the low weight in anorexia nervosa. Thus people with bulimia nervosa diet intensely, they may over exercise, and many engage in self-induced vomiting. In bulimia nervosa, however, body weight is generally unremarkable. This is because of the effect on weight of the third diagnostic feature: repeated episodes of uncontrolled overeating. These bulimic episodes (commonly referred to as 'binges') involve the consumption of unusually large amounts of food, given the circumstances, and a sense of loss of control at the time. It is this latter feature that distinguishes binge-eating from everyday overeating. Since the binges pose a considerable threat to weight control, many people with bulimia nervosa attempt to compensate for them by induced vomiting or taking large quantities of laxatives or diuretics. However, none of these forms of behavior is an effective means of preventing food absorption: self-induced vomiting results in the retrieval of only about one-half to two-thirds of what has been eaten; the taking of laxatives has a minimal effect on food absorption; and diuretic-taking has none. As a result, body weight in bulimia nervosa is typically unremarkable (generally the BMI is within the range of 20–25), the effects of dietary restriction being cancelled out by those of binge-eating. See also **Diet**.

Frequency and Clinical Importance

Anorexia nervosa appears to be largely confined to females aged between 10 and 30 years. Estimates of the incidence of the disorder range from 0.10 to 8.2 per 100 000 population per annum, the higher value being likely to be the more accurate. Estimates of the prevalence of the disorder amongst adolescent girls, the group most at risk, range from 0.2% to 0.8%. The disorder is uncommon among males, who comprise about 10% of cases. The social class distribution seems to be uneven, with an overrepresentation of cases from higher socioeconomic groups, but the extent to which this is a result of referral bias is not known. It used to be thought that the disorder was restricted to Western societies, but there is evidence that equivalent states occur (albeit at lower rates) in non-Western countries. Similarly, the disorder was thought to have become much more common over recent decades. This has recently been questioned, the increased incidence of the disorder being attributed instead to improved case detection. Irrespective of whether there has been a genuine increase in the incidence of the disorder, anorexia nervosa is a major cause for concern. The disorder has one of the highest mortality rates of any psychiatric illness and it can be extremely difficult to treat.

Bulimia nervosa affects a slightly older age group than anorexia nervosa, with most cases being in their twenties. It also appears to have a broader social class distribution. The disorder is considerably more common than anorexia nervosa, the prevalence rate among young women (15–40 years) being 1–2%. Most sufferers are not in treatment, and the subgroup that seeks help appears to be unrepresentative in a number of respects; for example, their eating disorder is more severe, their interpersonal functioning is more disturbed, they are lighter, and they have less strong

family histories of obesity. Whilst there are no satisfactory data on the incidence of bulimia nervosa, it seems that the disorder has become more common since the mid 1970s. From being an unusual variant of anorexia nervosa, it is now the most common eating disorder encountered in clinical practice. Bulimia nervosa is rarely seen in men.

Major Clinical Features and Complications

In anorexia nervosa the over evaluation of shape and weight results in a pursuit of thinness and weight loss. To the extent that this is successful, the disorder is "egosyntonic," that is, it is not viewed by the person as a problem. As a result there is little motivation to change or seek help. This is a major obstacle to treatment.

The low weight is primarily the result of the strict and self-imposed restriction of food intake. Typically the range of foods eaten is limited, with those foods viewed as fattening being avoided. Except in longstanding cases, appetite persists and for this reason the term 'anorexia' is not truly appropriate. Frequent intense exercising is a common feature and it contributes to the weight loss. Self-induced vomiting and the misuse of laxative and diuretics are practiced by a minority, and some have occasional bulimic episodes (binges).

Driving the disturbed eating habits is the so-called body image disturbance. This has several aspects. There is the attitudinal component, already mentioned, in which self-worth is judged largely in terms of shape and weight. In addition, there is also a perceptual element involving the overestimation of body size. The concerns about shape and weight lead to various forms of body checking, including frequent weighing, self-scrutiny in mirrors, body pinching and the repeated measurement of certain body parts especially the waist, hips and thighs. These behaviors are designed to evaluate progress in terms of controlling shape and weight, but instead they magnify the person's concerns. In some, the constant checking becomes so aversive and distressing that it is abandoned altogether, while the concerns about shape and weight persist unabated. In almost every case there is preoccupation with thoughts about food, eating, shape and weight, and often this is expressed as an avid interest in cooking, nutrition and allied topics.

Depression and anxiety, lability of mood, irritability, and obsessional thoughts and acts, are all common concomitants of anorexia nervosa. Typically these features become worse as weight is lost and improve with weight regain. Outside interests also decline as weight is lost and there is often marked social withdrawal. Suicidal thoughts are not uncommon with about one-third of the deaths being the result of suicide.

The physical abnormalities seen in anorexia nervosa have been the subject of much interest. They used to be viewed as evidence of a primary pituitary or hypothalamic disorder but it is now recognized that the great majority are secondary to the disturbed eating and state of starvation. The abnormalities include a wide range of endocrine changes (one effect of which is amenorrhoea), cerebral 'pseudoatrophy' in which there is a reversible enlargement of the lateral ventricles and cortical sulci accompanied by deficits in the volume of cerebral grey and white matter, and in long-standing cases decreased bone density leading to a heightened risk of fractures.

The clinical features of bulimia nervosa are similar to those of anorexia nervosa. There is the same over evaluation of shape and weight, and this leads to the same methods of weight control and body checking. The main difference lies in the frequent bulimic episodes and the resulting normal weight. The other important difference is that the disorder is "egodystonic," that is, it is viewed by the person as a problem that they would like to overcome. This difference in attitude to the eating problem is a direct consequence of the episodes of loss of control over eating.

The "binges" of people with bulimia nervosa generally involve the consumption of sizeable amounts of food (typically over 2000 kcal per episode), and they are a source of great distress and shame. As a result, they tend to be kept secret from others. In the majority of cases, they are followed by self-induced vomiting or the taking of laxatives. Between the bulimic episodes, food intake is severely restricted. Symptoms of depression and anxiety are prominent; indeed more so than in anorexia nervosa and a subgroup has problems with alcohol or drug misuse.

The physical abnormalities encountered in bulimia nervosa resemble those seen in anorexia nervosa, but they are not as severe. The abnormality of greatest potential clinical importance is the electrolyte disturbance found in those who vomit frequently or take large quantities of laxatives or diuretics. In extreme cases there is a risk of cardiac irregularities and renal damage. However, the mortality rate does not appear to be increased in bulimia nervosa.

Psychopathology

It is generally accepted that anorexia nervosa and bulimia nervosa are the result of a complex interplay of biological, psychological and social processes that have different influences at different stages in the development and subsequent course of the disorder. The understanding of the exact nature of these processes is limited, although there is increasing convergence between the findings of biological and psychosocial studies. It is evident that some processes are more relevant to anorexia nervosa than to bulimia nervosa, and some serve more to maintain these disorders than to initiate them.

Development of Anorexia Nervosa and Bulimia Nervosa. Anorexia nervosa generally starts in mid adolescence with a period of voluntary dietary restriction which proceeds to get out of control. Whereas everyday adolescent dieting is neither extreme nor persistent, in anorexia nervosa the dietary restriction rapidly becomes unremitting and intense. As a result body weight falls and a state of starvation eventually develops. Shape and weight concerns may predate the onset of the dieting or develop as weight is lost.

Bulimia nervosa starts in a similar way although the age of onset is typically some years later and the shape and weight concerns tend to antedate the dieting. The dietary restriction is similar to that seen in anorexia nervosa and it leads to weight loss (sufficient to result in a period of anorexia nervosa in about one-quarter of cases), but instead of strict dietary control being maintained it eventually becomes punctuated by episodes of overeating. This breakdown in control generally occurs within 2 years of the onset of the dieting. At first the episodes of overeating may be both modest in size and intermittent, but gradually they become larger and more frequent. As a result, the lost weight is regained, with body weight returning more or less to the level at which the dieting first began. By this point the disorder tends to be self-perpetuating. At some stage self-induced vomiting and laxative misuse are adopted by many in an attempt to compensate for the episodes of overeating. In practice, however, both behaviours have the opposite effect because belief in their effectiveness undermines efforts to control eating.

Predisposing Factors and Processes. A variety of factors is known to increase the risk of developing anorexia nervosa. These may be usefully divided into four classes. First, there are demographic risk factors, which are being female and adolescent. Second, there are factors that are known to increase the risk of psychiatric disturbance in general and of depression in particular. These include a family history of psychiatric disorder, especially depression, and exposure to a variety of adverse childhood experiences including parenting deficits and sexual and physical abuse. A profound sense of low self-esteem and ineffectiveness is also common and is likely to be in part the result of these negative experiences.

The third class of risk factor is a distinctive set of psychological traits. This comprises perfectionism (i.e. imposing on oneself impossibly demanding personal standards); steadfast determination and persistence in trying to achieve personal goals; and a tendency towards inflexibility. Clearly such traits are assets when present to a moderate degree and directed towards a constructive end. Unfortunately, in anorexia nervosa they tend to be extreme and employed in the service of controlling eating and achieving weight loss.

The fourth, but apparently least influential, class of risk factor consists of exposure to a social environment that encourages dieting. One example is being brought up in a family in which there is intense interest in shape, weight and eating, possibly as a result of one or more family members having an eating disorder or medical condition that affects eating or weight (such as diabetes mellitus). Another example is being exposed to social or occupational pressures to diet, for example by participating in sports in which weight or shape are important or by taking part in activities such as ballet or modeling.

A similar set of aetiological processes appears to operate in bulimia nervosa. The demographic risk factors are the same as those for anorexia nervosa, that is being a young woman, although in the case of bulimia nervosa the disorder appears to be largely restricted to westernized societies.

The three other classes of risk factor are also relevant although their relative influence appears to differ. The risk factors for psychiatric disturbance in general are more prominent than in anorexia nervosa, whereas

the psychological traits of perfectionism, determination and inflexibility are somewhat less pronounced. However, it is the level of exposure to factors that directly encourage dieting that most clearly differentiates bulimia nervosa from anorexia nervosa. For example, there are strikingly raised rates of both parental and childhood obesity (antedating the eating disorder), both of which are likely to sensitize individuals to their appearance and weight, and thereby make them prone to diet. See also **Obesity**.

There is one further class of risk factor that appears relevant to bulimia nervosa in particular. This is parental substance abuse. How it operates is not clear, but it may be that some people who develop bulimia nervosa have a heightened vulnerability to mood instability which they learn to modulate by consuming large quantities of food, alcohol or psychoactive drugs. See also **Mood Disorders**.

It is not understood why people with anorexia nervosa are able successfully to maintain strict control over their eating whereas those with bulimia nervosa are not. Several factors appear to be of relevance. First, the traits of perfectionism, determination and inflexibility are more prominent in anorexia nervosa and these are likely to underlie the striking degree of self-control. Second, there appears to be a marked vulnerability to obesity in bulimia nervosa which may somehow undermine dietary restriction. Third, there is more mood lability in bulimia nervosa and this too seems to interfere with successful dietary restraint.

Contribution of Genetic Factors and Abnormalities in Brain Serotonin Activity. There is evidence that genetic factors contribute to the aetiology of anorexia nervosa. Family–genetic studies have shown that the risk of an eating disorder is substantially increased among the female biological relatives of people with anorexia nervosa, and twin studies have shown that the concordance rate is higher among monozygotic than dizygotic twin pairs. Similar findings are emerging from family and twin studies of bulimia nervosa, although the extent of the genetic contribution is less clear. See also **Serotonin**.

The nature of the inherited vulnerability is not known. The findings of the family–genetic studies suggest that the liability is not shared with that for other psychiatric disorders, whereas there is evidence of shared familial transmission between anorexia nervosa and 'obsessive compulsive personality disorder', a construct that overlaps considerably with the psychological traits mentioned above. Thus anorexia nervosa and obsessive compulsive personality disorder may be common phenotypic expressions of a similar genotype. There may also be genetically determined abnormalities in the regulation of weight and eating habits. This seems especially likely in bulimia nervosa where there are raised rates of parental and childhood obesity. See also **Hypothalamic Control of Food Intake and Body Weight**.

Attempts to identify the genes that confer susceptibility to anorexia nervosa and bulimia nervosa are at an early stage, the main focus being on those implicated in serotonin (5-hydroxytryptamine; 5-HT) neurotransmission. This neurotransmitter is of particular interest for a number of reasons: first, it is known to have an important role in the control of both eating and mood; second, there is evidence that there may be trait-related abnormalities in brain 5-HT function in both anorexia nervosa and bulimia nervosa; and third, it has been shown that dieting influences brain 5-HT function in women. This raises the possibility that in women dieting has the potential to exaggerate a preexisting genetically determined abnormality in brain 5-HT function and that this somehow contributes to the development of an eating disorder.

Maintenance of Anorexia Nervosa and Bulimia Nervosa

Several different processes appear to maintain the dietary restriction that is central to anorexia nervosa. One is the powerful and strongly reinforcing sense of self-control that these people obtain from restricting their eating. Another is the resulting weight loss, given the overevaluation of shape and weight. A third is the effect on others of refusing to eat. This can be of special significance if there are preexisting dysfunctional relationships, as may be the case. A fourth arises from various facets of the starvation state. For example, the social withdrawal and preoccupation with food and eating both serve to narrow the focus of these people's concerns, and the delayed gastric emptying produces feelings of fullness after eating relatively little.

In bulimia nervosa similar maintaining processes operate. For example, the periods of successful dietary control are strongly reinforcing, just as in anorexia nervosa, as is the initial weight loss. However, there are also important differences. First, since body weight is generally unremarkable, starvation-related perpetuating mechanisms tend not to operate. Second, since the disorder is often successfully kept secret, there may be no secondary effects on others. Third, the repeated binges, while being aversive and a stimulus to change, strongly encourage further dieting since they magnify fears of weight gain and undermine any sense of being in control.

Management

People with anorexia nervosa and bulimia nervosa vary in the severity of their presenting symptoms and their response to treatment. Some have a brief period of disturbance which remits spontaneously and does not recur; in others treatment is needed, but there is a full and lasting response; while in others the disorder persists and proves resistant to all attempts at treatment. As mentioned above, the mortality rate is substantially raised in anorexia nervosa. The period of greatest risk is the year after presentation. The best predictor of death is the severity of the emaciation.

The treatment of bulimia nervosa has been studied particularly intensively. The most effective treatment is a specific form of cognitive behavior therapy. This is a psychological treatment that addresses both the disturbed eating habits and the abnormal attitudes to shape and weight. It involves about 20 sessions over 5 months and results in substantial improvement in all aspects of functioning, with between one-half and two-thirds of patients making a full and lasting recovery. Antidepressant drugs are the only pharmacological treatment to have shown promise. They result in a decline in the frequency of binge eating and associated compensatory behavior, and an improvement in mood, but their effect is not as great as that obtained with cognitive behavior therapy and, more importantly, it is often not maintained. Some patients respond to simpler and briefer treatments including cognitive behavioral self-help manuals. For this reason a 'stepped care' approach to management has been advocated in which a simple treatment is used first with more intensive and specialized treatments being reserved for those who do not respond.

There has been relatively little research on the treatment of anorexia nervosa. This is for a number of reasons; including the low prevalence of the disorder and the fact that treatment may take a year or more. Another barrier to research, and indeed treatment, is its egosyntonic character which results in patients being reluctant to receive help.

In principle there are three aspects to the management of anorexia nervosa. First, there is persuading patients that they need help and maintaining their motivation thereafter. This is crucial given their reluctance to change. Second, there is weight restoration which may be achieved on an outpatient, day-patient or inpatient basis. This is also an essential part of treatment since it is needed to reverse the effects of starvation. In itself, weight restoration usually leads to a substantial improvement in the patient's physical and psychological state. Third, there needs to be specialized psychological interventions designed to improve eating habits, lessen shape and weight concerns, and enhance general psychosocial functioning. Usually these involve a combination of one-to-one cognitive behavior therapy and some form of family therapy. Drug treatment appears to have almost no role.

Summary

The eating disorders anorexia nervosa and bulimia nervosa are an important source of physical and psychosocial morbidity among adolescent girls and young women. They are the product of a complex interplay of biological, psychological and social processes. They vary greatly in their severity and response to treatment.

EBERT ION COUNTER. An ion counter of the aspiration condenser type, used for the measurement of the concentration and mobility of small ions in the atmosphere.

EBOLA HEMORRHAGIC FEVER. Ebola hemorrhagic fever (Ebola HF) is a severe, often-fatal disease in humans and nonhuman primates (monkeys and chimpanzees), that has appeared sporadically since its initial recognition in 1976.

The disease is caused by infection with Ebola virus. It is named after a river in the Democratic Republic of the Congo (formerly Zaire) in Africa where it was first recognized. The virus is one of two members of a family of RNA viruses called the Filoviridae. Three of the four subtypes of Ebola virus identified so far have caused disease in humans: Ebola-Zaire, Ebola-Sudan, and Ebola-Ivory Coast. The fourth, Ebola-Reston, has caused disease in nonhuman primates, but not in humans.

The exact origin, locations, and natural habitat (known as the natural reservoir) of Ebola virus remain unknown. However, on the basis of available evidence and the nature of similar viruses, researchers believe that the virus is zoonotic (animal-borne) and is normally maintained in an animal host that is native to the African continent. A similar host is probably associated with the Ebola-Reston virus subtype isolated from infected cynomolgous monkeys that were imported to the United States and Italy from the Philippines. The virus is not known to be native to other continents, such as North America.

Confirmed cases of Ebola HF have been reported in the Democratic Republic of the Congo, Gabon, Sudan, and the Ivory Coast. An individual with serologic evidence of infection, but showing no apparent illness has been reported in Liberia. A laboratory worker in England became ill as a result of an accidental needle-stick. No case of the disease in humans has ever been reported in the United States. The Ebola-Reston virus caused severe illness and death in monkeys imported to research facilities in the United States and Italy from the Philippines. During these outbreaks, several research workers became infected with the virus, but did not become ill.

Ebola HF typically appears in sporadic outbreaks, usually spread within a health-care setting (a situation known as amplification). It is likely that sporadic, isolated cases occur as well, but go unrecognized.

Infection with Ebola virus in humans is incidental as humans do not "carry" the virus. Because the natural reservoir of the virus is unknown, the manner in which the virus first appears in a human, at the start of an outbreak, has not been determined. However, researchers have hypothesized that the first patient becomes infected through contact with an infected animal. After the first case-patient in an outbreak setting (often called the index case) is infected, the virus can be transmitted in several ways. People can be exposed to Ebola virus from direct contact with the blood and/or secretions of an infected person. This is why the virus has often been spread through the families and friends of infected persons. In the course of feeding, holding, or otherwise caring for them, family members and friends would come into close contact with such secretions. People can also be exposed to Ebola virus through contact with objects, such as needles, that have been contaminated with infected secretions.

Nosocomial transmission frequently has been associated with outbreaks of Ebola HF. Nosocomial spread includes both types of transmission described above, but the term is used to describe the spread of disease in a health-care setting such as a clinic or hospital. In African health-care facilities, patients are often cared for without the use of a mask, gown, or gloves. Exposure to the virus has occurred when health care workers treated individuals with Ebola HF without wearing these types of protective clothing. In addition, when needles or syringes are used, they may not be of the disposable type, or may not have been sterilized, but only rinsed before re-insertion into multi-use vials of medicine. If needles or syringes become contaminated with virus and are then reused, numbers of people can become infected.

The Ebola-Reston virus subtype, which was first recognized in a primate research facility in Virginia, may have been transmitted from monkey to monkey through the air in the facility. While all Ebola virus subtypes have displayed the ability to be spread through airborne particles (aerosols) under research conditions, this type of spread has not been documented among humans in a real-world setting, such as a hospital or household.

The signs and symptoms of Ebola HF are not the same for all patients. *The* Table 1 *below* outlines symptoms of the disease, according to the frequency with which they have been reported in known cases.

TABLE 1. SYMPTOMS OF EBOLA HF

Time Frame	Symptoms that occur in most Ebola patients	Symptoms that occur in some Ebola patients
Within a dew days of becoming infected with the virus:	High fever, headache, muscle aches, stomach pain, fatigue, and diarrhea.	Sore throat, hiccups, rash, red and itchy eyes, vomiting blood, and bloody diarrhea.
Within one week of becoming infected with the virus:	Chest pain, shock, and death.	Blindness and bleeding.

Researchers do not understand why some people are able to recover from Ebola HF and others are not. However, it is known that patients who die usually have not developed a significant immune response to the virus at the time of death.

Diagnosing Ebola HF in an individual who has been infected only a few days is difficult because early symptoms, such as red and itchy eyes and a skin rash, are nonspecific to the virus and are seen in other patients with diseases that occur much more frequently. If a person has the constellation of symptoms described in the Table 1 and infection with Ebola virus is suspected, several laboratory tests should be done promptly. These include a blood film examination for malaria and a blood culture. If the suspected patient has bloody diarrhea, a stool culture should also be performed.

Laboratory tests used to diagnose Ebola hemorrhagic fever are Antigen-capture enzyme-linked immunosorbent assay (ELISA) testing, IgG ELISA, polymerase chain reaction (PCR), and virus isolation can be used to diagnose a case of Ebola HF within a few days of the onset of symptoms. Persons tested later in the course of the disease or after recovery can be tested for IgM and IgG antibodies. The disease can also be diagnosed retrospectively in deceased patients by using immunohistochemistry testing, virus isolation, or PCR.

There is no standard treatment for Ebola HF. Currently, patients receive supportive therapy. This consists of balancing the patient's fluids and electrolytes, maintaining their oxygen status and blood pressure, and treating them for any complicating infections. During a large outbreak of Ebola HF in Kikwit, Democratic Republic of the Congo, in 1995, eight patients were given blood of individuals who had been infected with Ebola virus but who had recovered. Seven of the eight patients survived. However, because the study size was small, and because the characteristics of the participants predisposed them towards recovery, the efficacy of the treatment remains unknown.

The prevention of Ebola hemorrhagic fever in Africa presents many challenges. Because the identity and location of the natural reservoir of Ebola virus are unknown, there are few established primary prevention measures.

If cases of the disease do appear, current social and economic conditions favor the spread of an epidemic within health-care facilities. Therefore, health-care providers must be able to recognize a case of Ebola HF should one appear. They must also have the capability to perform diagnostic tests and be ready to employ practical viral hemorrhagic fever isolation precautions or barrier nursing techniques. These techniques include the wearing of protective clothing, such as masks, gloves, gowns, and goggles;

the use of infection-control measures, including complete equipment sterilization; and the isolation of Ebola HF patients from contact with unprotected persons. The aim of all of these techniques is to avoid any person's contact with the blood or secretions of any patient. If a patient with Ebola HF dies, it is equally important that direct contact with the body of the deceased patient be prevented.

In conjunction with the World Health Organization, the CDC has developed practical, hospital-based guidelines, titled *Infection Control for Viral Haemorrhagic Fevers in the African Health Care Setting*. The manual describes how health care facilities can recognize cases of viral hemorrhagic fever, such as Ebola HF, and prevent further hospital-based disease transmission by using locally available materials and few financial resources if a case of VHF is diagnosed in the facility. A similarly practical diagnostic test that uses tiny samples from patients' skin has been developed to diagnose Ebola HF in suspected case-patients who have died retrospectively.

Scientists and researchers are faced with the challenges of developing additional diagnostic tools to assist in early diagnosis of the disease and ecological investigations of Ebola virus and the disease it causes. In addition, one of the research goals is to monitor suspected areas to determine the incidence of the disease. More extensive knowledge of the natural reservoir of Ebola virus and how the virus is spread must be acquired to prevent future outbreaks effectively.

EBONY TREE. See **Persimmon Trees**.

EBULLIOMETER. An instrument, sometimes referred to as an ebullioscope, that measures the property of a substance by noting a deviation from a normal known boiling point. The term applies to apparatus for estimating the percentage of alcohol in a mixture through observation of the boiling point. Beckmann's apparatus for molecular weight determination is an ebullioscope. The ebullioscopic constant is a quantity calculated to represent the molal elevation of the boiling point of a solution by the relationship:

$$K = \frac{RT_0^2}{1000l_e}$$

in which K is the ebullioscopic constant, R is the gas constant, T_0 is the boiling point of the pure solvent, and l_e is the latent heat of evaporation per gram. The product of the ebullioscopic constant and the molality of the solution gives the actual elevation of the boiling point for the range of values for which this relationship applies. Unfortunately, this range is limited to very dilute solutions, not extending to solutions of unit molality.

See also **Beckmann Method**.

EBULLISM. The formation of bubbles, with particular reference to water vapor bubbles in biological fluids caused by reduced ambient pressure; the boiling of body fluids. See also **Ebulliometer**.

EBULLITION. The boiling of a liquid; specifically, the formation within the liquid of bubbles of that liquid's vapor and the vigorous ascent of the bubbles to the liquid's surface, a process that usually begins at that liquid's nominal boiling point. Ebullition produces a much greater rate of escape of liquid molecules into the vapor phase than does evaporation, since the effective area for phase change is much greater in a boiling liquid than in a liquid evaporating from the same container, in that each bubble affords surface area for local evaporation. See also **Boiler (Steam Generator)**; and **Boiling**.

ECCENTRIC. The eccentric is a machine element employed to convert rotating to reciprocating motion. Its function is similar to that of the crank. The eccentric is used chiefly for short throws, where it would be undesirable to break the shaft, as is necessary in the case of a crank. It consists of a disk mounted on a shaft in such a way that the geometric center of the disk does not coincide with the center of rotation. The distance between the center of rotation and the geometric center of the eccentric is the throw. This corresponds to the crank-arm distance of an equivalent crank. The eccentric must be used in conjunction with an eccentric strap which surrounds the eccentric, and which transmits the reciprocating motion to an eccentric rod rigidly attached. The eccentric is chiefly used to drive auxiliaries such as valve gear, and where reciprocation of small magnitude is needed. The cam and crank may be employed to provide similar motion. See Fig. 1.

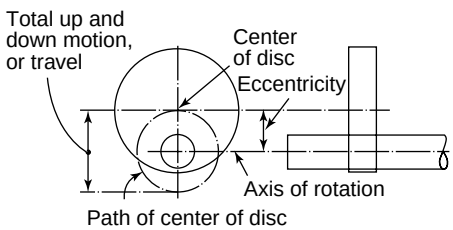

Fig. 1. Simple eccentric.

ECCLES, JOHN CAREW (1903–1997). John Eccles was an Australian neurophysiologist, renowned for his work on the nature of synaptic transmission. Eccles was born in 1903 in Melbourne, Australia. After gaining his medical degree from Melbourne University in 1925, he travelled to Oxford University on a Rhodes Scholarship to study physiology under Sir Charles S. Sherrington. His PhD thesis, completed in 1929, was on the excitation and inhibition of the nervous system, a subject to which he would devote much of his career. As part of Sherrington's 'school' he studied the reflexes of the spinal cord, research for which Sherrington shared the 1932 Nobel Prize for Medicine or Physiology with E. D. Adrian. See also **Adrian, Edgar Douglas (1889–1977)**; and **Sherrington, Charles Scott (1857–1952)**.

In 1928 Eccles married Irene Miller. He remained in Oxford, first as a Fellow at Exeter College, then at Magdalen College. Here he became involved in a controversy surrounding the nature of synaptic transmission. Eccles Sir Henry Dale, argued that it was chemical in nature. This fundamental difference believed that transmission was an electrical process, whereas other eminent figures, notably of opinion led Eccles to focus his research on the mechanism behind the transmission process. See also **Dale, Henry Hallett (1875–1968)**; and **Synapse**.

Sherrington retired in 1935 and Eccles returned to Australia. In 1937 he was appointed Director of the Kanematsu Memorial Institute of Pathology at the Sydney Hospital. Due to the demands of the Second World War his research was sidelined. In 1944 he accepted the Professorship of Physiology at the University of Otago, Dunedin, New Zealand. It was here that he was inspired by the philosopher Karl Popper, who lectured on philosophy of science at Canterbury University College, Christchurch. Eccles began a series of experiments designed to disprove his notion that transmission was an electrical rather than a chemical process. According to Popper it was not possible to prove a hypothesis, only to disprove it. With instrumentation designed by Jack Coombs, an electrical engineer, Eccles studied synaptic transmission in the spinal cord, at the cellular level. This series of experiments led him to conclude that synaptic transmission must be chemical. Sir Henry Dale likened this conversion to that of Saul on the road to Damascus.

In 1951 he accepted the Chair of Physiology at the newly formed Australian National University. Using special apparatus to record intracellular activity, he produced a series of papers in 1955 which detailed the ionic mechanisms underlying excitation and inhibition at spinal synapses. It was for this research that he received a share of the 1963 Nobel Prize for

Medicine and Physiology. Around him he created a highly productive group of researchers on neurophysiology. He was knighted in 1958.

ECHELETTE. The relative intensities of the light in various orders of a diffraction grating depend on the groove shape of the rulings. With only 1,000–2,000 lines per inch (394–787 per centimeter) of ruled surface and proper groove shape, usually rather broad, 75% or more of the reflected light can be thrown into a single order. Such a grating is called an echelette.

ECHELLE GRATING. In studies of high resolution diffraction gratings, it is observed that resolving power at a given wavelength depends only on the ruled width of the grating and the angles of illumination and observation, and not specifically on the number of ruled grooves. The ruling of many inches of a grating, within a few tens of thousands of lines per inch, is an almost impossible task. An echelle grating has very fine lines ruled much farther apart than is customary. Such a grating has very high resolution, but over only a quite narrow band of wavelengths. Hence it is customary to cross an echelle grating with a second grating (or prism) of lower resolving power, thus producing what is essentially a two-dimensional spectrogram or echellegram.

The resolving power of a diffraction grating depends primarily on the total ruled width and the angles of incidence and refraction. Thus high resolving power should be obtainable with coarse rulings, 100 or so per inch, if the grooves are properly shaped. When the grooves are fixed to reflect light of all colors in a narrow bundle, the resulting echelle grating may have a resolving power equivalent to that of a diffraction grating with 30,000 lines per inch (11,811 per centimeter). It lacks, however, the angular dispersion needed to separate the spectra of consecutive orders; thus this grating is usually crossed with a prism or another grating of lower resolving power.

ECHELON. A highly specialized form of diffraction grating, devised by Michelson. It consists of a row of glass plates of exactly equal thickness, packed together to form a miniature stairway of equal risers. The light enters normally to the largest plate at one end (see Fig. 1) and emerges at various deviations through the low "risers." It is easily shown that if the thickness of the plates is a, the height of the "risers" b, and the refractive index of the glass n, the equivalent path difference between successive emergent streams for any angle of deviation Δ is $na = a\cos\Delta + b\sin\Delta$; or since Δ is in practice always small, $\cos\Delta = 1$ and $\sin\Delta = \Delta$ (in radians), giving $(n-1)a + b\Delta$. This must be equal to an integral multiple, N, of the wavelength λ for any spectrum line, the deviation of which is therefore:

$$\Delta = N\frac{\lambda}{b} - (n-1)\frac{a}{b}$$

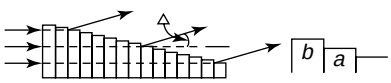

Fig. 1. Echelon.

The smallest value N can have (for $\Delta = 0$) is $(n-1)a/\lambda$, which, since a is usually several millimeters and $(n-1)$ is 0.5 or more, is of the order of several thousand. The disposition, viz.,

$$D = \frac{d\Delta}{d\lambda} = \frac{N}{b} - \frac{a}{b}\frac{dn}{d\lambda}$$

is correspondingly large. The echelon is thus especially adapted to the study of the hyperfine structure of spectrum lines. For other instruments of high resolving power, see **Echelette**; **Echelle Grating**; and **Interferometer**. See also **Diffraction Grating**.

ECHIDNA. See **Fossils and Paleontology**.

ECHINODERMATA. A large division of the animal kingdom including the starfishes, sea cucumbers, brittle stars, sea lilies, sea urchins, and basket stars, all marine animals.

This phylum is characterized by the following structures: (1) The adult is almost perfectly radially symmetrical, although the young are bilateral. (2) The wall of the body contains a hard skeleton in most forms, made up of calcareous bodies called ossicles. (3) The coelom is well developed. (4) A water vascular system is present, consisting of a closed series of tubes opening to the exterior at one point on the body and bearing many delicate sacs, the tube feet or tentacles, which protrude at the surface of the body. (5) There is no special excretory system.

The echinoderms are divided into several classes, which fall into two subphyla:

Subphylum *Eleutherozoa*. Without a stalk.
- Class *Asteroidea*. The starfishes.
- Class *Ophiuroidea*. The brittle stars.
- Class *Echinoidea*. The sea urchins, sand dollars, etc.
- Class *Holothuroidea*. The sea cucumbers.

Subphylum *Pelmatozoa*. With a stalk at least when young.
- Class *Crinoidea*. The feather stars, basket stars, and sea lilies.

See also **Invertebrate Paleontology**.

ECHINOIDEA. The sea urchins, keyhole urchins, and sand dollars. A class of the phylum *Echinodermata*.

The members of this class are distinguished by the following characteristics: (1) The body varies from almost globular to thin disks. (2) The tube feet are suckers. (3) The surface bears long spines and pedicellariae. (4) There are no radiating arms. (5) The ossicles are closely associated to form a shell. See Fig. 1.

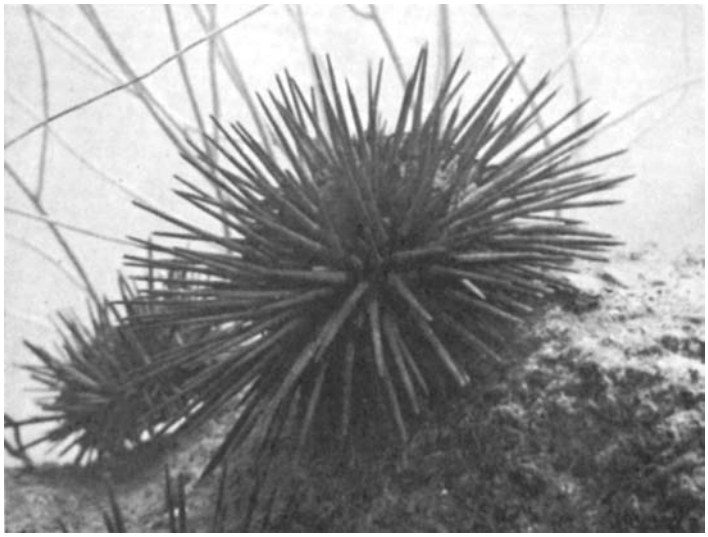

Fig. 1. Sea urchin (*Echinoidea*). (*A.M. Winchester*.)

Sea urchins live on organic matter of all kinds, including small animals, plant tissues, and waste matter. They are of little economic importance but in some of the Mediterranean countries and to a limited extent in the Orient they are used as food.

The class is divided into the following subclasses:

Subclass I. *Bothriocidaroidea* — extinct.
Subclass II. *Regularia* or *Endocyclica* — periproct encircled by apical system of plates.
Subclass III. *Irregularia* or *Exocyclica* — periproct outside apical system of plates.

ECHO. A wave which has been reflected at one or more points in the transmission medium, or otherwise returned with sufficient magnitude and delay to be perceived in some manner as a wave distinct from that directly transmitted. There are several types of natural echoes, including: (1) The discrete single echo. (2) The discrete multiple echo (a number of successive reflections). (3) The overlapping multiple echo — reverberation.

(4) The diffuse echo, due to the scattering of sound by many small objects. (5) The harmonic echo, due to the greater scattering of an overtone than of the fundamental. (6) The musical echo, due to reflection from, or scattering by, a series of objects spaced at uniformly increasing distances from the source. (7) In radar, a general term for the appearance, on a radar indicator, of the radio energy returned from a target. More explicitly, it refers to the energy reflected or scattered back from a target. See also **Sonar**.

ECHO BOX. A type of electronic instrument used to test and adjust radar equipment. It operates on the principle of a cavity resonator. A small amount of electromagnetic energy from the transmitting antenna is fed into a small cavity (or box), the volume of which can be adjusted to resonate electrically, or "ring," to signals of this frequency, like a tuning fork responding to a musical note of proper pitch. This resonance is detected by the radar receiver. The amount of resonance appearing at the receiver output (the oscilloscope) is a function of the power transmitted, the tuning of the cavity, and the tuning and amplification of the receiver. Accordingly, the echo box provides a test of the overall efficiency of the radar system, eliminating atmospheric variables.

AMS

ECHOCARDIOGRAPHY. The use of ultrasound in a technique known as *echocardiography* has been available since the late 1960s. It has proved of particular value in evaluating such conditions as pericardial effusion, rheumatic disease of the mitral valve, mitral valve prolapse, left atrial tumors, hypertrophic cardiomyopathy, and abnormal dilation of the left ventricle, among other heart problems. See **Heart and Circulatory System (Physiology)**. In heart examinations, the ultrasound beam (narrowly focused) is directed so that it will provide three standard views (left ventricle; mitral valve; aorta and left atrium). The ultrasound reflected from blood-tissue interfaces within the heart and great vessels reveals much concerning the internal anatomy of the heart. The reflected ultrasound radiation is displaced against time, yielding a detailed picture of the motion of the structures of the heart during the cardiac cycle.

In a refinement known as two-sector scanning, a large series of ultrasound beams produces a two-dimensional image of cardiac anatomy.

There appear to be no risks or discomfort associated with echocardiography.

ECHO INTENSITY. The brightness or brilliance of a radar echo as displayed on an intensity-modulated indicator. Echo intensity is, within certain limits, proportional to the voltage of the target signal or to the square root of its power.

ECHO POWER. The electrical strength, or power, of a radar target signal. Echo power is normally measured in watts or dbm (decibels referred to a milliwatt).

ECHO PULSE. A pulse of radio energy received at the radar after reflection from a target; that is, the target signal of a pulse radar.

ECHO SOUNDER. A device used to determine the depth of the sea floor beneath sea level. The device emits a high-pitched sound from the ship's hull. Traveling through sea water at a rate of 4,800 feet (1,440 meters) per second, the sound is echoed back from the sea floor to the ship for detection. Since each leg of the round trip is equal, the elapsed time (in seconds) is divided in two and multiplied by 4,800 to give the total depth in feet (or multiplied by 1,440 to give the total depth in meters). Present models can plot a continuous record of depth as the ship travels.

ECHO SUPPRESSOR. When an electric wave on a line encounters a discontinuity or point at which the impedances do not match (see also **Impedance Matching**) some of it is reflected. This reflected wave may return to the sending end of the line with sufficient amplitude to be objectionable. This is especially true in telephone service. While an effort is made to prevent reflections, there are cases where energy is fed back along the line and returns to the sender as an echo. In certain systems two lines (4 wires) are employed for transmission in the two directions and in such systems echo suppressors may be used to suppress the returning wave. One rather simple method of achieving this result is to use a relay to short one line when there is a signal on the other. Thus, if party A is talking and sending a voice signal to B, the voice currents on the line from A to B operate a shorting relay across the line from B to A so party A does not receive his own voice as an echo.

ECLIPSE. A term applied to the obscuration of a celestial body due to the interposition of another body or object. There are fundamentally two kinds of eclipse situations, distinguished by whether (1) the eclipsed object is *self-luminous*; or (2) the eclipsed object normally *shines* by *reflected light*.

In the first case, an eclipse occurs when an opaque object passes between the luminous body and the observer. The best known eclipse of this type, of course, is an *eclipse of the sun*, as caused by the moon blocking off light from the sun before the light can reach an observer on earth. Depending upon several factors, such an eclipse may be *total*, where to observers within the *shadow path* of the moon all light is blocked off. Or, such an eclipse may be *partial*, where only part of the light is cut off. Details of a solar eclipse are given a bit later.

In the second case, a body that normally shines by reflected light is eclipsed by putting that body in the shadow cast by an opaque body that intervenes in the direct path from the luminous body and the eclipsed body. The best known eclipse of this type is an *eclipse of the moon*, as caused by the earth blocking off light from the sun before the light can reach the moon. Thus, during the period of an eclipse of the moon, an observer on earth will see the moon pass into and out of darkness. Again, depending upon several factors, such an eclipse may be *total*, where the moon is completely within the shadow of the earth, or *partial*, where only part of the sun's light is cut off. Details of a lunar eclipse are given later.

Eclipses of the first kind also apply to instances where the moon may block off the radiation from a star or reflected light from a planet from reaching earth; and also in the case of eclipsing binary stars. See also **Eclipsing Binary**. Where relatively small objects come between earth and sun, as in the case of a planet blocking off radiation from a star, the term occultation is usually used instead of eclipse. *Occultation* of a planet by the moon also may occur. When an apparently very small object intervenes between sun and earth, as in the case of the planet Mercury, the path of the planet across the face of the sun can be observed. The amount of radiation reaching earth from the sun when this occurs is reduced by such a tiny amount that using the term eclipse is hardly appropriate. For situations of this kind, the term *transit* is commonly used.

Eclipses of the sun and moon have been scientifically important as well as very interesting to lay people and, in fact, to some cultures the eclipses are associated with matters of mystique, superstition, taboos, prophecy, and fear. Mention of eclipses in history is also important to scholars for fixing accurate dates to past events. As an example, reference may be made to an Assyrian table which states; "Insurrection in the city of Assur. In the month of Sivan the sun was eclipsed." This probably also refers to the solar eclipse of June 15, 763 B.C. This is the same eclipse referred to in Amos VII:9: "I will cause the sun to go down at noon, and I will darken the earth in the clear day."

Eclipses, particularly total eclipses of the sun, have been scientifically important in terms of bettering astronomical measurements, the development of solar physics, and proving and disproving various hypotheses and theories, among other scientific objectives. These developments are reviewed briefly a bit later.

Over the years, instruments (see **Sun (The)**) have been developed that essentially duplicate many of the observational advantages of a total eclipse, such as investigating the corona of the sun. However, large groups of scientists from all over the world continue to travel to areas, sometimes quite inaccessible, to view and carry on special scientific measurements during the period of totality. In recent years, scientists have been joined by growing numbers of lay astronomers who desire the personal experience of witnessing such an event. For example, hundreds of persons, including representatives of the news media, traveled to Kenya's Taita Hills to view the total eclipse of the sun on February 16, 1980.

This occurred again in the case of the 1991 total solar eclipse visible from Hawaii's Mauna Kea.

Geometry of Eclipses

Distances from earth, the relative size or apparent diameters of the participating bodies, and orbital speeds and eccentricities are among the major factors which contribute to positioning the participating bodies at just the right places in the same time frame that result in some kind of eclipse situation. Since all of the foregoing factors relate in a varying manner with

time, circumstances for eclipses of the sun and moon occur comparatively infrequently. In only a few years in a given century will circumstances permit up to seven eclipses. In such years, there may be either two of the moon and five of the sun; or three of the moon and four of the sun. Only two years of the 20th century permitted the first of the two foregoing situations — in 1935 and 1982. During this century (1901 through 2000 A.D.), there will have been a total of 375 eclipses, of which 228 will have been solar and 147 lunar eclipses. This is an average of approximately four eclipses per year. Eclipses of the moon, particularly to the layman, may seem more frequent than solar eclipses simply because lunar eclipses are observable over wide areas of earth — in fact, any observer who would be seeing the moon during a given period will witness the moon in eclipse. In contrast, viewing of solar eclipses is limited to a relatively narrow shadow path on earth. Further, the period of totality of a solar eclipse, in the extreme, will not exceed about 7.5 minutes; whereas the moon may be fully darkened up to a period of about 2 hours.

Variations in the sun-earth-moon system not only affect the exact dates on which eclipses will occur, but the type of eclipse (total or partial), the duration of the eclipse, and the locations on earth from which an eclipse can be observed.

With reference to the diagram of Fig. 1 in the entry on **Moon (Earth's)**, it will be noted that an eclipse situation can occur only when the moon is at one of its nodes.[1] These nodes occur at those positions when there is a new moon and when there is a full moon. In the idealized diagram of the figure, not allowing for tilt or eccentricity of orbits, these are the points where the moon is most directly between the earth and the sun (new moon); and where the earth is most directly between the moon and the sun (full moon). Total eclipses of the sun occur when there is a new moon; total eclipses of the moon occur when there is a full moon.

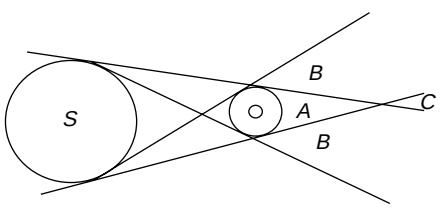

Fig. 1. Formation of shadows for eclipse of sun or moon.

The diagram of Fig. 1 (of the present entry) can be used to illustrate the circumstances of an eclipse of the sun as well as an eclipse of the moon. The opaque body is *O*. The luminous body is *S*.

Eclipses of the Sun

In the case of an eclipse of the sun, Consider *S* to be sun; *O* the moon. The moon will cast a shadow toward earth, known as the umbra, and represented by area *A*. The umbra is the darkest central part of a shadow. (When a source of light, not a point source, casts a shadow of an object, the shadow consists of two parts — the umbra, just defined, where the region is completely cut off from the light, and the penumbra, which is partly illuminated by some part of the light. The penumbra is a region of semi-shadow over which the illumination gradually increases from total darkness to full illumination. From a point within the penumbra, the light source is partially, but not totally occulted by another body.)

A solar eclipse viewed from the region of the umbra will be a *total eclipse*. Viewed from the regions of the penumbra (*B* areas located on either side of the umbra), the occurrence will be seen as a *partial eclipse* of the sun. For an observer within the umbra, the progress of the solar eclipse will appear as diagramed in Fig. 2. For an observer within the *penumbra*, the disk of the sun will be viewed with a circular segment cut out, thus with the light reduced, but not completely cut off. The viewing path of the solar eclipse of 1979 is shown in Fig. 3.

In an annular eclipse of the sun, the moon obscures the central part of the disk of the sun, but leaves a thin ring of light showing round the

[1] Nodes are the points at which the orbit of any satellite crosses the plane of the primary's equator or other fundamental reference plane such as the ecliptic. Movement of these crossing points caused by pertubations is termed the *regression of the nodes*.

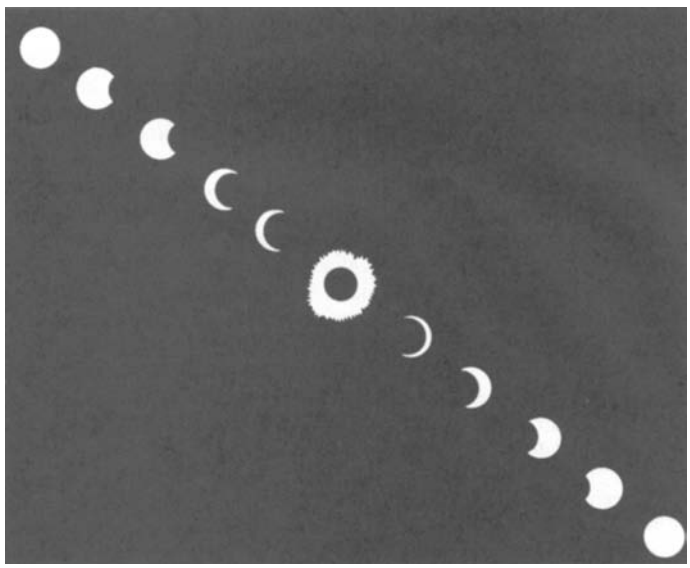

Fig. 2. Progress of a total eclipse of the sun at intervals of approximately 10 minutes.

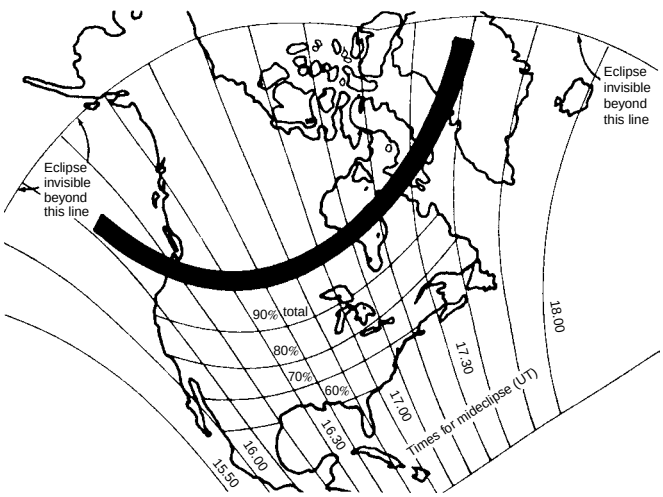

Fig. 3. Viewing path of total solar eclipse of 1979. (*Kitt Peak National Observatory*.)

circumference. With reference to Fig. 1, this is the situation as viewed from *C*. An annular eclipse occurs when the moon is directly between earth and sun, but when the moon is near its farthest point from earth and where the umbra of the shadow does not quite reach the earth. From knowledge of the diameters of *S* and *O* and the distance between the two objects, the dimensions of the various parts of the shadow may be calculated. The apparent diameters of sun and moon must be nearly the same to assure a total eclipse. This is not true for annular eclipses.

Because the orbit of the earth-moon system about the sun is eccentric, the length of the umbra cone *A* varies between the following approximate distances: at *aphelion* (point where earth-moon system is farthest from the sun), the length of the embra cone is 236,000 miles (377,800 kilometers); and at *perihelion* (point where earth-moon system is closest to the sun), the length of the umbra cone is 228,000 miles (365,000 kilometers). Also, owing to the eccentricity of the moon's orbit, the distance of the moon from the surface of the earth varies between 221,463 miles (356,334 kilometers) at *perigee* (the point where the moon is nearest to the earth) and 252,710 miles (406,610 kilometers) at *apogee* (the point where the moon is farthest from the earth). Examination of these numbers indicates that with the earth at aphelion and the moon at perigee, the surface of the earth is about 18,200 miles (29,284 kilometers) inside of the apex of the umbra. Under these conditions, the most favorable for an eclipse of the sun, the shadow of the moon on the earth will be a spot about 170 miles (274 kilometers) in diameter and, within this area, a total eclipse of the sun may be observed. Surrounding the spot of totality, there will be a region

of about 3000 miles (4827 kilometers) radius, within which the sun will be partially eclipsed. With the earth at perihelion and the moon at apogee, the surface of the earth will be 19,500 miles (31,376 kilometers) beyond the apex of the umbra cone, a condition permitting the observation of an annular eclipse, but where totality is not possible.

As the moon revolves about the earth in its orbit, the shadow sweeps along the plane of the moon's orbit with a velocity of about 2100 miles (3379 kilometers) per hour to the eastward. The earth is rotating at such a rate that a point on the equator is moving to the east with a velocity of about 1040 miles (1673 kilometers) per hour. Accordingly, under the most favorable conditions for a solar eclipse (moon at perigee: earth at aphelion; eclipse occurring at noon; observer on equator), the shadow will pass the observer with a speed of $2100 - 1040 = 1060$ miles ($3379 - 1673 = 1706$ kilometers) per hour. The shadow will pass the observer from west to east. The spot will pass the observer in slightly less than 8 minutes. The duration of a partial eclipse, on the other hand, may be several hours.

As stated previously, because the plane of the moon's orbit is inclined to the plane of the ecliptic, an eclipse of either the sun or the moon may occur only when the moon is close to one of the nodes, i.e., close to the plane of the ecliptic, and must also be in conjunction (for an eclipse of the sun), or in opposition (for an eclipse of the moon). Since the earth-moon system revolves about the sun once each year, the line of nodes would pass through the sun twice in each year if the direction of that line were fixed in space. Regression of the moon's nodes causes the line to pass close to the sun three times each year. The period when the line of nodes is close to the sun is known as an *eclipse season*. Two solar eclipses, either total or partial, must occur each year, and five may take place. No lunar eclipse

TABLE 1. RECORD OF TOTAL ECLIPSES OF THE SUN SINCE 1962 AND FORECAST THROUGH 1999

Year	Month and Day	Location of Shadow Path	Type of Eclipse	Duration (Minutes)
Saros period beginning in 1962				
1962	February 5	Papua New Guinea, Pacific	Total	4
	July 31	Guyana, central Africa	Annular	4
1963	January 25	South Atlantic	Annular	1
	July 20	Japan, Alaska, Canada	Total	1
1965	May 30	South Pacific	Total	5
	November 23	Northern India, southeast Asia, Borneo and the Pacific	Annular	4
1966	May 20	Northern Africa, the former U.S.S.R., and China	Annular	1
	November 12	Pacific, Argentina, South Atlantic	Total	2
1967	November 2	South Atlantic	Total	—
1968	September 22	Arctic, the former U.S.S.R.	Total	1
1969	March 18	Indian Ocean, Pacific	Annular	1
	September 11	Northern Pacific, Peru, Brazil	Annular	2
1970	March 7	Pacific, Mexico, Georgia, north Atlantic	Total	3
	August 31	South Pacific	Annular	7
1972	January 16	Antarctica	Annular	—
	July 10	Siberia, Alaska, northern Canada	Total	3
1973	January 4	South Pacific, South Atlantic	Annular	8
	June 30	Guyana, Atlantic, northern Africa	Total	7
	December 24	Pacific, Brazil, Atlantic, Sahara	Annular	12
1974	June 20	Indian Ocean, southwestern Australia	Total	5
1976	April 29	Algeria, Turkey, southern former U.S.S.R., Tibet	Annular	7
	October 23	Tanzania, Indian Ocean, southern Australia	Total	5
1977	April 18	Atlantic, South Africa, Indian Ocean	Annular	7
	October 12	Northern Pacific, Venezuela	Total	3
1979	February 26	Northwestern United States, Canada, Greenland	Total	3
	August 22	South Pacific	Annular	7
End of Saros period beginning in 1962. Start of Saros period beginning in 1980				
1980	February 16	Congo, Zaire, Kenya, India, southeast Asia	Total	4
	August 10	Pacific, Brazil, Peru	Annular	3
1981	February 4	South Pacific	Annular	3
	July 31	The former U.S.S.R., northern Pacific	Total	2
1983	June 11	Indian Ocean, Indonesia, Papua New Guinea	Total	5
	December 4	Mid-Atlantic, Zaire, Somalia	Annular	4
1984	May 30	Mexico, southeastern United States, Algeria	Annular	1
	November 22	Papua New Guinea, South Pacific	Total	2
1985	November 12	South Pacific	Total	—
1986	October 3	North Atlantic, Greenland	Total	1
1987	March 29	Southern Argentina, South Atlantic, Zaire, Somalia	Annular	—
1988	March 18	Indonesia, Philippines, North Pacific	Total	4
	September 11	Indian Ocean	Annular	7
1990	January 26	Indian Ocean	Annular	—
	July 12	Finland, Siberia, North Pacific	Total	3
1991	January 15	South Pacific	Annular	9
	July 11	Hawaii, Central America, Brazil	Total	7
1992	January 4	Mid-Pacific, California	Annular	12
	June 30	South Atlantic	Total	5
1994	May 10	United States, North Atlantic, Morocco	Annular	7
	November 3	Pacific, middle South America, South Atlantic	Total	4
1995	April 29	Pacific, Peru, Brazil	Annular	7
	October 24	Iran, India, southeast Asia, Pacific	Total	3
1997	March 9	Mongolia, Siberia, Arctic	Total	3
1998	February 26	Pacific, Colombia, North Atlantic	Total	4
1998	August 22	Indonesia, Borneo, Papua New Guinea, South Pacific	Annular	3
1999	February 16	Indian Ocean, northern Australia	Annular	1
	August 11	North Atlantic, central Europe, India	Total	2

need occur in any year, although three are possible. The minimum number of eclipses in any year is two, both solar.

The sequence of eclipses may be determined by an ancient method known as the *Saros*. The revolution of the moon's nodes is westward at the rate of 19.5° per year. Thus, the sun meets the same node in 346.62 days, the length of an eclipse year. The Babylonians are generally credited for first recognizing the cycle of eclipses. The duration of this cycle is 6585 days (refined to 6585.32 days). This is equivalent to 223 synodic months,[2] and is nearly the same length as 19 eclipse years (6585.78 days). As pointed out by Tver, "After a Saros interval, the sun and moon have returned to nearly the same position relative to each other and to the node, and their distances from earth are nearly the same as before, allowing recurrence of a similar pattern of eclipses." Knowledge of the Saros, as it applied to cycles of lunar eclipses, goes back to about 1000 B.C. The Saros, depending upon the number of intervening leap years, is a period of 18 years, 10.32 days; or 18 years, 11.32 days. The Greeks are accredited with first recognizing the triple Saros cycle of 54 years. This is known as the "exeligmos."

At the end of a Saros cycle, eclipses (both lunar and solar) will recur in the same order and kind (total or partial). However, the essentially identical eclipse will not be observable from the same region on earth — because of the $\frac{1}{3}$ day in excess of the 6585 days. During $\frac{1}{3}$ day, the earth turns 120° and thus the eclipse will be seen about 120° longitude farther west than before. For example, the February 16, 1980 total eclipse of the sun that was observed in parts of Africa (including Kenya), in India, and in southeastern Asia, and of a duration of slightly over 4 minutes, was a repeat of the total eclipse of February 5, 1962, of similar duration and observed in Papua New Guinea. After about 3 Saros cycles (54 years), the eclipses are observable in very near the same longitudes from which they were seen 54 years prior. The number of eclipses in 1 Saros is about 70 (41 solar; 29 lunar). Of the solar eclipses, 10 are total, 14 are partial, and 17 are annular. Because of minor deviations not fully accounted for by the Saros cycle, it is estimated that there are longer cycles. For example, it is estimated that a lunar eclipse may repeat itself about 48 or 49 times, over a series lasting about 865 years. A solar eclipse may have from 68 to 75 returns over a cycle lasting some 1260 years.

As early as 1887, Theodor van Oppolzer prepared a comprehensive table of eclipses for the period through the year 2000. See Table 1. As an indication of the characteristics of a total eclipse of the sun, information pertaining to the October 12, 1977, the February 16, 1980, and the July 11, 1991, eclipses are given in Table 2.

The progress of an eclipse of the sun is designated by a series of "contacts." The first contact comes when the edge of the penumbra *B* (Fig. 1) first touches the sun; second contact when the sun first passes into the umbra *A*; third contact when the umbra leaves the sun; and fourth contact when the last edge of penumbra leaves the sun. Accurate recording of the times of these contacts yields valuable information regarding the complex motions of the moon.

During the progress of a total solar eclipse, about 1 hour before the totality interval, the moon may be seen gradually commencing to cover the sun's disk. About $\frac{1}{4}$ hour before totality, a definite diminution of the light can be noticed and the landscape exhibits hues and tones of color that do not quite seem natural. Most birds and animals seem to sense that something unusual is taking place and become restless. As the crescent of light becomes narrower, images of a crescent shape, known as Baily's beads, may be noticed on the ground, particularly where the diminished sunlight is filtered through the leaves of trees and bushes. These light patches are believed to be caused by the penetration of the last rays of sunlight between the irregularities of the moon's surface. Although not always noticed, within 2 to 3 minutes prior to full disappearance of the sun's disk, shadow bands may appear to be moving over the ground. These bands also are present during the same interval after totality and there have been reports of their presence during totality. Although not fully explained, it is believed that these bands are the result of irregular refraction of light in the earth's atmosphere. Darkness falls suddenly and the white corona seems to flash into position. Almost concurrent with the appearance of the corona an intensely bright region, known as the "diamond-ring" effect may be seen.

[2] A synodic month is the interval between successive conjunctions of the moon and sun from new moon to new moon again. This interval is a little more than 29.5 days and varies by more than half a day during the year.

TABLE 2. REPRESENTATIVE CIRCUMSTANCES OF RECENT TOTAL ECLIPSES OF THE SUN

1977 (October 12) — Maximum Duration of Totality = 2 min, 27.4 sec

Partial phases visible from all 50 of the United States, western and southeastern Canada, Mexico, and Central America. Path of totality commenced in the Pacific Ocean, ran north and parallel to the Hawaiian Island chain, entered South America in the Darien region of Colombia, and ended in Venezuela.

1989 (February 16) — Maximum Duration of Totality = 4 min, 12.4 sec

Partial phases visible from all parts of Africa except extreme northern part, all of the Arabian Peninsula, all of India, much of southeastern Asia, and China. Path of totality passed from the eastern Atlantic to mouth of the Zaire (Congo) River into Tanzania, passed into the Indian Ocean at Malindi, Kenya, touched land again in Ankola, India, and entered the Bay of Bengal south of Calcutta and ended in China near north latitude 26.5° and east longitude 108.5°.

1991 (July 11) — Maximum Duration of Totality = 6 min, 51 sec

Partial phases visible from western Canada and the United States, Mexico, northern and southern South America as far south as Chile, and wide stretches of the Pacific Ocean. Path of totality commenced in the Hawaiian Islands northeasterly, then passed southeasterly to Mexico City, Colombia, and central Brazil.

This eclipse will be remembered for two major factors: (1) It was, by far, subjected to the most intensive scientific investigation of any solar eclipse to date, and (2) the time of totality was exceptionally long (only 40 sec short of the theoretical maximum). It was the last eclipse to occur with such a long span of totality until the year 2,132.

The path of the total eclipse (umbra) passed directly over Mauna Kea in Hawaii, where telescopes and other solar observing instrumentation is located. Included was the Canada-France-Hawaii (CFH) telescope and, as mentioned by Jay Pasachoff, "the largest ever pointed at the sun." Other instrumentation was brought into play. For example, some 10,000 images of the sun's corona in infrared (IR) wavelengths were made by an imaging system that consisted of an IR camera featuring a 128 × 128 indium antimode focal plane array, video acquisition and processing electronics, a real-time digital recorder, and image generation and enhancement capabilities. Although the brightness of the corona during the eclipse may have masked faint targets, such as rings, the information gained will assist in updating the multispectral model of the sun's outer surface.

Although, at one time, total solar eclipses were essentially the only way an astronomer could study the outer edges (corona) of the sun, there since have been many advances achieved by way of satellite-based observations. Notably, the Japanese Yohkoh satellite has captured much new information from x-ray imaging of the solar corona and surface. See **Satellites (Scientific and Reconaissance)**.

The beams of darkness that swept across the earth's surface resulting from the eclipse were observed from space for the first time by the GOES weather satellite.

The full *corona* of a total solar eclipse is shown in Fig. 4. The corona is the outermost part of the sun's atmosphere, which becomes visible during a total eclipse of the sun. The shape of the corona changes periodically, in sequence with the sunspot cycles and extends outward some 30 solar radii. Estimated temperature of the ionized gases in the corona range between 1 and 2 million K. Elements such as iron, nickel, and calcium are contained in the gaseous corona. See entry on **Sun** for more detail. Adjacent to the silhouette of the moon during the interval of totality is the *chromosphere*. This is a layer of the sun's atmosphere that lies just above the photosphere or visible surface, and below the corona. The lower chromosphere is mainly neutral hydrogen gas at a temperature of about 7500 K. The upper chromosphere contains ionized hydrogen at temperatures up to about 1 million K. Prominences in the form of bright pink spots which extend outward from the chromosphere usually can be observed.

Considerably dependent upon local climatic conditions, during the period of totality there is usually a noticeable drop in air and ground temperatures. For example, during the February 16, 1980 total eclipse, it was unofficially reported from Ankola, India that the air temperature dropped from 95 °F (35 °C) to 68 °F (20 °C) from first contact to totality; while the ground temperature fell from 125 °F (51.5 °C) to 85 °F (about 29 °C).

Total Solar Eclipse Research. Considerable attention of a scientific nature to total eclipses of the sun is generally regarded as having commenced with the eclipse of July 8, 1842. The path of that eclipse passed from Spain through France, Italy, Austria, Russia, and central Asia. Along the path were located the leading astronomers of Europe. For the first time, large red solar prominences were reliably described. The extent of the corona was measured. Improvements in the examination of the corona and prominences continued during the total eclipse of July 28, 1851. A successful daguerreotype photo was taken in Königsberg, using a

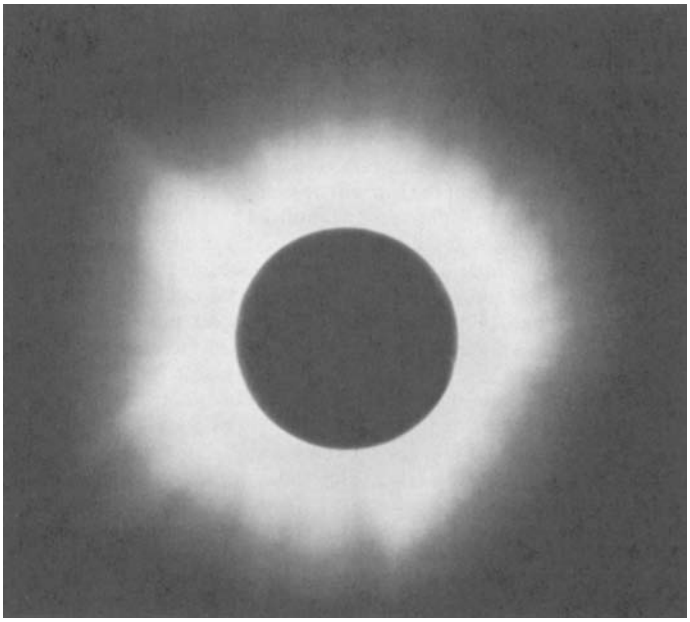

Fig. 4. Total solar eclipse of March 7, 1990, showing full corona. (*Sacramento Peak Laboratory*.)

telescope with a 2.4-inch (6-centimeter) aperture. Exposure was 1 minute, 24 seconds. The corona and several prominences were well pictured. Scientists were better prepared when the path of the eclipse of July 18, 1860 crossed through Spain, the Mediterranean, and northeastern Africa. Photographic and optical techniques had substantially improved during the 9-year interval between these eclipses and the astronomers also had prior knowledge and experience as a guide to the best exposure time to use.

Spectroscopic techniques were first used in connection with the total eclipse of August 18, 1868. The period of total of 5.5 minutes of this eclipse was relatively long. The bright prominences clearly produced several bright lines, this indicating the gaseous nature of the prominences. Identification was made of the hydrogen lines C and F and of a yellow line, later found to be due to helium and designated the D line. Immediately after the 1868 eclipse, it was erroneously identified as a sodium line. The *flash spectrum* is described under **Sun (The)**.

The interest of Janssen was spurred by the 1868 eclipse and he soon found that the bright lines of the prominences could be observed on any clear day without waiting for another eclipse. He soon noted the marked and rapid changes that occur in the prominences. Lockyer came up with the same concept at about the same time, and the achievements of both Janssen and Lockyer were reported at the same meeting of the French Academy.

Observations made of the eclipse of August 7, 1869 showed a bright green line across the continuous spectrum of the corona. For awhile, a new element (*coronium*) was proposed as the source of the line, but spectroscopic analyses of the total eclipses of 1896 and 1898 disproved that.

The possible relationship between sun spots and the corona was first investigated during the total eclipse of July 29, 1878, the path of which went diagonally across North America. Langley observed this eclipse from Pike's Peak at an elevation of 14,100 feet (4298 meters). Further evidence of a relationship was noted during the total eclipse-of May 17, 1882.

Coupled with a growing sophistication of instrumentation during the later 1800s and up to the present time were discussions of an increasingly complex nature, based upon knowledge gained from and inspired by eclipse studies. Some of these factors are further discussed in entry on **Sun**.

The availability of greatly improved telescopes and solar instrumentation data gathering techniques, coupled with the long duration of totality of the July 11, 1991, total eclipse, without doubt makes that eclipse the most thoroughly researched of all to date. See Table 2. One of numerous new techniques was application of infrared imaging. See Fig. 5. With the employment today of space satellite observations of the sun, there is less dependence on total solar eclipses for numerous studies.

Precautions in Viewing a Solar Eclipse. Kitt Peak National Observatory astronomers caution sky watchers who plan to observe an eclipse of the sun that *partial and permanent eye damage can be caused by looking at the sun, even for only an instant, without adequate protection.* They further observe, "Sunglasses, smoked glass, welder's goggles, photographic neutral-density filters or color film are not safe to use, even in combination". They are not dark enough for protection. A solar eclipse is most safely observed by not looking at the sun at all, but instead by watching its image projected on a piece of paper or board.

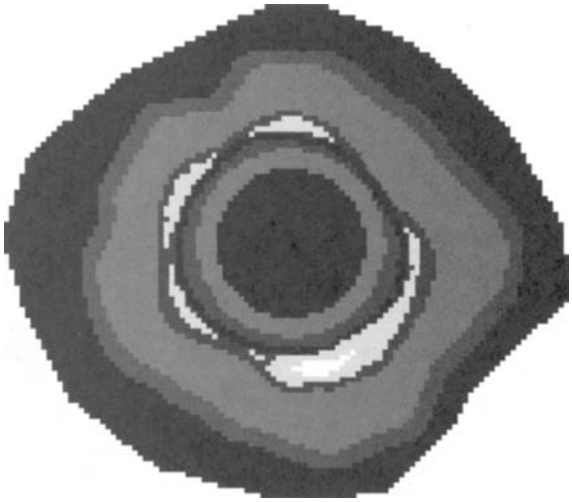

Fig. 5. Facsimile of digitized infrared (IF) image of sun during total eclipse over Mauna Kea, Hawaii, on July 11, 1991.

"To make your own projector, begin with two white sheets of poster board, or heavy paper. Punch a small, round hole in the center of one sheet. This will serve as your 'lens.' Aim the lens at the sun, holding the second board in your other hand. By moving the two boards, you will find that you can project a sharp image of the sun through the lens onto the second board. Information on how to photograph a solar eclipse can be obtained from the Public Information Office, Kitt Peak National Observatory, P.O. Box 26732, Tucson, Arizona 85726."

Eclipses of the Moon

Referring back to Fig. 1, for an eclipse of the moon, consider *S* as the sun and *O* as the earth. From the relative dimensions and distances, we find that even under the most unfavorable conditions, i.e., with the earth at perihelion and the moon at apogee, the shadow of the umbra cone of the earth will extend well out beyond the distance of the moon. Hence, there are no annular eclipses of the moon. However, partial eclipses, i.e., eclipses that occur when the moon passes through the earth's shadow far enough off the central line to pass outside the umbra, are quite common. These

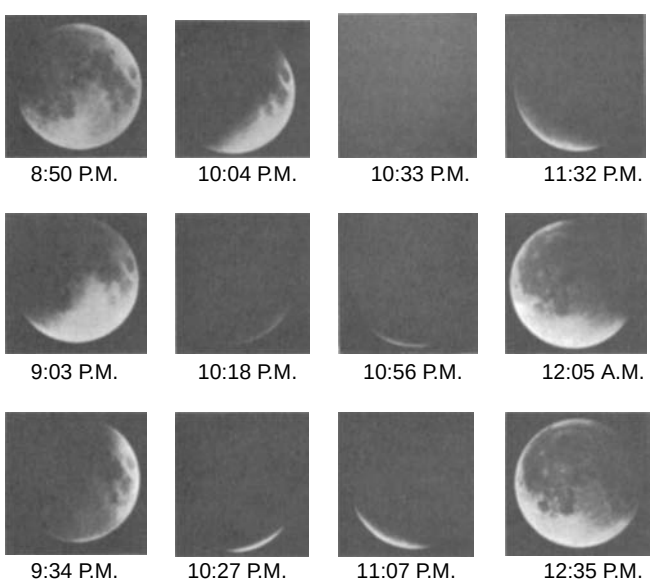

Fig. 6. A lunar eclipse sequence. (*Griffith Observatory*.)

are known as *penumbral* eclipses. The progress of a total lunar eclipse is shown in Fig. 6. Although not visible in Fig. 6, when the moon is in darkness, it is not completely dark during eclipse, but is illuminated by a dull-orange light refracted into the umbra by the atmosphere of the earth. For possibly 30 minutes before the moon reaches the earth's shadow, the darkening of the eastern side will proceed quite gradually. Although the edge of the earth's shadow appears sharp to the naked eye, it appears fuzzy with a field glass or telescope. An eclipse of the moon is visible over an entire hemisphere (sometimes a little more) of the earth; thus, for persons in any given locality, a lunar eclipse is more common than a solar eclipse, since even though the latter occur more frequently, they are only visible in much more limited areas. On occasions when the sunlight must pass through clouds, the moon's disk may become completely invisible during the period of totality. Total lunar eclipses in the recent past and up to the year 2000 are listed in Table 3.

TABLE 3. LUNAR ECLIPSES THROUGH YEAR 2000

Year	Month and Day	Location Where Moon Is at Zenith	Duration (Minutes) Complete	Total Phase
1982	January 9	Pakistan	214	84
	July 6	Easter Island	224	102
	December 30	Hawaiian Islands	210	66
1983	June 25	Pitcairn Island	130	—
1985	May 4	Mauritius	212	70
	October 28	Bay of Bengal	204	42
1986	April 24	New Hebrides	210	68
	October 17	Arabian Sea	212	74
1987	October 7	Venezuela	22	—
1988	August 27	Samoa	122	—
1989	February 20	Philippines	212	76
	August 17	Central Brazil	220	98
1990	February 9	Southern India	204	46
	August 6	Northeastern Australia	174	—
1991	December 21	Hawaiian Islands	70	—
1992	June 15	Northern Chile	174	—
	December 9	Southern Algeria	212	74
1993	June 4	New Caledonia	220	98
	November 29	Mexico City	206	50
1994	May 25	Southern Brazil	116	—
1995	April 15	Fiji Islands	78	—
1996	April 4	Gulf of Guinea	216	84
	September 27	French Guiana	212	72
1997	March 24	Northwestern Brazil	194	—
	September 16	Maldives	210	66
1999	July 28	Samoa	142	—
2000	January 21	Puerto Rico	214	84

ECLIPSE YEAR. The interval between two successive conjunctions of the sun with the same node of the moon's orbit, averaging 346 days 14 hours 52 minutes 52.42 seconds in 1962, and increasing at the rate of 0.0276 second annually. See also **Eclipse**.

ECLIPSING BINARY. When the orbit plane of a binary star lies so nearly in the line of sight of the observer that the components undergo mutual eclipses, the object is known as an eclipsing binary. If the binary is also a spectroscopic binary, and if the parallax of the system is known, we have one of the most valuable specimens for stellar analysis. Eclipsing binaries are variable stars, not because the light of the individual components vary, but because of the eclipses. The most notable of the eclipsing binaries is the star Algol (β Persei).

The light curve of an eclipsing binary is characterized by periods of practically constant light with periodic drops in intensity. In the Fig. 1 we have a characteristic light curve of such an object. Here, the eclipse of the larger and brighter primary star by the secondary star is annular, and the eclipse of the secondary by the primary is total.

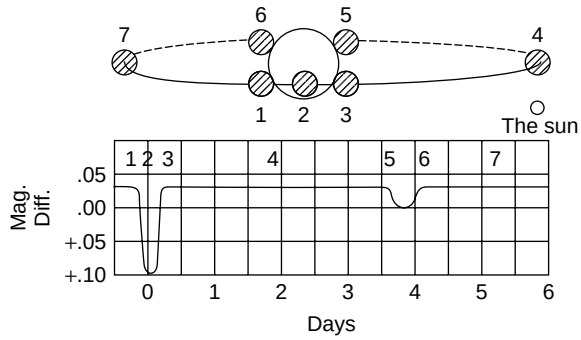

Fig. 1. Apparent relative orbit and light curve of the eclipsing binary 1 H Cassiopeiae. (Curve and orbit determined by Joel Stebbins from observations with the photoelectric photometer at the University of Illinois.)

The orbit of an eclipsing binary may be determined from a study of the light curve. In addition to the seven elements of the orbit, it is also possible to determine the relative sizes of the individual stars in terms of the radius of the orbit. In the determination of the orbit of a spectroscopic binary, it is impossible to determine the semimajor axis, a, and the inclination of the orbit plane, i, independently; but a quantity ($a \sin i$) expressed directly in linear units (i.e., miles or kilometers) may be determined. If a star is both an eclipsing and spectroscopic binary, one can determine all seven elements of the orbit, including a and i, in angular units from the light curve, and the quantity ($a \sin i$) in linear units from the spectroscopic data. Hence, one can determine the radius of the orbit in linear units and then get the sizes of the individual stars in linear units. Since the relative masses of the two stars can be obtained from the period, and since the relative sizes are determinable from the combination of the photometric and spectroscopic orbits, then the densities of the individual stars can be found from relative masses and sizes.

S. N. S.

ECLIPTIC. The great circle cut out on the celestial sphere by the plane containing the orbit of the earth. The ecliptic is the fundamental plane for the system of spherical coordinates in which celestial latitude and longitude are measured. The ecliptic is also the reference plane to which the planes of the orbits of all the members of the solar system are referred.

The plane of the ecliptic is inclined to the plane of the equator by an angle of approximately $23^\circ 27'$, known as the obliquity of the ecliptic. The two planes intersect in a line known as the line of nodes. The points where this line of nodes intersects the celestial sphere are known as the equinoxes. The apparent motion of the sun in the ecliptic about the earth, due to the actual motion of the earth in its orbit, causes the sun to pass through each one of the equinoxes once each year. The point where the sun crosses the equator from south to north is known as the vernal equinox, and the opposite extremity of the line of nodes is the autumnal equinox. Due to precession, the direction of the line of nodes is continually changing relative to the stars. At present, the vernal equinox is in the constellation of Pisces. It is continually moving along the ecliptic, in a direction contrary to the annual motion of the sun, at such a rate that it will complete one revolution of the ecliptic in approximately 26,000 years. See also **Celestial Sphere and Astronomical Triangle**.

ECLIPTIC SYSTEM OF COORDINATES. A set of celestial coordinates based on the ecliptic as the primary great circle. The points 90° from the ecliptic are the north and south ecliptic poles. Angular distance north or south of the ecliptic, analogous to latitude, is celestial latitude. Celestial longitude is measured eastward along the ecliptic from the vernal equinox through 360°. See also **Ecliptic**.

ECLOGITE. This is a coarse, granular rock composed chiefly of garnet and pyroxene with subordinate amounts of various minerals such as rutile,

magnetite, and apatite. Hornblende sometimes is present, replacing the pyroxene, often to the extent that a garnet amphibolite is produced. The origin of eclogites is obscure, they may result in part from the deep-seated metamorphism of gabbronic rocks, but some may have resulted from crystallization of a primary basic magma under conditions of great pressure. They may represent segregations in a highly basic magma analogous to segregations of basic minerals in granites and other common igneous rocks. Seemingly confirmatory evidence of this idea is found in the chunks of ecologite-like material found in kimberlite in the Republic of South Africa.

ECOLOGICAL SYSTEM. A habitable environment, either created artificially, as in a manned space vehicle, or occurring naturally, such as the environment on the surface of the earth, in which humans, animals, or other organisms can live in mutual relationship with one another and the environment. Ideally the environment furnishes the sustenance for life, and the resulting waste products revert or cycle back into the environment to be used again for the continuous support of life. See also **Ecology**.

ECOLOGY. A branch of biology that deals with the relations of organisms and their environment, including their relations with other organisms. It is an interdisciplinary field, cutting across the life and geophysical sciences. Ecological investigations look into two directions: (1) The nature of environments and the demands which these environments make upon the organisms that inhabit them; and (2) the characteristics of organisms (plant or animal), species, and groups that permit or promote their tolerance of specific environmental conditions. In recent years, particular emphasis has been placed on the studies of groups rather than single species and this has given rise to the term *ecosystem*. Odum defines an ecosystem as "any entity or natural unit that includes living and nonliving parts interacting to produce a stable system in which the exchange of materials between the living and nonliving parts follows circular paths."

Environmental or Habitat Approach. Characteristics of an environment fall into three major categories: (1) *physical*; (2) *chemical*; and (3) *biotic*. In connection with any of these factors, if the presence or absence of a given condition is necessary for sustenance of whatever group, species, etc. that is being considered, such condition is referred to as a *limiting factor*. Physical factors include light, temperature, wind, fire, soil texture, etc. Chemical factors include the composition of the water (pH, dissolved gases and solids, etc.); the composition of the air (pollutants, water vapor, etc.); the composition of the soil (alkalinity, acidity, presence of various elements and compounds); etc. Biotic factors are related to food supply and the presence and behavior of neighboring organisms (predators, parasites, etc.).

Environments can be classified into four major types: (1) *freshwater*; (2) *marine*; (3) *terrestrial*; and (4) *symbiotic*. There are several subdivisions of each.

Freshwater environments are of two principal types: (1) *standing-water* and (2) *running-water habitats*. In the first category, there are ponds, lakes, and bogs; in the latter category, streams, rivers, and springs. Limiting factors of significance include temperature, water clarity, concentrations of oxygen and various salts, and evaporation rate in the case of standing waters.

Marine environments, although similar in many respects to freshwater environments, pose special environmental conditions, including depth, salinity, general presence of greater stability, and less, if any, light at great depths. Subdivisions of marine environments include: (1) the *neritic zone*, the relatively shallow waters of the continental shelf; and (2) *oceanic region*, the deep waters beyond the continental shelves. The oceanic region is subdivided into: (a) the *euphotic zone*, the upper portion of the oceanic region where photosynthesis occurs; (b) *bathyal zones*, depths below the euphotic zone but still located on continental slopes; and (c) *abyssal zones*, depths below the euphotic zone in all other parts of the oceans.

Terrestrial environments are divided into nine or more types, called *biomes*. Examples include deserts, tundras, grasslands, savannas, deciduous forests, coniferous forests, tropical forests, and woodlands. These are described under **Biome**. The ocean is also sometimes referred to as a biome.

The environments described thus far have related essentially to nonorganic factors. In the case of the symbiotic environment, the factors of concern are other organisms. There are numerous examples where two or more species may inhabit a given area of close proximity in the absence of predatoriness. Usually, each species present will contribute in some fashion to the well being of others, although what might be called "stand-off" conditions also are found. See also **Symbiosis (Ecology)**.

Communities Approach. Where the interrelationships of a single individual or species with its environment is studied, the term *autecology* may be applied. In contrast, if entire populations are studied as units, the term *synecology* is used. The latter approach is most popular today. The term *population* is used to describe a group of individuals composed of members of a single species or of several closely associated species that occupy a definite environmental area. Where all of the populations that occupy a given geographic area are studied, the term *biotic community* is used.

The portion of the earth on or in which life exists is termed the *biosphere*. This is a shallow surface region, including the oceans and part of the atmosphere. An ecosystem, as previously defined, can be small and simple or large and complex and, in fact, it is not inaccurate to refer to the entire biosphere as an ecosystem. If life were found in other areas of the cosmos, for example, then it is likely that the first ecosystems to be compared would be those of a scale of the biosphere.

Habitat may be defined as that particular environment in which a population lives. A catfish that likes slow-moving streams and lakes is described as having this particular habitat. Obviously, the variation among habitats considering the tens of thousands of life forms is tremendous, although generalizations can be made. *Niche* is a term used to describe that role played by a population within its community and ecosystem. Numerous factors determine niche — eating habits, predatoriness, etc.

The first branch of ecology to develop beyond the stage of life-history study was the description of vegetation. Its basic method is to study the detailed distribution of vascular plants in terms of communities of various types, the pattern and complexity of which depend largely upon the climate and soil.

The major theoretical contribution of this school is the idea of *seral succession* toward a stable climax. According to this idea, if a new environment is created for terrestrial plants, or if an old one is drastically changed, the vegetation that first develops on it does not remain unchanged for eternity. Rather, it alters the environment so that it becomes more suitable for some new and different kind of vegetation and so on. Ultimately, a *climax* vegetation develops that is stable under the prevailing climatic conditions and remains until the climate changes to favor something else, or until some new catastrophe changes the environment drastically once again.

Further study of seral succession showed that vegetation patterns were seldom so simple. The climax community is regarded as a useful concept. Even under constant climatic conditions, some sorts of vegetation are not stable, but undergo local cyclical changes. At the other extreme, a few kinds of vegetation replace themselves after disturbance without intervening seral stages. It is clear that the sort of climatic constancy that was implied in the climax idea has not prevailed at least since the beginning of the Pleistocene, and that the climax is best considered an ever-changing end-point toward which vegetation develops rather than a state it actually attains.

Populations. Probably the greatest body of coherent ecological theory has been created by students of populations. The study of field populations has uncovered many interesting phenomena, such as the periodic oscillation of arctic small vertebrate populations and the seasonal changes in abundance of planktonic organisms. These observations have stimulated both laboratory experiments and the development of deductive mathematical theory.

If a small number of organisms is provided with a new unexploited environment, the ensuing population growth curve exhibits a roughly sigmoid form, with an initial phase of very rapid, almost logarithmic increase and a later phase in which the rate of growth gradually declines to zero. Such a population history can be described by a curve of the form:

$$dN/dt = rN\frac{(K - N)}{K} \tag{1}$$

where dN/dt is the instantaneous rate of growth; r the intrinsic rate of natural increase in the absence of crowding; N the population size at any time; and K the maximum population size. A formula of this kind is simple to use and easy to comprehend, and although few populations justify the assumptions on which it is based, it has been used not only for curve-fitting and the description of population growth, but as a point of departure for population theory. The principal developments of importance from it have

been the prey-predator equations of Volterra:

$$dN/dt = r_1N_1 - \alpha_1N_1N_2 \tag{2}$$

$$dN_2dt = \alpha_2N_1N_2 - d_2N_2 \tag{3}$$

and the Gause equations of species interaction:

$$dN_1/dt = r_1N_1\frac{(K_1 - N_1 - \beta N_1)}{K_1} \tag{4}$$

$$dN_2/dt = r_2N_2\frac{(K_2 - N_2 - \beta N_1)}{K_2} \tag{5}$$

In these equations, N_2 is the size of one population and N_1 that of another; α_1 expresses the effect of predatoriness on the prey population, and α_2 expresses its effect on the predator. In the absence of prey, the predator should die at the rate of d_2; K_1 and K_2 are the saturation values of two species grown alone; r_1 and r_2 are the intrinsic rates of natural increase of species N_1 and N_2; and α and β express the inhibitory effects of these species on each other. If $\alpha > K_1/K_2$ and $\beta > K_2/K_1$, then either N_1 or N_2 may win out in competition, the result depending upon the initial concentration of the two species. If $\alpha < K_1/K_2$, and $\beta < K_2/K_1$, the species will coexist. If $\alpha < K_1/K_2$ and $\beta > K_2/K_1$, N_1 will be the sole survivor of competition; and if $\alpha > K_1/K_2$ and $\beta < K_2/K_1$, only N_2 will survive.

Work with models of this sort and with experimental laboratory populations that behave more or less in the ways that the models predict has led to concepts about the *ecological niche*, or the way in which an organism fits into the ecological system of which it forms a part. Some authorities hold that Gause's axiom, which states that two species cannot live indefinitely the same way in the same place under constant conditions, is essentially trivial, while others regard it as one of the great generalizations of ecology. Probably its principal value lies in raising the question of how the niches of apparently similar organisms differ, and so compelling ecologists to examine their material very closely. In this, Gause's axiom is similar to the idea of seral succession, which directs attention to the environmental requirements as well as to the ways in which the environment is changed by it. Both ideas stimulate the acquisition of useful information, although they imply an environmental constancy that is seldom found in nature.

Niche theory has led to renewed interest in the taxonomic diversity of natural communities. MacArthur, assuming that there must be some way in which the niches of organisms in an ecological system did not overlap, developed a model of the relative abundance of the individual species in a natural community. According to this model, the expected abundance of the r th rarest species, where there are n species and m individuals and i is the species rank, is given by

$$\frac{m}{n}\sum_{i=1}^{r}\frac{1}{(n-i+1)} \tag{6}$$

The predictions of the model have been borne out in a number of taxonomically homogeneous cases, but do not seem to hold generally for natural communities.

A different line of approach has been developed by ecologists interested in practical problems of population management, particularly the exploitation of fish populations. The method has been to start with a formula that is essentially a simple equation of continuity:

$$S_2 = S_1 + (A + G) - (M + C) \tag{7}$$

where S_1 and S_2 are the total weight of the population at the beginning and end of the time under consideration; A is recruitment of new individuals to the population; G is growth of the population; M is natural mortality; and C is capture by fishing.

Such an equation is modified as data become available for a specific case and is gradually refined until it is a very powerful predictive tool. The equations become cumbersome in the process, but the mathematics involved is essentially simple, and electronic computation avoids tedium and human errors. Unfortunately, such models are limited to the populations for which they have been formulated, or for others similar to them in essential respects. There seems little immediate likelihood of the development of simple and accurate general models for the dynamics of natural populations. Many ecologists working with organisms other than fish despair of producing useful models without recourse to stochastic theory. The stochastic approach is appealing, for the processes of population change are certainly not deterministic ones, but such a shift involves a great increase in mathematical complexity. The sophistication necessary to handle stochastic models is rare among ecologists, and it has usually been applied to new methods of constructing a deterministic theory. Cole, for example, used finite difference equations to demonstrate that the reproductive potential of a species depends very greatly upon the timing of reproduction in its life cycle. Cole pointed out the critical importance of pieces of information, such as the age at first reproduction, which might otherwise be overlooked in life history studies. See also **Population (Statistics)**.

Chemical Aspects. In any community, the interactions of the organisms with each other and with their environment are so complex as to defy complete understanding. One way of asking answerable questions is to restrict attention to the chemical aspects of ecological processes, and to regard organisms as the causes or effects of geochemical processes. This approach has led to an understanding of the quantitative role of organisms in the major chemical cycles, such as the carbon cycle and the nitrogen cycle, and is being strengthened by the use of isotopic methods. The introduction of isotopic tracers into biogeochemical cycles permits the estimation of reservoir sizes and exchange rates and seems likely to lead to new theoretical developments.

Energy Flow. Energy transfer can be considered instead of chemical reactions. See Fig. 1. The principal contribution of the energy flow concept has been to demonstrate that organisms, like most machines, are not efficient converters of energy, so that an organism will incorporate into its body only a small part of the stored chemical energy of its food. This places a severe practical limit on the number of steps that can be maintained in the food chain and has important practical consequences for an expanding human population trying to increase its food supply.

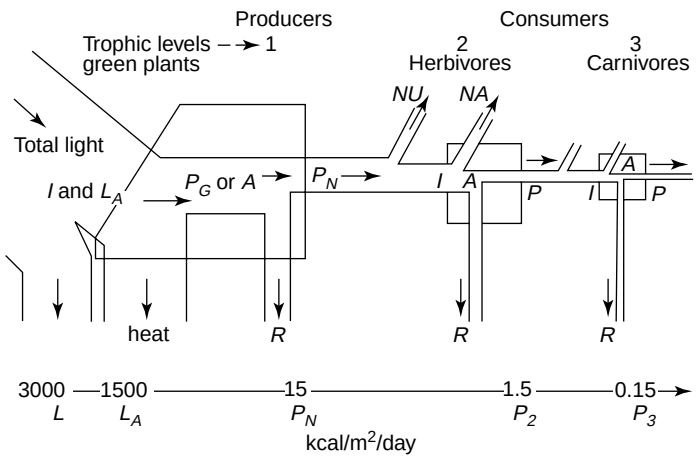

Fig. 1. A simplified energy flow diagram. The boxes represent the standing crop of organisms: (1) Producers or autotrophs; (2) primary consumers or herbivores; (3) secondary consumers or carnivores; and the pipes represent the flow of energy through the biotic community. L = total light; L_A = absorbed light; P_G = gross production; P_N = net production; I = energy intake; A = assimilated energy; NA = nonassimilated energy; NU = unused energy (stored or exported); R = respiratory energy loss. The chain of figures along the lower margin of the diagram indicates the order of magnitude expected at each successive transfer, starting with 3,000 kcal of incident light per square meter per day.

The measurement of energy flow in natural communities presents many difficulties, only some of which are technical in nature. Although the subject is suitable for theoretical development, this has been limited by the lack of methods for dealing with the thermodynamics of open systems. With a better understanding of the thermodynamics of open systems, as being attained by physical chemists, the study of energy flow seems likely to be productive in the future.

Behavior. The experimental analysis of animal behavior patterns has led to a renewed interest among ecologists in the social and psychological aspects of their subject. In particular, studies have focused on territoriality, social stress, hierarchies, and other behavioral mechanisms that control population density, on the transmission of traditional information about

nesting and feeding sites, and on feeding behavior as it affects an animal's role in the community. Although some behavioral studies have relevance to species diversity, community stability, and population growth rates, much of this work can be carried on profitably outside an ecological context, and behaviorists seem closer to establishing an independent discipline than most other ecologists.

The meaning of the word *ecology* has expanded much during the past few decades. Part of this is due to the fact that ecological matters have broadened and the concerns for ecology have become more intense, thus spawning numerous subtopics of specialization. Thus, check the Alphabetical Index for such topics as air and water pollution, meteorology, climate, and global change. The latter topic will affect the future ecology of the planet Earth, including the interactions between humans and other life forms. The outline of ecology as given in this particular article can serve as an excellent outline for attacking a myriad ecological problems.

ECONOMIZER. See **Boiler**.

ECOSPHERE. See **Atmosphere (Earth)**.

ECOTONE. The often rather blurred and indefinite boundary between two ecological communities. There is usually some tension between two or more communities present at these boundaries. In some instances, the ecotone may represent a fairly wide strip, sometimes referred to as the transition zone. In other instances, the ecotone may be rather sharply marked, as by a stream, edge of a grassland or forest, water hole, etc. See also **Ecology**.

ECTODERM. See **Embryo**.

ECTOPIC. Often as used in medicine, a tumor or growth (or any body tissue) that occurs in an unusual (abnormal) position or in an unnatural form or manner.

ECTOPROCTA. Members of this group make up the phylum *Bryozoa*. The included species live in colonies of many forms and are characterized by the retractile tentacles and by the anus lying outside of the circlet of tentacles (lophophore).

The phylum is divided into two orders:

Order *Gymnolaemata*. Lophophore circular. Mouth usually closed by a flap called the operculum. Marine.

Order *Phylactolaemata*. Lophophore horseshoe-shaped or oval. Freshwater species.

EDDY. 1. By analogy with a molecule, a "glob" of fluid within the fluid mass that has a certain structure and life history of its own, the activities of the bulk fluid being the net result of the motion of the eddies. The concept is applied with varying results to phenomena ranging from the momentary spasms of the wind to storms and anticyclones.

2. Any circulation drawing its energy from a flow of much larger scale, and brought about by pressure irregularities, as in the lee of a solid obstacle.

3. In studies of the general circulation, departures of a field (e.g., temperature or relative vorticity) from the zonal mean of that field.

4. A closed circulation system produced as an offshoot from an ocean current. Eddies are the result of the turbulence of the oceanic circulation and are common throughout the World Ocean. The corresponding features in the atmosphere are the wind currents around high and low pressure disturbances. Oceanic cyclonic eddies have a shallow thermocline at the center and are therefore also known as cold-core eddies; anticyclonic eddies are associated with a depressed thermocline in the center and are also known as warm-core eddies. The most prominent eddies are those shed by western boundary currents, also known as rings; they are about 200 kilometers (124 miles) in diameter and reach beyond a depth of 1,500 meters (4,921 feet). Another class of eddies is produced by shear between currents flowing in opposing directions. These eddies tend to be smaller (10–50 kilometers (6–31 miles) in diameter) and shallower.

EDDY CONTINUUM. In general, the continuum hypothesis used to generalize Newton's laws for point masses to continuous media such as fluids or gases. At any point in the continuous media it must be possible to identify volumes small enough that derivatives exist, yet large enough to contain sufficient particles that the average macroscopic property (such as momentum, mass, or temperature) may be defined. The eddy continuum hypothesis is used to extend the concept of a fluid continuum to a turbulent flow in which small-scale eddies are substituted for fluid particles. To apply the eddy continuum hypothesis, a scale analysis must be performed to verify that the averaging periods are sufficiently long that enough small-scale turbulent eddies are sampled that their dynamical effect on the mean flow is captured. If the eddies' length scales are comparable to the mean flow length scales, the eddy continuum most likely can be defined. The eddy continuum hypothesis is often applied in the study of large-scale organization (of the smaller-scale turbulent eddies) in the planetary boundary layer turbulence.

AMS

EDDY CORRELATION. 1. The covariance between two variables, associated with turbulent motions. For example, if the overbar represents a mean value, and the prime denotes a deviation from the mean, then

$$\overline{w'\theta'} = \frac{1}{N}\sum_{i=1}^{N}(wi - \overline{w})(\theta_i - \overline{\theta})$$

is the eddy correlation of vertical velocity w and potential temperature θ, where i is a data index and N is the total number of data points. If one of the two variables is a velocity, such as in the example here, then the eddy correlation represents a kinematic flux associated with turbulence. In this example, the correlation is a vertical kinematic heat flux (units of K m s^{-1}), which can be transformed into a dynamic flux (W m^{-2}) by multiplying by air density times specific heat at constant pressure.

2. A method of measuring the flux densities of mass, heat, and momentum across a plane at a point in turbulent flow. For vertical fluxes, the fluxes are found as the covariance of the fluctuations in the vertical wind velocity with local variations in concentration, heat content, or horizontal wind velocity, respectively. For conservative quantities in the atmospheric surface layer, such vertical fluxes are virtually equal to the fluxes at the surface of the earth. Measurements from towers require sensors with a speed of response that is typically no larger than about 1 s, but the required response varies with height, wind speed, and amount of buoyancy-induced

mixing. Observations from eddy correlation systems on fixed-wing aircraft in the planetary boundary layer typically require a response that is about ten times faster than stationary systems.

AMS

EDDY CURRENT. A term generally applied to currents set up in a substance by variation of an applied magnetic field. Eddy currents result in power loss and reduction of magnetic flux. Transformer cores and dynamo frames are laminated to break up the iron structure into thin, insulated layers to reduce the effects of eddy currents. Eddy currents also are used to advantage in induction heating and various damping devices.

Use of separately insulated strands of conductors or bundles of wires in some electrical apparatus accomplishes a reduction in eddy currents just as in the case of using the aforementioned thin, insulated sheets.

EDDY-CURRENT TRANSDUCER. When a nonmagnetic electrically conductive object is placed in the magnetic field of a coil, the effective inductance of the coil is decreased and its resistance is increased. This results because the field sets up eddy currents in the object that circulate so as to oppose the field that creates them. Moving the object closer to the coil increases the effect. Thus, coil characteristics are a function of spacing between coil and object. This effect is utilized in transducers to sense the position of a specific object or "target."

Various eddy-current transducer systems are available: (1) displacement systems, in which a noncontacting measurement is made of the position of a target, such as a panel being observed for flutter, or a shaft being studied for runout; (2) pressure systems, in which the target is a diaphragm displaced by the pressure being measured; (3) accelerometer systems, in which the target is a seismic mass displaced by inertial forces; and (4) differential transformer systems, in which the target is a thin metal sleeve mounted on a ceramic core support attached to the mechanism being monitored.

All such systems include electronic circuitry to generate an electrical analog signal related to target position. In some systems, the sensing coil is made part of an impedance bridge circuit so that changes in coil impedance produce an error signal related to target position. In other systems, the coil is part of an oscillator circuit so that the target movements produce frequency changes. Linearity of the output signal may be 1% or less, dependent upon system details. The output voltage may be up to 5 V. The coil excitation frequently may be 1 MHz or higher so that the frequency response of the system can be from 0 to at least 100 kHz. At 1 MHz, the eddy currents are confined near the surface of the target. For example, the "skin depth" in aluminum is 0.0035 inch. Therefore, only a thin target is required and nonconductors can be made into suitable targets by applying, as examples, aluminum foil tape or copper plating.

Operation of eddy-current transducers does not depend upon magnetic properties. Therefore, the devices can avoid problems caused by changes in permeability resulting from temperature changes or stray magnetic fields. Eddy-current transducers are suited to extreme environments and can be fabricated entirely of inorganic and nonmagnetic materials that are highly resistant to the effects of temperature, magnetic fields, and nuclear radiation, including a low cross section of x-rays. The operating principle of the eddy-current transducer is inherently different from the usual magnetic principle, in which coil inductance is increased by an approaching target. These transducers will operate with targets of magnetic materials with reduced, but often with adequate sensitivity.

EDDY FLUX (OR TURBULENT FLUX). The rate of transfer of a conservative fluid property through a surface by turbulent eddies. In the case of an unchanging mean state, the eddy flux of a property S in the z direction is expressed by

$$F_t = \overline{\rho}\,\overline{ws},$$

where lower case represents turbulence values (fluctuations from the mean), w represents vertical velocity, density, and the bar represents the mean over a chosen period. By analogy with molecular diffusion, the eddy flux in the planetary boundary layer is often expressed by

$$F_s = -\rho K_s \frac{\partial S}{\partial z},$$

where K_s is the turbulent transfer coefficient (also turbulent exchange coefficient, or eddy diffusivity). This can be generalized to include eddy diffusion in the horizontal (x, y) plane. If S is replaced by cpT, where cp represents specific heat at constant pressure and T represents temperature, the vertical turbulent heat flux (or eddy heat flux) can be represented by

$$F_h = c_p\overline{\rho}\,\overline{w\theta} = -\rho K_h\left(\frac{\partial \overline{T}}{\partial z} + \Gamma\right),$$

where θ is the temperature fluctuation, K_h the eddy thermal diffusion coefficient (or eddy conductivity), and Γ represents the adiabatic lapse rate. Similarly, eddy momentum flux is represented by

$$F_m = -\rho K_m \frac{\partial U}{\partial z},$$

where U represents the mean speed in the direction of the mean wind, and K_m represents the eddy viscosity coefficient (or eddy viscosity). Also, the turbulent transfer of water vapor may be expressed in energy units by

$$F_e = -\rho L K_e \frac{\partial \overline{q}}{\partial z},$$

where L represents the latent heat of vaporization, K_e is the eddy diffusion coefficient, and $\overline{q}$ is the specific humidity.

See also **Diffusion**; and **Turbulence**.

AMS

EDDY VISCOSITY. The turbulent transfer of momentum by eddies, giving rise to an internal fluid friction, in a manner analogous to the action of molecular viscosity in laminar flow (see also **Fluid and Fluid Flow**), but taking place on a much larger scale. If the eddy viscosity is the same at all positions, the equations of motion take the laminar forms but the magnitude of the eddy viscosity must be inferred from other considerations. Values in the atmosphere may be as large as 10 cm^2/sec in kinematic units.

EDELMAN, GERALD MAURICE (1929 –). Gerald Edelman was born on 1 July 1929 in New York, the son of a physician. Graduating from Ursinus College, Pennsylvania in 1950 he studied medicine at the University of Pennsylvania Medical School, where he gained the MD in 1954. After a year as a medical house officer in Massachusetts General Hospital he served with the US Army medical corps inParis. In 1957 he went to the Rockefeller University in New York City where, following his PhD in 1960 for a study of the immunoglobulins, he joined the staff. Produced on the surface of $\delta\Omega$-lymphocytes, the immunoglobulins are released into the body fluids as antibodies, each capable of combining with a particular antigen. They are part of the vertebrates' defense against infection. Edelman found human immunoglobulin to be a large protein molecule consisting of two kinds of protein chains, "light" and "heavy," linked bybridging sulfur atoms. Rodney R. Porter proposed a four-chain structure for the moleculeof immunoglobulin G (IgG) and Edelman proceeded to study the sequence of amino acids in the chains. He recognized that Bence-Jones proteins, first discovered in 1847, were structurally similar to the light chains of antibodies. By 1969, with his research team, hesucceeded in constructing a precise model of the entire molecule consisting of more than 1300 amino acids. Most of the molecule was unchanging, but the tips of the chains were highly variable and it seemed likely that these areas would be identified with the active antigen-binding regions, their variability enabling IgG to bind many different antigens. In 1970 Edelman argued for a major modification of the clonal theory of antibody formationproposed by Macfarlane Burnet in 1957. Edelman suggested that the signal to the immune system to increase production was the change in shape of the antibody molecule as it combined with an antigen. In 1972 Edelman and Porter shared the Nobel Prize in Physiology or Medicine. See also **Antibody**; **Burnet, Frank Macfarlane (1899–1985)**; and **Porter, Rodney Robert (1917–1985)**.

Edelman subsequently worked on morphogenesis (the formation and differentiation of tissues and organs). In 1975 he and his colleagues

discovered the proteins called *cell-adhesion molecules*, which act to attach individual cells to one another to form tissues.

Similarities between the immune and nervous systems led Edelman to investigate the neurosciences. He suggested that just as a lymphocyte can recognize and respond to a newantigen, so the nervous system can respond to novel stimuli. Appointed Director of the Neurosciences Institute at Rockefeller University in 1981, Edelman proposed a new theory of neural development and brain function in which the variations in the connections between nerve cells account for the variety of brain function between individuals. Frequently used connections will be selected, but others will decay or be used for other purposes. He argued that developmental selection occurs before birth and is followed by experientialselection; there are also "innate values," built-in preferences for such features as light and warmth. Edelman also suggested that higher consciousness, including self-awareness and memory, requires the emergence of new neuronal circuits. These views were considered obscure by some neurologists and have not been accepted widely.

EDEMA. Accumulation of excess fluids in the tissues of the body. The condition may rise from several causes. Physiologically the balance of the body fluids between the cells (intracellular fluid), the fluid bathing the cells (extracellular fluid), and the blood plasma is upset. Fluid is drawn from the blood into the tissues when there is a higher osmotic pressure in the tissues than in the blood. This higher pressure may be due to an actual increase (e.g., in salt retention due to impaired kidney function) or it may be a relative increase, as in edema associated with low serum proteins in the blood due to nutritional deficiency. Obstruction to venous flow also results in edema, by the mechanical factor of increased pressure in the capillaries. Capillary damage due to infection, bacterial toxins, or trauma will allow the passage of fluid from the blood into the tissue spaces and produce edema. Exudation of fluid into the extracellular spaces is part of the general process of inflammation and is found at the site of any localized inflammatory reaction or infection.

The common conditions characterized by edema are congestive heart failure, nephritis, varicose veins, cirrhosis, and allergic phenomena such as angioneurotic edema. In congestive failure, the fluid tends to collect in dependent portions, the feet, legs, and over the sacrum. In nephritis these areas plus the loose tissue around the eyes and other easily distensible tissues become edematous. In filariasis, obstruction of lymphatic channels by the parasites results in lymphatic edema, leading to elephantiasis.

See also **Kidney and Urinary Tract**.

EDENTATA *(Mammalia).* This comparatively small order of mammals includes mammals without teeth in the front part of the jaws and with no enamel on the teeth. The feet bear claws. A literal translation of *Edentata* is "without teeth," and thus the term does not seem very appropriate for an order where the majority of animals contained in it do have teeth. In fact, one of the animals, the giant armadillo, has more teeth than all other mammals with exception of certain species of whale. An approximate classification of *Edentata* includes:

Anteaters (*Myrmecophagidae*)
- The Giant Anteater (*Myrmecophaga*)
- Lesser Anteater (*Tamandua*)

The Pigmy Anteater (*Cyclopes*)
- *Note*: The spiny anteaters are of a different order (*Monotremata*); the scaly anteaters are of the order *Pholidota*.

Sloths (*Bradypodidae*)
- The Two-fingered Sloth (*Choloepus*)
- The Three-fingered Sloth (*Bradypus*)

Armadillos (*Dasypodidae*)
- Peludos (*Chaetophractus*, . . .)
- Giant Armadillo (*Priodontes*)
- The Cabassou (*Cabassous*)
- Pebas (*Tolypeutes*)

All of the foregoing creatures are considered to be primitive and of very early origin. Although some huge animals of this type once lived, as, for example, ground sloths, they appear to have become extinct during the sixteenth century. Some of these animals were as large as elephants. At that time, the ground sloths were found in Patagonia and the environs of the Andes. It is also believed that these animals existed in the southwest of North America and some of the islands of the West Indies.

Specializations of the anteaters include a slender elongate snout, a long sticky tongue, which aids in gathering a sufficient number of the small prey, and strong claws for tearing open ant nests. Some of the giant anteaters may attain a length of 6 feet (1.8 meters) from head to tail. One pound of ants may be consumed at a single meal. They are gray-black in color, with long hair and a long bushy tail. One young is produced at birth; it rides on the mother's back when very young. See Fig. 1.

Fig. 1. Giant anteater, female with young. (*New York Zoological Society*.)

The lesser anteater differs considerably from the giant. The ears are large, the muzzle is short, the tail is opossum-like and, although appearing naked, it is covered with dense, hard fur of various colorations. The tail is used in a prehensile fashion. The animal prefers living in trees where it feeds on ants and termites. They have a reputation of being very strong for their size and quite agile when on the ground. They are considered to be excellent defenders of themselves, usually fighting from a sitting position with their strong arms and sharp claws slashing any predators.

The pigmy anteater is short, about 1 foot (0.3 meter) in length, and inhabits the forests of Trinidad and South America. It is of reddish-brown coloration, has small ears, a short snout, and is seldom seen.

Sloths are animals of Central and South America, highly specialized for arboreal life. Their claws are large hooks by which they suspend themselves from branches, and they are so thoroughly adapted to this inverted position that the hair runs from belly to back, opposite to its direction in animals who maintain the usual position. Sloths eat the foliage of cecropia tress by preference.

The sloths are of two forms: The two-fingered (or sometimes called two-toed) and the three-fingered. Actually, there is a need to differentiate between these two types, but the names are extremely misleading because both types have five toes! The so-called two-fingered sloth is about the size of a large domestic cat, covered with very shaggy and coarse fur along the back. The fingers are ideally shaped, hardly requiring flexing for clinging to vines and tree boughs. The animals prefer leaves and fruits. They are known for their durability and ruggedness and can recover from extremely bad wounds and injuries. When provoked, they also can inflict very bad bites and tears. Generally, however, they are considered rather lazy and mindful of their own business.

The three-fingered sloth or *ai* is a smaller animal, with a dense and hard hair coat. They are of a silver-gray coloration and have a bright yellow or cream-colored face. They have an unusual bright yellow and black sunburst type of marking between their shoulder blades. Although the marking may be coincidental, it is interesting to note that the marking is quite similar to the flower clusters of the wild pawpaw tree on which the animals feed. The young, one at a birth, are tiny. Some experimenters believe that the ais can sense color because they refuse to eat artificially colored cecropia flowers, or any food that is colored by artificial lighting.

Armadillos are burrowing animals with many bony plates in the skin, which form a more or less complete armor when the animal rolls up.

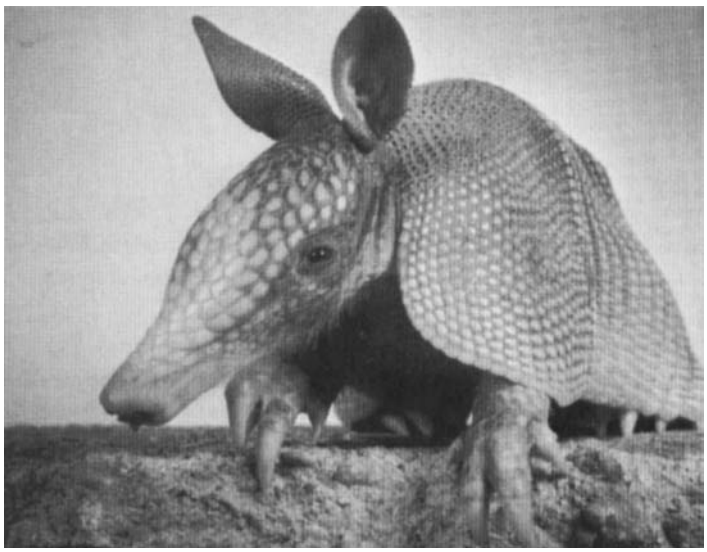

Fig. 2. Armadillo. (*A.M. Winchester*.)

Several species occur from Argentina northward through South America, and one, the nine-branded armadillo, is found in the southwestern United States. They range in size from the 5-inch (13 centimeters) pichiciago to the 3-foot (0.9 meter) giant armadillo. As with the other animals previously described in the order of *Edentata*, the mother armadillo carries the baby on her back and in case of trouble rolls around it, assuming the shape of a ball wherein the baby is completely hidden. Some of the particular varieties of armadillo include: the peludo (the hairy armadillo of Argentina, *Tatu pilosa*); the tatoquay (the broad-banded armadillo of South America, *Cabassous unicinctus*); the pichi (the pigmy armadillo, *Chalamyphorus*, of Argentina); the peba (the nine-banded armadillo, *Tatusia novemcinctus*, found from southern Texas and New Mexico to Argentina); and the apar (the three-banded armadillo, *Tolypeutes*, of South America). See Fig. 2.

EDGE. Two distinct points (endpoints) and a line segment joining them. Considering the edge as point-closed (including endpoints) is the conventional procedure although open line segments are also used by some authors. Similarly the insistence upon the distinctness of the endpoints of an edge is motivated by the desire to exclude closed "loops" in which the endpoints coincide.

See **Graph (Mathematics)**; **Tree (Mathematics)**; and **Vertex**.

EDGE DISLOCATION (Crystal). See **Crystal**.

EDGE EFFECT. In a capacitor comprising two parallel plates, the electric field is normal to the plates except near the edges, where the field lines bulge outward. This edge effect introduces a correction to the capacitance as computed from the parallel field idealization. By giving one plate greater area than the other, and surrounding the smaller plate with an auxiliary guard ring maintained at the potential of the smaller plate, the edge effect is eliminated, and the capacitance between the small plate and the large plate is given by the simple theory.

EDGE SEQUENCE. A subgraph whose edges admit an ordering possessing the following property: Each edge has one vertex in common with the preceding edge and the other vertex in common with the succeeding edge. The words "preceding" and "succeeding" are defined with respect to the ordering imposed on the edges.

EDGE TONES. The tones produced by the splitting of an air-jet by a sharp edge maintained in the jet.

EDGEWORTH SERIES. A form of expansion of a frequency function in terms of derivatives of the normal distribution. For a distribution in standard form (i.e., with zero mean and unit variance), the expansion is

$$f(x) = \left[\exp \left\{ \sum_{j=3}^{\infty} k_j \frac{(-D)^j}{j!} \right\} \right] \alpha(x),$$

where k_j is the jth cumulant; D is the operator d/dx and a(x) is the normal function $e^{-1/2x^2}/\sqrt{(2\pi}$.

See also **Gram-Charlier Series**.

EDIBLE OIL. As commonly used, the term refers to any fatty oil obtained from the flesh or seeds of plants that is used primarily in foodstuffs (margarine, salad dressing, shortening, etc.). Among these are olive, safflower, cottonseed, coconut, peanut, soybean, and corn oils, some of which may be hydrogenated to solid form. They vary in degree of unsaturation, ranging from 78% for safflower to about 10% for coconut. Castor oil, though technically edible, is not usually considered in this classification, nor are medicinal oils derived from animal sources (cod liver, mineral oil, etc.).

See also **Vegetable Oils (Edible)**.

EDISON, THOMAS ALVA (1847–1931). Edison's name is almost an American household word. He is well known as a modern inventor and often referred to as a wizard. Interestingly, most of his education was from home schooling by his mother and father. He began work as a telegraph operator. While working, he studied and experimented with telegraph technology. From 1886–1889, he began his career as an inventor. He first inventions included stock tickers, fire alarms, and an electrochemical telegraph. In 1886, Edison built a research facility in Menlo Park, New Jersey and here developed some of his most famous inventions. He developed a telephone and then in 1877, Edison captured sound and invented the first phonograph. He also developed an incandescent electric lighting system. Edison also worked with William Dickson and built the first real usable motion-picture camera.

By the time he died in 1931, Edison held more than a thousand U.S. patents.

See also **Illumination**.

J. M. I.

E-DISPLAY. In radar, a rectangular display in which targets appear as blips with distance indicated by the horizontal coordinate and elevation by the vertical coordinate. Also called *E-scan* and *E-scope*.

EDTA (Ethylenediaminetetraacetate). See **Chelates and Chelation**.

EEL GRASS *(Zosterna marina;* Najadaceae*).* Eel grass is a common plant of sandy or muddy ocean shores. The plant has a creeping somewhat fleshy stem, which roots freely at the nodes and has short erect branches. Usually it grows in salt water from a foot to over 4 feet (1.2 meters) deep, and is frequently found in tidal pools.

Quantities of eel grass are raked up and dried. It is used for packing, for stuffing for various objects, in the manufacture of certain kinds of wall board and for insulation in walls.

The plants suffer periodically from a certain disease that seriously depletes their numbers. In some regions the natural growth of eel grass has been practically wiped out by this disease.

Freshwater eel grass, *Vallisneria spiralis*, is an entirely different plant, with an interesting method of pollination. It is frequently used in aquaria.

EELS *(Osteichthyes).* Members of the order Apodes, eels are elongate slender fishes without pelvic fins and in some species lacking pectoral or median fins.

Eels fall into several classifications: (1) freshwater eels (family *Anguillidae*); (2) parasitic snubnosed eel (family *Simenchelidae*); (3) moray eels

(family *Muraenidae*); (4) snake eels (family *Ophichthidae*); (5) snipe eels (family *Nemichthyidae*); (6) deep-sea eels (family *Synaphobranchidae* and family *Serrivomeridae*); (7) conger eels (family *Congridae*); and (8) worm eels (family *Moringuidae*). Also, of the order Heteromi, there are deep-sea spiny eels. The latter are not true eels. The so-called electric eel is not an eel. See **Gymnotid Eels**.

Fig. 1. European eel (*Anguilla anguilla*).

European Eels. The anguillid eels are found in a number of freshwater areas, such as lakes, ponds, rivers, and streams. See Fig. 1. To spawn, they return to the sea. In the European eel, well known as an edible fish, females do not spawn until they have reached an age of about 12 years (length of about 5 feet; 1.5 meters). The males migrate for spawning much earlier — when they are from 4 to 8 years old (about 20 inches; 51 centimeters long). During this migration, the eels change color — from their normal yellow to silver and, at this time, they also are quite fat and thus most attractive from a food standpoint. Thus, the European fisheries gear their operations to catching the eels during the downstream migration. By instinct, the eels head for the Sargasso Sea in the Bermuda region. They spawn after having traveled thousands of miles, requiring about a year. After spawning, the adults die. The eggs float to the surface from a spawning depth of some 1,500 feet (450 meters). After hatching, the leptocephalous larvae commence the return trip, requiring in this case some 3 years. Usually arriving in European waters in the spring, the young elvers (about 3 inches; 7.5 centimeters long) seek out fresh water. The designers of the Zuider Zee dike did not contemplate the life cycle of the eel and hence millions of the elvers perished until so-called elver runs were created especially for them.

The mystery of eel migration was studied extensively by Danish biologist Johannes Schmidt who, in 1906, proposed a solution to the puzzle. From his investigations, he learned that the American eel (*Anguilla rostrata*) spawns in about the same area as the European eel (*Anguilla anguilla*). The puzzling problem was the difference in time required for the return trip, one year for the American eel; about three years for the European eel. The American eel can be found northward from Brazil to Greenland and Labrador and has penetrated into the central portions of the United States.

There are several species of freshwater eels, but none have been identified in the South Atlantic or eastern Pacific. These latter waters are not sufficiently saline and at the desired temperature at spawning depths.

The blood of the anguillids contains a toxin, which affects the nerves and penetrates a wound if exposed during handling and preparation of the eel for food.

Snubnosed Eels. The parasitic snubnosed eel habitates waters at depths between 4,000 and 5,000 feet (1200 and 1500 meters). Maximum length is about 2 feet (0.6 meter). Found in the waters along the American Atlantic coasts, Japan, and the Azores, the *S. parasiticus* obtains its nourishment by drilling into the bodies of larger fishes.

Moray Eels. There are numerous species of moray eels, of which most attain a length up to 5 feet (1.5 meters), although some have been reported as long as 10 feet (3 meters). Although a number of species are poisonous (with a number of deaths recorded as the result of eating), other species are routinely eaten. The several species of moray eels differ considerably in appearance, due mainly to their rostral development and nostril profile. Some appear as dragons and sea monsters. They prefer temperate or tropical waters and dwelling in a rock or reef environment.

Spiny Eels. The deep-sea spiny eels (*Heteromi*) look like eels, but are not related to eels. They are found in very cold waters at considerable depths — in excess of 1000 feet (300 meters) and sometimes reaching a depth of nearly 9000 feet (2700 meters). Some species possess luminous organs along their sides and on their head. They are highly elongated fishes and are seldom seen because of the great depths which they prefer.

Congers. The many genera and species of conger eels (*Congridae*) are distributed in almost all tropical and subtropical seas. The best known of them is the conger eel (*Conger conger*), which reaches a length of about 10 feet (3 meters) and a weight of about 243 pounds (65 kilograms). Distribution is almost worldwide, since it is caught in every ocean except the eastern Pacific. The species prefers rocky coasts, in the crevices of which it hides during the day. It is occasionally caught in brackish water of river mouths. The powerful teeth reflect that this is a predator which is dangerous. Its diet consists of various fishes, crustaceans, and squid. In addition to size, this species is distinguished from the European eel by the longer dorsal fin, which has its base shortly before that of the pectoral fins, and by the scaleless skin.

Not all is understood concerning the spawning of conger eels. Occasionally, females have been captured which have not yet emptied all their contents. Females have also reached maturity in aquariums. After maturity, it is estimated that the highest number of eggs a female can lay is about 8 million. Pathological changes take place concomitantly with maturation of the gonads, these changes being in the intestinal tract and other organs, including the skeleton and teeth. The adults cannot recover from these post-spawning changes and die as a result of them. Eels probably spawn in the open sea at depths of about 8350 feet (2500 meters), but specific spawning grounds have not been found for this group. All other genera and species of this family are considerably smaller than the congers and are almost exclusively deep-sea inhabitants.

Garden Eel. These eels (*Heterocongridae*) are classed with congers by a number of zoologists, while others treat them as an individual family. Garden eels are some 12 to 20 inches (30 to 50 centimeters) long and live in tubes, which extend vertically about 1.5 feet (0.5 meter) deep in loose sand or fine-grained coral sand. It is quite an experience for a diver to encounter such a garden eel "settlement." They often cover 120 square yards (100 square meters) of sandy bottom and the garden eels inhabit the floor at intervals of 8 to 24 inches (20 to 60 centimeters). With a slightly bent fore-end, which protrudes about two-thirds out of the tube, the eels sway to and fro with the head directed against the current, seeking the zooplankton upon which they feed. Such garden eel colonies have only been found at places constantly covered with water, and only where the current is uniform. The garden eels also avoid areas where breakers occur. It is reported that these eels flee from a diver by sliding into the soil when the diver reaches a distance of about 10 feet (3 meters) from them, and only their heads protrude. At a distance of about 3 feet (1 meter), they withdraw completely into their tubes and thus wait for about 5 minutes before shyly looking out again. Most attempts to dig healthy garden eels out of the sand fail, since the animals can dig back into the soil very rapidly. With a poison solution, they can be readily driven out of their tubes. As long as they are uninjured, they swim headfirst with undulating motions over the sandy bottom, in a completely flat position. But after swimming about 3 feet (1 meter) they turn about quickly and rapidly bore tail-first with powerful movements into the sand. Thus, the garden eels are excellent in their maneuvers to avoid capture. Secretion of a mucus substance enables the eels to maneuver in and out of their tubes with ease.

EELWORM *(Nematoda).* 1. A group of roundworms of the genus *Heterodera* that acts as parasites on the roots and underground stems of vascular plants. They cause serious damage to many cultivated crops — potato, sugar beet, beetroot and cereals. Resistant cysts are formed, viable for many years, but the root-knot eelworm causes galls to appear on the roots of tomato, cucumber, and others grown under glass. Entirely satisfactory chemical control has not been achieved as yet, but biological methods using crop rotation have been more successful and economical.

2. The roundworm *Ascaris lumbricoides*, parasitic as adult in the intestine of man and domestic animals, is called an eelworm in some countries.

EFFECTIVE ATMOSPHERE. That part of the atmosphere which effectively influences a particular process or motion, its outer limit varying according to the terms of the process or motion considered. For example, an earth satellite orbiting at 250 miles altitude remains within the ionosphere, but because the air particles are so sparse at this altitude as to cause no appreciable friction of deflection, the satellite may be considered to be outside the effective atmosphere. For movement of air vehicles the effective atmosphere ends at the aeropause.

EFFECTIVE EXHAUST VELOCITY. A fictitious exhaust velocity that would theoretically produce the observed value of jet thrust. The effective exhaust velocity c_e is determined by the equation:

$$c_e = V + [A(p_1 - p_2)g/w]$$

where V is the velocity of the exhaust gases; A is the nozzle exit area; p_1 is static pressure at the nozzle exit; p_2 is ambient pressure; g is the acceleration of gravity; and w is the weight flow rate of exhaust gases.

EFFECTIVE NEUTRON CYCLE TIME. The lifetime of an average neutron within a reactor from the time it is produced to the time it is fission captured. This average takes into account delayed, as well as prompt neutrons.

EFFECTIVE PROPAGATION VELOCITY. The velocity of an electromagnetic signal which, when multiplied by the transit time for a ray path, gives a value for actual path length.

EFFECTIVE RADIUS OF THE EARTH. A fictitious value for the radius of the earth, used in place of the geometrical radius to correct for atmospheric refraction when the index of refraction in the atmosphere changes linearly with height. Under conditions of standard refraction the effective radius of the earth is 8.5×10^6 meters, or four-thirds the geometrical radius. If the effective radius is used in ray tracing diagrams, the rays may be drawn as though they were traveling in straight lines.

EFFECTIVE SOUND PRESSURE. The root-mean-square value of the instantaneous pressure of sound waves, taken over a complete cycle or a period long compared with a cycle, at that point. The unit is the microbar (dynes per square centimeter).

EFFECTIVE TEMPERATURE. 1. In astrophysics, a measure of the temperature of a star deduced by means of the Stefan-Boltzmann law, from the total energy emitted per unit area. Compare brightness temperature, color temperature. Effective temperature is always less than actual temperature.

2. In physiology, the temperature at which motionless, saturated air would induce, in a sedentary worker wearing ordinary indoor clothing, the same sensation of comfort as that induced by the actual conditions of temperature, humidity, and air movement. Compare sensible temperature, standard operative temperature, operative temperature.

Effective temperature is used as a guide in air-conditioning practice, and, on the comfort chart (American Society of Heating and Air Conditioning Engineers) it appears as a family of curves which serves as one coordinate in defining comfort zones.

Brightness temperature. 1. In astrophysics, the temperature of a black body radiating the same amount of energy per unit area at the wavelengths under consideration as the observed body.

2. The temperature of a nonblack body determined by measurement with an optical pyrometer.

Color temperature. 1. An estimate of the temperature of an incandescent body, determined by observing the wavelength at which it is emitting with peak intensity (its color) and using that wavelength in Wien law. See also **Wien Laws**. If such a body were an ideal black body, the temperature so estimated would be its true temperature and would also agree with its effective temperature; but for actual bodies, the color temperature is generally only an approximate value. Thus, the sun's color temperature is about 6100 K, a few hundred degrees hotter than most approximations of its effective temperature.

2. The temperature to which a black body radiator must be raised in order that the light it emits may match a given light source in color. [Usually expressed in Kelvin (K).]

EFFECTIVE TERRESTRIAL RADIATION. The amount by which outgoing infrared terrestrial radiation of the earth's surface exceeds downcoming infrared counter-radiation from the atmosphere. Also called *nocturnal radiation*, or *effective radiation*. See also **Actinometer**. It is to be emphasized that this amount is a positive quantity, of the order of several tenths of a langley per minute, at all times of day (except under conditions of low overcast clouds). It typically attains its diurnal maximum during the midday hours when high soil temperatures create high rates of outgoing terrestrial radiation. (For this reason, the synonym nocturnal radiation is apt to lead to slight confusion.) However, in daylight hours the effective terrestrial radiation is generally much smaller than the insolation, while at night it typically dominates the energy budget of the earth's surface.

EFFICIENCY. The general significance of this term as applied to a device or machine may be expressed as the ratio of output to input of energy or of power. If a dc motor, for example, is operating on 4 amperes at 100 volts (the power input is 400 watts), and if the motor actually delivers only 280 watts of mechanical power, its efficiency at that load is 280 watts ÷ 400 watts, or 70%. In general, the efficiency of a machine varies somewhat with the conditions under which it operates. Usually there is a load for which the efficiency is a maximum. This may be illustrated by a heavy block-and-tackle. For a small load the efficiency would be very low, because of power wasted in bending the ropes; for an excessive load it would again be low, on account of the large friction which would then develop; while for intermediate loads, higher efficiencies would prevail. The concept may be extended to other than purely mechanical systems. Thus the efficiency of an electric lamp may be expressed in candles or lumens of luminous flux (output) per watt of electric power (input); or that of an automobile horn in watts of acoustic power (noise) per watt of electric input. Various types of heat engine exhibit different thermodynamic efficiencies, i.e., the ratio of the work derived in the engine to the heat energy applied to it. See also **Thermal Efficiency**. In statistics, the relative efficiency of two consistent estimators t_1, t_2 of a parameter ϕ is defined as the limiting value of the inverse ratio of their variances as the sample size increases. It can be shown that no statistic can have a large-sample variance less than a certain lower bound; estimators whose large-sample variance achieves this lower bound are said to be fully efficient or simply efficient. See also **Machine (Simple)**.

EFFLORESCENCE. When a substance evolves moisture upon exposure to the atmosphere, the substance is said to be efflorescent, and the phenomenon is known as efflorescence. At ordinary temperatures, the vapor pressure of water is shown by Table 1. If the substance has a higher water vapor pressure than corresponds to that of the atmosphere at the given temperature, water vapor is evolved from the substance until the water vapor pressure of the substance equals the water vapor pressure of the surrounding atmosphere.

Substances that are ordinarily efflorescent are sodium sulfate decahydrate, sodium carbonate decahydrate, magnesium sulfate heptahydrate, and ferrous sulfate heptahydrate. When the saturated solution of a substance in water has a water vapor pressure greater than that of the surrounding atmosphere, evaporation of the water from solution takes place.

See **Deliquescence** for the converse phenomenon.

TABLE 1. VAPOR PRESSURE OF WATER

Temperature, °C	Water Vapor Pressure in mm Mercury	
	At Saturation	At 50% Humidity
0	4.6	2.3
10	9.2	4.6
20	17.5	8.8
30	31.8	15.9
40	55.3	27.7

EFFLUENT STREAM. A stream that flows out of another stream or out of a lake. Also a stream whose upper surface is below the surface of the local ground water table. The term *effluent* is frequently used in the processing field to indicate a gaseous or liquid stream that is discharged after some form of treating or processing.

EFFUSION. Effusion is a general term denoting a process of discharge; it is also used specifically to denote the passage of gas under pressure through a small orifice.

EFFUSIVE. The term applied by geologists to molten material (lava) which has been poured out on the surface of the earth from a vent or fissure, as distinguished from ejected volcanic material (ashes and bombs) and injected magmas (plutonic rocks).

EGG. See **Poultry**; and **Protein**.

EHRLICH, PAUL (1854–1915). Ehrlich was a German medical scientist who developed the side-chain or receptor theory and discovered the drug Salvarsan for the treatment of syphilis.

The son of a Jewish distiller, innkeeper and lottery collector, Ehrlich was born in Strehlen, Germany (now Strzelin, Poland). After pursuing medical studies at the universities of Breslau and Strasbourg, he received his medical degree from Leipzig in 1878 for athesis that dealt with the theory and practice of histological staining. This dissertation foreshadowed his lifelong interest in dyes and in the principle of selective affinity,in this case the affinity of particular dyes for certain types of tissues. After receiving his medical degree, Ehrlich accepted a position at the Charité Hospital in Berlin.

While at the Charité, Ehrlich continued his research with dyes, publishing in 1885 a study of the ability of various tissues to reduce certain dyestuffs. This work contained the germ of the side-chain (or receptor) theory that he was later to apply in his research in immunology and chemotherapy. Ehrlich also enhanced the usefulness of Robert Koch's 1882 discovery of the tubercle bacillus by developing a method for staining themicroorganism to make it more visible under the microscope. Probably as a result of his investigations with the bacillus, he developed tuberculosis and resigned from the Charité in 1888 to spend over a year recuperating in Egypt. See also **Immunology (The History)**; **Koch, Heinrich Hermann Robert (1843–1910)**; and **Tuberculosis**.

In 1891, Ehrlich was given laboratory space in Koch's Institute for Infectious Disease in Berlin, and was also appointed as extraordinary professor at Berlin University. Soon after joining Koch's staff, he assisted Emil von Behring in developing the latter's diphtheria antitoxin into a useful clinical preparation by increasing the potency of and standardizing the antitoxin. In 1896, the Prussian government established a laboratory for serum research and testing in Stieglitz with Ehrlich at its head. A new Institute for Experimental Therapy was created especially for Ehrlich in Frankfurt in 1899, and he remained as its director for the rest of his life. See also **Von Behring, Emil Adolf (1854–1917)**.

Ehrlich pursued his work in immunology and developed his side-chain theory more fully to explain the process of immunization. He postulated that chemical side-chains in the cell, which are normally involved in ordinary physiological processes such as oxidation, contain chemical groups capable of combining with bacterial toxins, such as the diphtheria toxin, and neutralizing them. Combination with the toxin renders the side-chain incapable of performing its normal physiological function, and the cell produces more side-chains to make up the deficiency. The cell overcompensates, however, and produces excess side-chains which break away from the cell and are released into the bloodstream. These excess side-chains are what we call antitoxins or antibodies. See also **Antibody**; and **Antigen**.

Ehrlich's theory became more elaborate as he struggled to explain various immunological phenomena. His concepts of the toxin–antitoxin (or antigen–antibody) reaction, although significantly modified by later developments, stimulated immunological research by providing a theoretical framework for discussion of the subject. He also demonstrated that the antigen–antibody reaction was understandable in terms of ordinarychemical reactions. For his contributions to immunology, Ehrlich shared the Nobel Prize in Physiology or Medicine for 1908 with Ilya Metchnikoff. See also **Metchnikoff, Elie (Ilya) (1845–1916)**.

By this time, however, his attention had turned to the development of chemical agents against disease. In 1906, the Georg-Speyer Haus, a laboratory for chemotherapeutic research adjacent to the Institute for Experimental Therapy, was built for him with private funds. Recognizing that many infectious diseases were not amenable to treatment with antitoxins and similar biological agents, Ehrlich saw a need to develop chemical drugs to fight these diseases. He compared the antitoxins of the organism to "magic bullets," which specifically seek out and neutralize toxins, and reasoned that it ought to be possible to produce chemical "magic bullets," chemical compounds that would specifically poison disease-causing microorganisms without harming the cells of the human host. He thus devoted himself to the task of experimental chemotherapy, a discipline that he essentially established.

Beginning with dyes and later expanding his studies to include arsenic compounds, Ehrlich and his co-workers modified the chemical structure of countless molecules in an effort to produce effective drugs against microorganisms such as the trypanosomes that cause sleeping sickness and the spirochetes that cause syphilis. They tested hundreds of compounds before they came upon one, number 606 (later named Salvarsan), that proved to be effective in the treatment of syphilis. Salvarsan was an organic arsenic compound that was also known as arsphenamine. See also **Syphilis**.

Ehrlich's announcement of the discovery of Salvarsan in 1910 created great enthusiasm for the chemotherapeutic approach, and stimulated the search for other chemical drugs effective against infectious disease. He modified the immunological concept of side-chains and applied it to explain the interaction between drugs and cells, referring to the side-chains now as receptors. He argued that an effective chemotherapeutic agent would be a toxic substance that has a significantly greater affinity for the receptors in the microorganism than for those in the cells of the human host. In this way, it would kill the microorganism without harming the human body. Ehrlich's receptor concept, along with the contemporary work of the English physiologist J. N. Langley, formed the basis of the modern receptor theory of drug action. Ehrlich also used this receptor theory to explain how microorganisms could develop a resistance to a drug, a phenomenon discovered in his laboratory about 1905. Ehrlich was nominated for a second Nobel Prize in 1912 and 1913 for his contributions in chemotherapy. The value of Salvarsan was still in dispute at the time, however, and Ehrlich's death in 1915 ended the matter. See also **Antibiotics**; and **Drug Discovery (The History)**.

EIDER DUCK. See **Waterfowl**.

EIGENFUNCTION. If a differential or integral equation possesses solutions satisfying the given boundary conditions for only certain values

of a parameter λ, such a value is an eigenvalue (proper or characteristic value) and the corresponding solution is the eigenfunction belonging to that eigenvalue. Thus, given the linear operator P, the solutions u to the equation $Pu = \lambda u$ are eigenfunctions of P belonging to the eigenvalue λ. The totality of eigenvalues of any linear operator constitute the complete set, which may be made orthonormal.

Matrix methods are often useful in discussing this subject. If λ is a scalar parameter, **A** a square matrix of order n, and **E** the unit matrix of the same order, then $\mathbf{K} = [\lambda\mathbf{E} - \mathbf{A}]$ is the characteristic matrix of **A**. The equation $det\ \mathbf{K} = 0 = \lambda^n = a_1\lambda^{n-1} + \cdots + a_n$, where the a_i are functions of the elements of **A**, is the characteristic equation of A and its roots are the eigenvalues, characteristic or latent roots. The trace of **A**, the sum of its diagonal elements, is the sum of the eigenvalues. Two matrices related by a similarity transformation have the same eigenvalues and hence the same trace.

An eigenfunction is often regarded as a vector in an abstract n-dimensional space; hence, it is often called an eigenvector.

EIGEN, MANFRED (1927–). A German physicist who shared the Nobel Prize for chemistry with Ronald George Wreyford Norrish and George Porter in 1967, for their studies of extremely fast chemical reactions, effected by disturbing the equilibrium by means of very short pulses of energy. His research concerned the rate of hydrogen-ion formation through disassociation of water. He also was concerned with enzyme control. He received his degree at the University of Gottingen.

EIGENVALUE (Proper Value). The concept described by this hybrid word has become extremely important in pure and applied mathematics, and in engineering, physics and chemistry. The German word "*eigen*" means "characteristic," a term already overburdened in mathematical English. The "characteristic values" of a physical system are numbers that describe, for example, the critical frequencies of a suspension bridge or of a rotating shaft, the critical load of a supporting column, or the energy levels of a system in quantum mechanics. In corresponding mathematical language, we shall define the eigenvalues of a square matrix, of the kernel of an integral equation, of a differential equation with boundary conditions, and of an operator or transformation, the last case including all the others.

If $\mathbf{A} = \{a_{ik}\}$ is a square matrix, then the number λ is an eigenvalue (also called a characteristic number, a proper value, a latent root, etc.) of the matrix **A** if the determinant

$$\begin{vmatrix} a_{11}-\lambda & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22}-\lambda & \cdots & a_{2n} \\ \vdots & \vdots & \cdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn}-\lambda \end{vmatrix}$$

is equal to zero. In other words, an eigenvalue of a matrix is a root of the characteristic equation of the matrix.

As a physical example, consider a suspension bridge that is vibrating with n degrees of freedom about a position of stable equilibrium. Its potential energy at any time will be a function, call it $A(q_1, q_2, \ldots, q_n)$, of its n position coordinates $q_1, q_2, \ldots, q_n$, which is approximated by the quadratic form $\sum a_{ik}q_iq_k$, the constants a_{ik} being given by $a_{ik} = \frac{1}{2}(\partial^2 A/\partial q_i\,\partial q_k)$ evaluated at the position of equilibrium. Then, the eigenvalues of the matrix $\{a_{ik}\}$ are the squares of the critical frequencies of the bridge, namely the frequencies at which an impressed force will cause dangerous resonance.

From the theory of linear equations it follows that this definition of the eigenvalues of a matrix can be restated as follows. The constant λ is an eigenvalue of the matrix $\{a_{ik}\}$ if the n homogeneous linear equations in the n unknowns $q_1, q_2, \ldots, q_n$

$$\begin{array}{ccccccccc} a_{11}q_1 & + & a_{12}q_2 & + & \cdots & + & a_{1n}q_n & = & \lambda q_1 \\ a_{21}q_1 & + & a_{22}q_2 & + & \cdots & + & a_{2n}q_n & = & \lambda q_2 \\ \vdots & & \vdots & & \cdots & & \vdots & & \vdots \\ a_{n1}q_1 & + & a_{n2}q_2 & + & \cdots & + & a_{nn}q_n & = & \lambda q_2 \end{array}$$

have a nontrivial solution (i.e., one for which not all the q_i vanish). In other words, regarding the matrix as a linear operator in n-dimensional Euclidean space, the constant λ is an eigenvalue of the operator A which transforms a vector $\mathbf{q} = (q_1, q_2, \ldots, q_n)$ into a vector denoted by $A\mathbf{q}$, if there exists a nonzero vector $\mathbf{q} = (q_1, q_2, \ldots, q_n)$ such that $A\mathbf{q} = \lambda\mathbf{q}$. Such a nonzero vector is called an *eigenvector* (of the operator A) belonging to the eigenvalue λ.

Similarly, let $A\ (x, y)$ be a continuous function of two variables (the infinite-dimensional analogue of a matrix with rows and columns) defined for $a \le x, y \le b$, and let A be the integral operator which transforms a function $\phi(x)$ into a function $f(x)$ according to the formula

$$f(x) = \iint A(x, y)\phi(y)dy,$$

where the integration is taken over the square $a \le x, y \le b$ and the functions $\phi(x)$ and $f(x) = A\phi(x)$ are infinite-dimensional analogues (in Hilbert space) of the above vectors **q** and $A\mathbf{q}$. Then the constant λ is defined to be an eigenvalue of the integral operator A if the integral equation

$$\iint A(x, y)\phi(y)dy = \lambda\phi(x),$$

which we may also write in the form $A\phi = \lambda\phi$, has a nontrivial solution $\phi(x)$. The solution $\phi(x)$ is called an eigensolution, or eigenfunction belonging to λ.

The type of eigenvalue problem occurring most frequently in practical applications involves a differential operator. For example, the critical frequencies of a vibrating plate (important in the theory of microphones and elsewhere) are the squares of the eigenvalues of the biharmonic operator discussed below.

In general, let A be any differential operator acting on functions ϕ of any number of variables; e.g., for the clamped plate, $\phi = \phi(x, y)$ and A is the biharmonic operator defined by the formula

$$A\phi = \partial^4\phi/\partial x^4 + 2\partial^4\phi/\partial x^2\partial y^2 + \partial^4\phi/\partial y^4.$$

Also, let us consider as admissible only those functions ϕ which satisfy certain boundary conditions; e.g., for the clamped plate, ϕ and its normal derivative must vanish on the boundary. Then the constant λ is an eigenvalue of the operator A if there exists an admissible function ϕ, called an eigenfunction of A, such that $A\phi = \lambda\phi$. Differential eigenvalue problems of this sort are of fundamental importance in the theory of vibrations and buckling and in quantum mechanics.

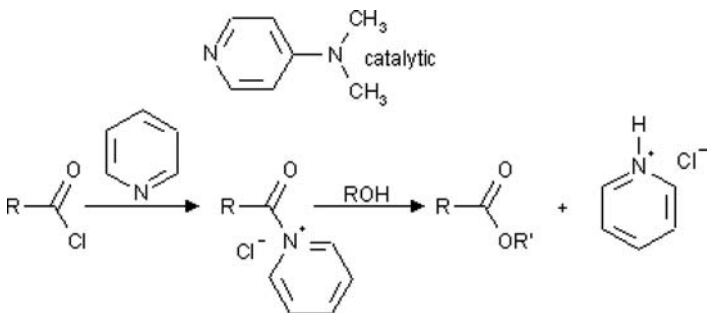
EIJKMAN, CHRISTIAAN (1858–1930). Christiaan Eijkman was a Dutch physician who used chickens as a model for the study of beriberi, and was a pioneer in research leading to the discovery of vitamins.

EIKONAL EQUATION. A fundamental equation of wave motion of the form:

$$|\nabla\psi|^2 = n^2(x, y, z)$$

where n is the refractive index of the medium for the waves, ∇ is the vector differential operator, and $\psi(x, y, z)$ is a function called the eikonal, which defines the wave fronts.

EINHORN VARIATION. Reaction of carboxylic acid chlorides analogous to the Schotten-Baumann Reaction, only using pyridine and a cat (e.g. *p-N*, *N*-**D**i**M**ethyl**A**mino**P**yridin :=DMAP or Steglich-Catalyst). See also **Schotten-Baumann Reaction.**



EINSTEIN, ALBERT (1879–1955). Einstein was a German-American physicist who revolutionized modern physics with his Theory of Relativity. Interestingly, school was always boring for Einstein and he dropped out as a teen. He eventually graduated from Zurich Polytechnic as a secondary school teacher of mathematics and physics. About two years later, he obtained a post at the Swiss patent office in Bern. While working at a patent office, he wrote his first scientific paper on the structure

of light. That paper marked the beginning of his career as a well-respected physicist. He went on to write more papers in theoretical physics, including three groundbreaking ones in 1905, which were published in the *German Yearbook of Physics*. One paper dealt with the motion of particles suspended in liquid. Einstein gave a formula explaining that the visible motion of the particles was due to the invisible motion of the molecules of the liquid. A second paper was on the photoelectric effect or the release of electrons from metal when light shines on it. Einstein used the recent ideas of Max Planck's quantum hypothesis to describe the electromagnetic radiation of light. He received the Nobel Prize in physics for this paper. The problems of gravity bothered Einstein the most. He kept working with the idea. A third radical paper is his famous, Theory of Relativity, with its conclusion that motion is not absolute. This paper includes his famous mathematical formula $E = mc^2$. By 1909 Einstein was recognized throughout Europe as a leading scientific thinker. He held professorships at the German University of Prague and at Zurich Polytechnic and then became professor at the Kaiser-Wilhelm Gesellschaft in Berlin. In 1919 after a solar eclipse occurred and astronomer's observations proved Einstein's general theory of relativity, he became a world-wide celebrity.

Einstein was in America when Hitler took power in 1933. He did not return to Germany. He took a position at the Institute for Advanced Studies in Princeton and remained there for the rest of his life. Einstein's formula $E = mc^2$ was key during World War II to the development of the atomic bomb for the United States but he, himself, was not involved in the Manhattan Project.

In 1940, Einstein became a U.S. citizen. In 1952, Israel offered him their presidency, but he declined. The ninety-ninth element, "einsteinium" is named after Einstein.

EINSTEIN DIFFUSION EQUATION. See **Diffusion Equation (Einstein)**.

EINSTEINIUM. [CAS: 7429-92-7] Chemical element symbol Es, at. no. 99, at. wt. 254 (mass number of the most stable isotope), radioactive metal of the *Actinide* series, also one of the *Transuranium* elements. Both einsteinium and fermium were formed in a thermonuclear explosion that occurred in the South Pacific in 1952. The elements were identified by scientists from the University of California's Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. It was observed that very heavy uranium isotopes which resulted from the action of the instantaneous neutron flux on uranium (contained in the explosive device) decayed to form Es and Fm. The probable electronic configuration of Es is

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^{11} 6s^2 6p^6 7s^2.$$

Ionic radius Es^{3+} 0.97 Å. See also **Chemical Elements**.

All known isotopes of einsteinium are radioactive. The first evidence of their existence was obtained by ion-exchange methods applied to coral rocks obtained from Eniwetok Atoll after the thermonuclear explosion. The first pure isotope found was ^{253}Es produced by prolonged treatment of plutonium-239 with neutrons in the Arco, Idaho, Testing Reactor. The most stable is ^{254}Es, half-life 270 days, and therefore the mass number 254 is carried in the atomic weight table. Others include ^{245}Es–^{246}Es, ^{248}Es–^{252}Es, and ^{253}Es, ^{255}Es.

The ion Es^{3+} is stable. The isotopes of mass numbers 245, 252, 253 and 254 decay by alpha-particle emission; that of mass number 250 by electron capture, those of mass numbers 246, 248, 249, and 251 by both of these processes, while those of mass numbers 255 and 256 emit electrons to form the corresponding fermium isotopes.

Sufficient einsteinium, produced through intense neutron bombardments of plutonium-239 in a reactor, was not available until 1961 to allow separation of a macroscopic amount. Cunningham, Wallmann, L. Phillips, and Gatti worked with submicrogram quantities to separate a small fraction of pure einsteinium-235 compound and measure its magnetic susceptibility. Only a few hundredths of a microgram were available at that time.

EINSTEIN LAW (Photochemistry). See **Stark-Einstein Equation**.

EINSTEIN OBSERVATORY (HEAO-2). HEAO-2, Einstein, was a NASA mission, that involved a consortium of scientist from several institutions, including the Harvard–Smithsonian Center for Astrophysics, Columbia University, NASA/Goddard Space Flight Center, and MIT. Einstein was launched into low Earth orbit by an Atlas-Centaur rocket on November 13, 1978 and operated without significant interruption until April 1981. It was the first X-ray mission to use focusing optics with imaging detectors with an angular resolution of a few arcseconds, a field-of-view of tens of arcminutes. The sensitivity was several 100 times greater than any previous X-ray astronomy mission. A new capability was created to study a broad range of what might be termed in this case "conventional" stars and celestial objects that have been observed optically for many years, as contrasted with the special kinds of situations observed during earlier x-ray work. The broadened and sharpened powers of the observatory made it possible to explore extra galactic x-ray stars. See Fig. 1, clusters of galaxies, and quasars, and to make further important studies of the diffuse background of x-radiation (photon energies above 2000 eV) that appears to originate outside our own galaxy.

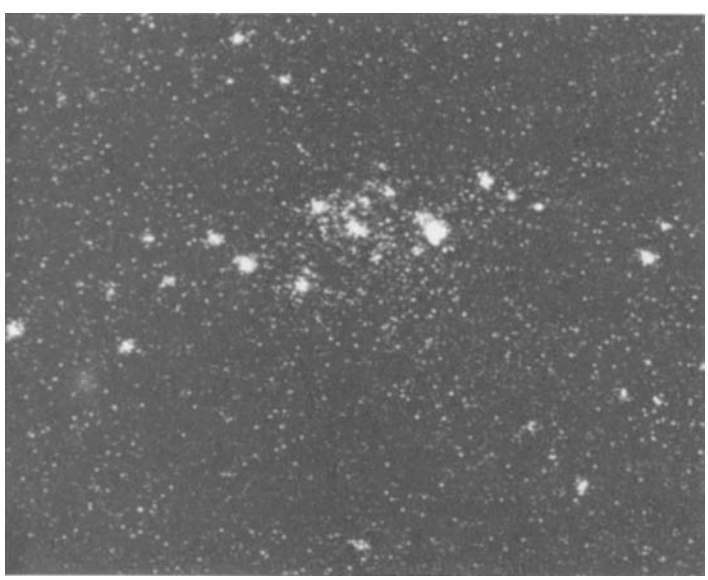

Fig. 1. X-ray sources in galaxy M-31 (in Andromeda), which is the closest neighbor to earth's galaxy. The central region of the galaxy is shown here. Note X-ray source just to the left of the brightest (largest) emission. The X-ray source is estimated to be at or very close to the exact center of the galactic nucleus. The other X-ray objects are stars of globular clusters. (*Smithsonian Astrophysical Observatory/NASA photo.*)

The payload consisted of a high resolution X-ray telescope and a focal plane assembly capable of positioning the focus at one of four instruments: the High Resolution Imaging detector (HRI); the broader field Imaging Proportional Counter (IPC); the Solid State Spectrometer (SSS);

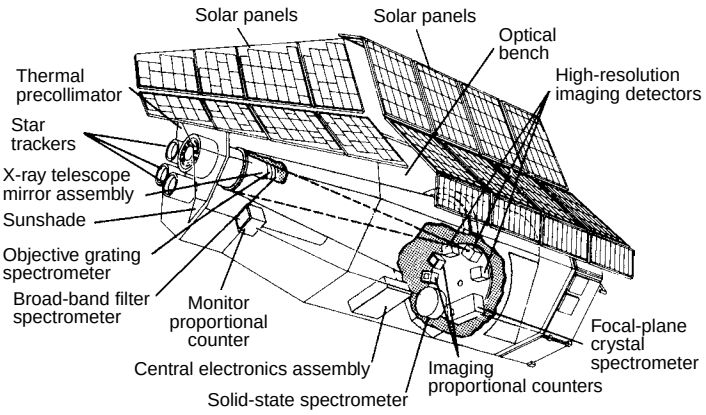

Fig. 2. Einstein (HEAO-2) X-ray Observatory Launched on November 13, 1978. Length: 6.7 meters (22 feet); diameter: 2. 4 meters (7.8 feet); weight: 3175 kilograms (7,000 pounds). Altitude of original orbit: 537 kilometers (334 miles). The high-resolution imaging detectors and the imaging proportional counters assure high-quality pictures. Several spectrometers aboard enable detailed information on the energy of the X-ray protons. (*National Aeronautics and Space Administration diagram*.)

and the Focal Plane Crystal Spectrometer (FPCS). Einstein also contained a Monitor Proportional Counter (MPC) co-aligned with the telescope. The MPC monitored the 1–20 keV X-ray flux of the source(s) being observed simultaneously by the operational focal plane instrument. See Fig. 2. Einstein was a pointing mission with an active attitude control system capable of arcminute pointing and arc second attitude determination. Einstein was the first X-ray observatory to open the utilization of its facility to a larger astronomical community via a Guest Observer Program. During its mission lifetime, the Einstein Observatory carried out over 5000 targeted observation including AGNs, X-ray binaries, CVs, SNRs, stars, and clusters of galaxies. These observations, and their scientific outcome, lifted X-ray astronomy into the mainstream of astronomical research.

The IPC was a position sensitive proportional counter that provided good efficiency and full focal plane coverage, with moderate spatial and spectral resolution. There were two such assemblies on Einstein, identical except for the entrance window material. The IPC had a FOV of $75' \times 75'$, with a spatial resolution of $\sim 1'$. The effective detector area was ~ 100 cm^2, and the time resolution was 63 msec. The energy range was 0.4–4.0 keV, and the background count rate was $\sim 10^{-2}$ cts/sec.

The HRI was a digital X-ray camera that provided high spatial and temporal resolution over the central 25 arcmin of the Einstein focal plane. The instrument had no inherent spectral resolution, but spectral studies could be performed using interchangeable broad band filters and Objective Grating Spectrometers (OGS). When operated with the OGS, the HRI had an energy resolution of 10–50. There were 3 HRI detectors onboard, identical except for the UV opaque shade material. The HRI had a $25'$ diameter FOV, with a spatial resolution of $2''$ within $5'$ of the axis. The effective area was 20 cm^2 at 0.25 keV; 10 cm^2 at 1 keV; and 5 cm^2 at 2 keV. The time resolution was 8 msec. The energy range was 0.15–3.0 keV. The background was $\sim 5 \times 10^{-3}$ cts/arcmin^2/sec.

The SSS consisted of a cryogenically cooled lithium-drifted Si(Li) detector at the focus of an X-ray imaging telescope. It subtended a six arcminute diameter circular aperture, and was slightly defocused so that a point source was blurred to a radius of ~ 1 arcmin. The spectral resolution was noise-limited, with a 160 eV FWHM, and was nearly energy independent over the detector range 0.5–4.5 keV. There was 128 energy channel resolution, with each channel being about 45 eV wide. A time-dependent build-up of ice (water) on the detector surface occurred because of cryopumping of ambient outgassing material onto the 100 K detector. It was periodically defrosted by heating to 220 K at the beginning of a series of three days of observations. Each defrost reduced the total amount of ice that returned, such that after nine months the ice covering was almost gone. A model had been developed that predicted the ice parameter as a function of time, and was used to obtain the correct response matrix for any given observation. The cryogen keeping the SSS at its operational temperature of 100 K ran out, as expected, in October 1979, between Day 276 (Oct 3) and Day 286 (Oct 13).

The Focal Plane Crystal Spectrometer (FPCS) was a Bragg crystal spectrometer with six different crystal diffractors and two redundant position-sensitive detectors that were multiwire proportional counters. The FPCS had a set of four apertures to select from, with dimensions of $1' \times 20'$, $2' \times 20'$, $3' \times 30'$, and $6'$ diameter, respectively. Only the latter three were actually used in observations. The effective area of the FPCS was of order 0.1–1.0 cm^2, and its energy resolution was 50–1000. In a typical FPCS observation, a small segment (20–80 eV) of spectrum would be obtained centered on a specific spectral feature by stepping the orientation of the selected crystal: features in the energy range from 0.42–2.6 keV were observed.

The MPC was a nonfocal plane instrument that monitored the 1–20 keV X-ray flux of the source(s) being observed simultaneously by the operational focal plane instrument. The MPC was a collimated proportional counter filled with argon and carbon dioxide. It had a circular field of view, 1.5° in diameter (FWHM), which was co-aligned with the telescope. A 1.5 mil Be window sealed the gas in the detector and shielded the detector from ultraviolet radiation. The active area of the MPC was 667 cm^2. Each photon detected by the MPC was pulse-height analyzed into one of eight bins, the size of which increased logarithmically with energy from 0.41 keV, for the lowest energy bin, to 6.72 keV for the highest energy bin. The MPC had an energy resolution of $\sim$20% at 6 keV. The MPC obtained useful data from November 19, 1978 until April 17, 1981 with the exception of a 3-month period from August 27, 1980 to December 8, 1980 when operation was intermittent, due to Einstein Observatory attitude control problems.

Some of the scientific highlights during the Einstein Observatory mission include the following:

- First high resolution spectroscopy and morphological studies of supernova remnants.
- Recognized that coronal emissions in normal stars are stronger than expected.
- Resolved numerous X-ray sources in the Andromeda Galaxy and the Magellanic Clouds.
- First study of the X-ray emitting gas in galaxies and clusters of galaxies revealing cooling inflow and cluster evolution.
- Detected X-ray jets from Cen A and M87 aligned with radio jets.
- First medium and Deep X-ray surveys.
- Discovery of thousands of "serendipitous" sources.

Overall, it was a key mission in X-ray astronomy and its scientific outcome completely changed the view of the X-ray sky. See also **X-Ray Astronomy**.

EINSTEIN SHIFT. According to the relativity theory, when radiation quanta leave a massive source like the sun or a star, they are retarded by the gravitational attraction and hence lose energy. This means that they lose frequency and that the wavelength λ increases. For a star of radius R and mass M, the fractional increase in wavelength is

$$\frac{\Delta}{\lambda} = \frac{G}{c^2} \cdot \frac{M}{R}$$

in which G is the gravitation constant and c is the electromagnetic constant (speed of light). The coefficient $G/c^2 = 7.414 \times 10^{-29}$ centimeters per gram. For the sun, $M = 2.3 \times 10^{33}$ grams and $R = 1.394 \times 10^{11}$ centimeters. Then $\Delta\lambda/\lambda = 1.23 \times 10^{-6}$, so that each solar spectrum line should be shifted toward the red by a little over a millionth of its own wavelength.

Measurements of this precision are hardly possible at present. But there are other stars (in particular, the white dwarfs) so massive and so dense that the shift has actually been observed and found to be of the correct order of magnitude. See also **Star**.

EJA *(Reptilia, Sauria)*. The desert saw viper of Egypt, a vicious poisonous snake.

EKMAN LAYER. The layer of transition between the surface boundary layer, where shearing stress is constant, and the free atmosphere, where the atmosphere is treated as an ideal fluid in approximate geostrophic equilibrium. Also called *spiral layer*. In Ekman's analysis the coefficient of eddy viscosity is assumed constant within this layer; subsequent calculations have relaxed this assumption. See also **Ekman Spiral (Oceanography)**.

EKMAN SPIRAL (METEOROLOGICAL). As used in meteorology, an idealized mathematical description of the wind distribution in the atmospheric boundary layer, within which the earth's surface has an appreciable effect on the air motion. The model is simplified by assuming that within this layer the eddy viscosity and density are constant, the motion is horizontal and steady, the isobars are straight and parallel, and the geostrophic wind is constant with height. The x direction is taken along the pressure gradient; the resulting approximate equations for the component wind speeds U and V in the x and y directions, respectively, at any level z are

$$U - Ge^{-\beta} \sin \beta, \mathrm{G}(1 - \beta \cos \beta),$$

where G is the geostrophic wind speed, $\beta = z(f/2K_M)^{\frac{1}{2}}$, f is the Coriolis parameter, and K_M is the eddy viscosity. The lowest level H where $U = 0$, so that the true wind and the geostrophic wind have the same direction, is called the geostrophic wind level (or gradient wind level). It is given by

$$H = (2K_M/f)^1/2\left(\frac{3}{4}\pi + \alpha_0\right),$$

where $\alpha = 0$ is the angle between the surface wind and the surface isobars. At this height the magnitude of the true wind will exceed that of the geostrophic wind by a small amount, depending on the value of β. The Ekman spiral is an equiangular spiral having the geostrophic wind as its limit point. Below the geostrophic wind level the wind blows across the isobars toward low pressure, at an angle that is a maximum at the surface and does not exceed 45°. The deviation of the wind vector from the geostrophic wind vector diminishes upward at an exponential rate. The theory of this spiral was developed by Ekman in 1902 for motion in the upper layers of the ocean under the influence of a steady wind. It was applied to the atmosphere by Åkerblom in 1908.

EKMAN SPIRAL (METEOROLOGY). See **Winds and Air Movement**.

EKMAN SPIRAL (OCEANOGRAPHY). As originally applied by Ekman to ocean currents, a graphic representation of the way in which the theoretical wind-driven currents in the surface layers of the sea vary with depth, in an ocean assumed to be homogeneous, infinitely deep, unbounded, and having a constant eddy viscosity, over which a uniform, steady wind blows. Ekman computed that the current induced in the surface layers by the wind have the following characteristics: (1) at the very surface, the water will move at an angle of 45° *cum sole* from the wind direction; (2) in successively deeper layers, the movement will be deflected farther and farther *cum sole* from the wind direction, and the speed will decrease; and (3) a hodograph of the velocity vectors would form a spiral descending into the water and decreasing in amplitude exponentially with depth. The depth at which the vector first points 180° from the wind vector is called the depth of frictional influence (or depth of frictional resistance). At this depth the speed is $e^{-\pi}$ times that at the surface. The layer from the surface to the depth of frictional influence is called the layer of frictional influence. If the velocity vectors from the surface to the depth of frictional influence are integrated, the resultant vertically integrated motion is 90° cum sole from the wind direction.

ELAIDINIZATION. Originally, the reaction by which oleic acid is converted into elaidic acid. However, it is now used in a more general sense to indicate the conversion of any unsaturated fatty acid or related compound from the geometric *cis* to the corresponding *trans* form. Nitrous acid and selenium compounds are commonly used as catalysts for this reaction. The resulting *trans* acids are more stable to oxidation.

ELASTIC CONSTANTS AND MODULI. These constants occur in relationships between the components of strain and stress in a medium that obeys Hooke's law. Under such conditions the strain components may be expressed as functions of the stress components by linear equations of the type:

$$e_{xx} = s_{11}X_x + s_{12}Y_y + s_{13}Z_z + s_{14}Y_z + s_{15}Z_x + s_{16}X_y$$

where e_{xx} is the strain component along x-axis, the capitalized quantities are the stress components (the stress component X_x, for example, representing a force applied in the x-direction to a unit area of a plane whose normal lies in the x-direction) and the s terms are called the elastic constants or compliance constants. Also, the stress components may be expressed as functions of the strain components by linear equations of the type:

$$X_x = c_{11}e_{xx} + c_{12}e_{yy} + c_{13}e_{zz} + c_{14}e_{yz} + c_{15}e_{zx} + c_{16}e_{xy}$$

where the c terms are called the stiffness constants or elastic moduli.

For the special moduli used in engineering, see also **Elasticity**.

ELASTIC CURVE. The curve of the neutral surface of a structural member subjected to loads that cause bending is called the elastic curve. The ordinates between this curve and the original position of the neutral surface represent the deflections due to bending.

ELASTIC DEFORMATION. See **Resilience**.

ELASTICITY. The property whereby a body, when deformed, automatically recovers its normal configuration as the deforming forces are removed. Each of its several types is probably due to the action of intermolecular forces that are in equilibrium only for certain configurations.

Deformation or, more briefly, strain is of various kinds; in each case its measure is a certain abstract ratio. For example, the elongation of a rod under tension is expressed as the ratio of the increase in length to the unstretched length. Linear compression is the reverse of elongation. They are both accompanied by a fractional change in diameter, the ratio of which to the elongation is called the Poisson ratio. Shear is a strain involving change of shape, such that an imaginary cube traced in the unstrained material becomes a rhombic prism. The measure of shear is the tangent of the angle through which the oblique edges have been made to depart from their original perpendicular direction. Volume strain is the ratio of a decrease in volume to the normal volume. Flexure, or bending, and torsion, or twisting, are combinations of these more elementary strains. A straight rod bent into a plane curve undergoes elongation on the convex side and linear compression on the concave side, while there is an intermediate neutral layer, which suffers neither.

In tests such as the tensile test it is necessary to differentiate between two basic ways of measuring strain. "Conventional strain" is the increase in length of the gage section divided by the original gage length, whereas the "true strain" is the natural logarithm

$$\ln \frac{l}{l_0}$$

where l_0 is the original value and l the instantaneous value of the length of the gage section.

For every strain, there arises, in an elastic substance, a corresponding stress, which represents the tendency of the substance to recover its normal condition. Stress is expressed in units of force per unit area. Tensile stress, for example, is the ratio of the force of tension to the normal cross section of the rod subjected to it. Shearing stress is the force tending to push one layer of the material past the adjacent layer, per unit area of the layers. Pressure, expressed in like units, is the stress corresponding to volume compression, etc.

For each type of strain and stress there is a modulus, which is the ratio of the stress to the corresponding strain. In the case of elongation or linear compression, it is commonly called Young's modulus; we also have the bulk modulus and the shear modulus of rigidity. See Table 1.

TABLE 1. NOMINAL MODULUS VALUES OF REPRESENTATIVE METALS (values in pounds per square inch)

Material	Young's Modulus	Rigidity of Shear Modulus
Magnesium	6.5×10^6	2.4×10^6
Aluminum	10.2×10^6	3.6×10^6
Copper	14.5×10^6	6.1×10^6
Steel	30×10^6	11.6×10^6

In engineering design, Young's modulus is used for tension and compression and the rigidity modulus for shear, as in torsion springs. According to Hooke's Law, the stress set up within an elastic body

is proportional to the strain to which the body is subjected by the applied load.

Theory of Elasticity. The fundamental quantities in elasticity are second-order tensors, or dyadics: the deformation is represented by the *strain dyadic*, and the internal forces are represented by the *stress dyadic*. The physical constitution of the deformable body determines the relation between the strain dyadic and the stress dyadic, which relation is, in the infinitesimal theory, assumed to be linear and homogeneous. While for anisotropic bodies this relation may involve as much as 21 independent constants, in the case of isotropic bodies, the number of elastic constants is reduced to two.

Let **s(r)** be the displacement vector, due to the deformation, of a particle that before the deformation was situated at point P having **r** as position vector with respect to some arbitrary origin. A neighboring point Q, whose position vector was $\mathbf{r} + d\mathbf{r}$ before the deformation, will suffer a displacement $\mathbf{s}(\mathbf{r} + d\mathbf{r})$ which will differ from **s(r)** by the quantity

$$d\mathbf{s} = d\mathbf{r} \cdot \nabla s$$

The hypothesis of small deformations means that ds, the change in the displacement vector when we go from P to the neighboring point Q, is very small compared to $d\mathbf{r}$, the position vector of Q relative to P. Consequently, the scalar components of the dyadic ∇s are all very small compared to unity. The geometrical meaning of the dyadic ∇s is obtained by separating it into its symmetric part $\mathbf{S} = \frac{1}{2}(\nabla\mathbf{s} + \mathbf{s}\nabla)$ and its antisymmetric part $\mathbf{R} = -\frac{1}{2}\mathbf{1} \times (\nabla \times \mathbf{s})$, where **1** is the unity dyadic. The antisymmetric part is interpreted as follows: if at some point M the symmetric part vanishes, then we have for the neighborhood of M the relation

$$d\mathbf{s} = d\mathbf{r} \cdot \mathrm{R_M} = \omega_\mathrm{M} \times d\mathbf{r}$$

where $\omega_\mathrm{M} = \frac{1}{2}(\nabla \times \mathbf{s})_\mathrm{M}$ is an infinitesimal vector. This means that the neighborhood of point M undergoes an infinitesimal rigid rotation, without any change in shape or size. Consequently, the deformation is represented by the symmetric part **S**, which is called the *strain dyadic*.

In a Cartesian orthonormal basis, in which we have $\mathbf{r} = \sum_{i=1}^{3} x_i \mathbf{a}_i$, we write $\mathbf{s} = \sum_{i=1}^{3} s_i \mathbf{a}_i$, and obtain

$$\mathbf{S} = \sum_{i,j=1}^{3} \mathbf{a}_i \mathbf{a}_j S_{ij}$$

where

$$S_{ij} = \frac{1}{2}\left[\frac{\partial}{\partial x_i} s_j + \frac{\partial}{\partial x_j} s_i\right].$$

The diagonal components S_{11}, S_{12}, and S_{33} are the coefficients of linear extension in the directions $\mathbf{a}_1, \mathbf{a}_2$, and $\mathbf{a}_3$, respectively, while the nondiagonal components $S_{12} = S_{21}, S_{13} = S_{31}$, and $S_{23} = S_{32}$ are called shear strains. For instance, $2S_{12}$ is the change in the angle of the dihedron formed by the planes that before the deformation were respectively normal to the directions $\mathbf{a}_1$ and $\mathbf{a}_2$. The shear strains are not essential for the complete representation of a deformation since they can be made to vanish by expressing **S** in the basis of its principal axes.

If an infinitesimal element of the body occupies the volume dV before the deformation and the volume dV' after, the relative increase of volume, or volumetric dilatation, is given by

$$\frac{dV' - dV}{dV} = S_{11} + S_{22} + S_{33} = |\mathbf{S}| = \nabla \cdot \mathbf{s}$$

The forces applied to a finite deformable body are either body forces acting on every volume element dV and represented by the notation $\mathbf{F} = dV\rho\mathbf{K}$, where **F** is the force per unit volume, **K** is the force per unit mass, and ρ is the density, or surface forces acting on every element dS of the bounding surface and represented by $dS\ \mathbf{T}$, where **T** is the surface stress, or surface force per unit area. The effect of these applied forces is transmitted throughout the body, so that through any surface element inside the body, there is a force exerted by the matter on one side of the element upon the matter on the other side. Such forces are called internal stresses and are defined as follows: let dS be a surface element completely inside the body, and let us choose arbitrarily the positive sense of the normal **n** to this surface element; this defines for dS a positive side, the one containing **n**, and a negative side. Then $\mathbf{T}_\mathrm{n}$, the stress vector on the positive side of dS is defined as a vector such that $dS\,\mathbf{T_n}$ is the surface force on the positive side of dS — i.e., the resultant of all the forces exerted through dS by the matter on the positive side of dS upon the matter on the negative side. In general there is a normal component $\mathbf{T_n} \cdot \mathbf{nn}$, which is a pressure or a traction depending upon whether the sign of $\mathbf{T_n} \cdot \mathbf{n}$ is negative or positive, and a tangent component $\mathbf{n} \times \mathbf{T_n} \times \mathbf{n}$ called the shear stress. The value of the stress vector $\mathbf{T_n}$ depends upon the orientation of the normal **n**, so that we can characterize the state of stress at a point by defining the *stress dyadic* **T** through the relation

$$\mathbf{T_n} = \mathbf{n} \cdot \mathbf{T}$$

The mechanical equilibrium conditions applied to an arbitrary volume V, bounded by the closed surface S, and completely inside the deformable body give

$$\int_\mathrm{v} dV\mathbf{F} + \int_s dS\mathbf{n} \cdot \mathbf{T} = 0$$

and

$$\int_\mathrm{V} dV\mathbf{r} \times \mathbf{F} + \int_\mathrm{S} dS\mathbf{r} \times (\mathbf{n} \cdot \mathbf{T}) = 0$$

By the use of the divergence theorem, the first condition gives the equation

$$\nabla \cdot \mathbf{T} + \mathbf{F} = 0$$

at any point inside the body, and the second condition implies that **T** is a symmetric dyadic. On the external surface of the body, we have usually to fulfill the boundary condition

$$\mathbf{n} \cdot \mathbf{T} = \mathbf{T}$$

where **T** is the applied external force per unit area. Other boundary conditions can also be met, such that the value of the displacement be prescribed.

For infinitesimal deformations, we assume that the relation between strain and stress is expressed by Hooke's law: the deformation is proportional to the applied force. For isotropic bodies, this linear relation is

$$\mathbf{S} = \frac{1}{E}[(1 + v)\mathbf{T} - v|\mathbf{T}|\mathbf{1}]$$

where E is Young's modulus and v is Poisson's ratio. These two elastic constants can be defined by considering the stretching of a cylindrical bar by normal traction forces uniformly distributed on the end sections; then we have

$$\text{Young's modulus} = \frac{\text{Normal traction force per unit cross sectional area}}{\text{Relative longitudinal extention}}$$

and

$$\text{Poisson's ratio} = \frac{\text{Relative lateral contraction}}{\text{Relative longitudinal extension}}$$

We can also write

$$\mathbf{T} = 2\mu\mathbf{S} + \lambda|\mathbf{S}|\mathbf{1}$$

where $\mu = E/2(1 + v)$ and $\lambda = vE/(1 + v)(1 - 2v)$ are Lamé's constants. μ is the rigidity modulus, the only constant necessary when the volumetric dilatation vanishes everywhere.

Substituting the preceding relation into the equilibrium equations, we transform them into

$$2\mu\nabla \cdot \mathbf{S} + \lambda\nabla|\mathbf{S}| + \mathbf{F} = 0 \text{ in side the body}$$

and

$$2\mu\mathbf{n} \cdot \mathbf{S} + \lambda\mathbf{n}|\mathbf{S}| = \mathbf{T} \text{ on the bounding surface.}$$

These vector relations are not sufficient for the complete determination of the symmetric dyadic **S**. To insure that a solution of the above equations corresponds to a possible displacement vector **s**, we must be able to integrate the relation

$$\mathbf{S} = \tfrac{1}{2}(\nabla\mathbf{s} + \mathbf{s}\nabla)$$

i.e., from a given expression for **S** obtain the value of **s**. From the vanishing of the curl of a gradient, it is easily seen that this integrability condition, also called the compatibility equation, is

$$\nabla \times \mathbf{S} \times \nabla = 0$$

By elimination of the vector products, we obtain the equivalent form

$$\nabla\nabla \cdot \mathbf{S} + \nabla \cdot \mathbf{S}\nabla - \nabla\nabla|\mathbf{S}| - \nabla \cdot \nabla\mathbf{S} = 0$$

Using the stress-strain relation and the equilibrium conditions, we obtain the Beltrami-Michell form of the compatibility equation:

$$\nabla \cdot \nabla \mathbf{T} + \frac{1}{1+\nu}\nabla\nabla|\mathbf{T}| = -\frac{\nu}{1-\nu}\nabla \cdot \mathbf{F}\mathbf{1} - (\nabla\mathbf{F} + \mathbf{F}\nabla)$$

Finally, by expressing the strain dyadic in terms of the displacement vector, we obtain Navier's form of the equilibrium equations:

$$\mu\nabla \cdot \nabla\mathbf{s} + (\lambda + \mu)\nabla\nabla \cdot \mathbf{s} + \mathbf{F} = 0$$

inside the body and

$$\lambda n\nabla \cdot \mathbf{s} + 2\mu\mathbf{n} \cdot \nabla\mathbf{s} + \mu\mathbf{n} \times (\nabla \times \mathbf{s}) = \mathbf{T}$$

on the bounding surface. Dealing here directly with the displacement vector, there is no need of considering the compatibility equation.

The propagation equation for elastic disturbances is obtained by adding the inertia force to the body force. We get then

$$\mu\nabla \cdot \nabla\mathbf{s} + (\lambda + \mu)\nabla\nabla \cdot \mathbf{s} + \rho\mathbf{K} = \rho\frac{\partial^2}{\partial t^2}\mathbf{s}$$

inside the body. The stress-strain relation and the boundary conditions are not affected, but we generally have to take into account initial conditions.

The energy density u, or energy per unit volume, is given by

$$u = \frac{1}{2}\mathbf{SS} : \mathbf{TT} + \frac{1}{2}\rho\frac{\partial\mathbf{s}}{\partial t} \cdot \frac{\partial\mathbf{s}}{\partial t}$$

where the first term is potential, or strain energy, and the second term is kinetic energy. The energy flux density vector

$$\mathbf{S} = -\frac{\partial\mathbf{s}}{\partial t}.$$

is a vector such that $dS\ \mathbf{n} \cdot \mathbf{S}$ gives the quantity of energy that flows per unit time through the surface element dS in the positive direction of **n**, the normal to dS. At any point the energy continuity equation

$$\frac{\partial u}{\partial t} + \nabla \cdot \mathbf{S} - \rho\frac{\partial\mathbf{s}}{\partial t} \cdot \mathbf{K} = 0$$

expresses the conservation of mechanical energy.

ELASTICITY (Modulus). See **Modulus of Elasticity**.

ELASTIC LIMIT. The maximum unit stress that can be obtained in a structural material without causing a permanent deformation is called the elastic limit.

ELASTIC REBOUND THEORY. See **Earth Tectonics and Earthquakes**.

ELASTOMERS. Of natural or synthetic origin, an elastomer is a polymer possessing elastic (rubbery) properties. A polymer is a substance consisting of molecules which are, in the most part, multiples of low-molecular-weight units, or monomers. As an example, isoprene (2-methylbutadiene-1,3) is C_5H_8, whereas polyisoprene is $(C_5H_8)_x$, where $x \geq 2$ and normally is from 1,000 to 10,000 for rubbers. Although they differ in composition from natural rubber, many of these high-molecular-weight materials are termed *synthetic rubbers*. See also **Rubber (Natural)**.

The serious development of synthetic rubbers commenced in the late 1930s and early 1940s, accelerated by a cutoff of supplies of natural rubber because of political turmoil and war. Synthetic rubbers fall into two major classifications: (1) general-purpose rubbers, the major volume of which is nevertheless used for tire production; and (2) specialty rubbers that essentially find little use in tires, but that are important for a number of other categories. Synthetic rubbers have not replaced natural rubber for numerous uses. For large, heavy-duty truck and bus tires, natural rubber tends to run considerably cooler and wears better than a blend of natural and synthetic rubbers. On the other hand, a tire tread made of a blend of styrene-butadiene (SBR) and butadiene rubber (polybutadiene) wears longer than natural rubber in conventional automobile, usage, where lower temperatures can be maintained.

Styrene-Butadiene (SBR) Rubbers. This series of rubbers includes monomer ratios up to about 50% styrene. The addition of more than 50% styrene makes the materials more like plastic than rubber. The most commonly used SBR rubbers contain about 25% styrene, which is polymerized in emulsion systems at 5–10 °C. Most SBR goes into tires, but the type for the tread differs from that of the sidewall or carcass. SBRs for adhesives, shoe soles, and other products also differ. The formulation permits vast varieties of end products. Among the processing variables that can be manipulated to provide different end characteristics are temperature, viscosity, use of different emulsifiers and solvents, use of different antioxidants for stabilization, different oils, carbon blacks, and coagulation techniques.

Initial processes for emulsion (E-SBR) called for polymerization at 50 °C. However, it was found later that cold processing produced a rubber particularly good for tires. This is sometimes referred to as *cold SBR*. The overall process for making SBR is shown in Fig. 1. Typical formulations are:

	Parts by Weight	
	Hot SBR	*Cold SBR*
Deionized water	180	200
Fatty acid soap	5	4.5
Styrene	25	28
t-Dodecyl-mercaptan	0.35	0.2
Butadiene	75	72
Potassium persulfate	0.3	0
Redox initiator	0	small quantity
Temperature	50 °C	5 °C
Time	12 hours	8 hours
Conversion	75%	60%

Polymerization of emulsion SBR is started by free radicals generated by the redox system in cold SBR and by persulfate or other initiator in hot SBR. The initiators are not involved in the molecular structure of the polymers. Almost all molecules are terminated by fragments of the chain transfer agent (a mercaptan). Schematically, the molecules are RSM_nH, where RS is the $C_{12}H_{25}S$ part of a dodecyl mercaptan molecule; M is the monomer involved; n is the degree of polymerization, and H is a hydrogen atom formerly attached to the sulfur of a mercaptan. In the case of free-radical-initiated polymerization of butadiene, by itself to form homopolymers or with other monomers for form copolymers, the butadiene will be about 18%; 16% *cis*-1,4; and 66% *trans*-1,4.

Considerable quantities of SBR latex are used in the manufacture of foam rubber, adhesives, fabric treating, and paints. The solid content of lattices runs from 50% to 65–70%.

Solution (S-SBR) consists of styrene butadiene copolymers prepared in solution. A wide range of styrene-butadiene ratios and molecular structures is possible. Copolymers with no chemically detectable blocks of polystyrene constitute a distinct class of solution SBRs and are most like styrene-butadiene copolymers made by emulsion processes. Solution SBRs with terminal blocks of polystyrene (S-B-S) have the properties of self-cured elastomers. They are processed like thermoplastics and do not require vulcanization. Lithium alkyls are used as the catalyst.

Stereospecific solution polymerization has been emphasized since the discovery of the complex coordination catalysts that yield polymers of butadiene and isoprene having highly ordered microstructures. The catalysts used are usually mixtures of organometallic and transition metal compounds. An example of one of these polymers is *cis*-1,4-polybutadiene, the bulk of which is used in tires. However, it must be blended with other materials because of its poor processability and traction.

Butyl Rubber. Known as IIR, butyl rubber is a copolymer of isobutylene and isoprene. The elastomers contain only 0.5–2.5 mole % of isoprene. This is introduced to effect sufficient unsaturation to make the rubber vulcanizable. Polymerizations are usually carried out at low temperature (−80 to −100 °C) with methyl chloride as solvent. Anhydrous aluminum chloride and a trace of water serve as catalyst.

Butyl is one of the earlier synthetic rubbers. However, it lost favor after the development of SBR. Butyl rubber is incompatible with natural rubber and is difficult to cure. Chlorobutyl rubbers, a much more recent development and containing up to 1.3% chlorine, apparently do not exhibit these former problems. Major uses for butyl rubber have been inner tubes for tires. The appearance of tubeless tires, however, depressed this market. Butyl rubber makes excellent motor mounts because of its high energy absorption and low rebound. Essentially free of double bonds, butyl rubber has a high resistance to aging, attractive properties for use in curing bags for tire production and in outside coating materials.

Acrylonitrile-Butadiene Rubbers (NBR). Except for the monomers used, the production of NBRs is quite similar to that described for the

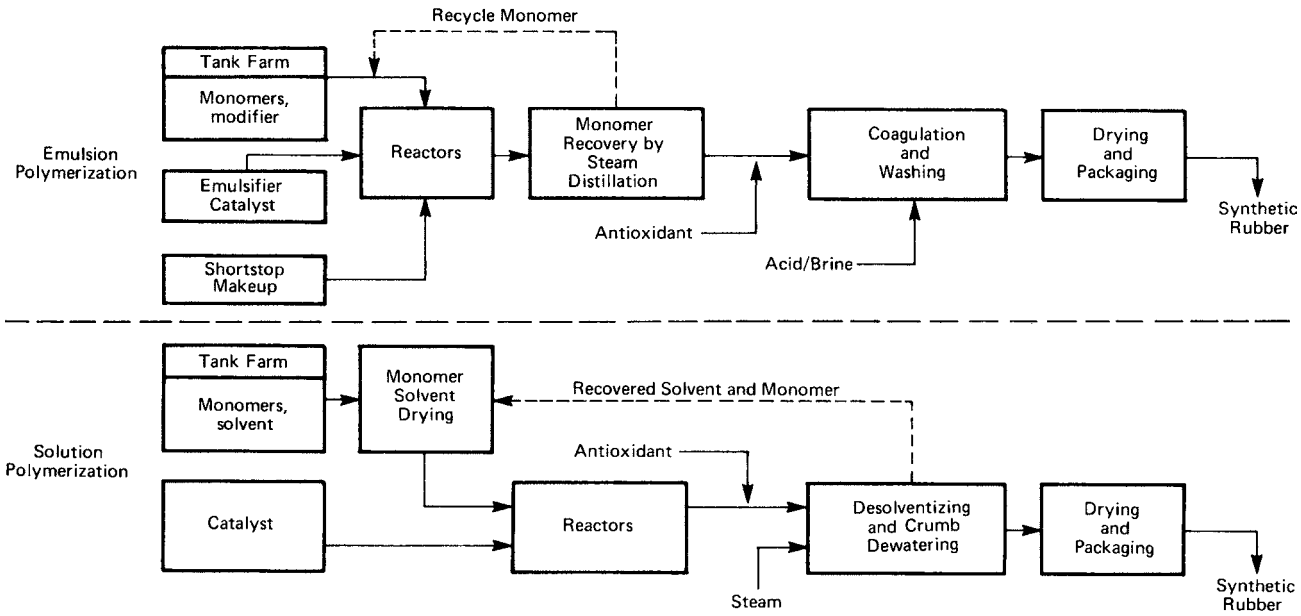

Fig. 1. Synthetic rubber production process.

SBRs. The NBR family is sometimes referred to as the *nitrile rubbers*. The acrylonitrile-butadiene ratios cover a wide range from 15:85 to 50:50. NBRs are noted for their solvent resistance, increasing with the acrylonitrile content. Thus, they are used for gaskets and oil and gasoline hoses, solvent-resistant electrical insulation, and food-wrapping films. Nitrile lattices also are used in treating fabrics for dry-cleaning durability. Because the NBRs become quite inflexible (stiff) at low temperatures (actually brittle at about $-20\,^{\circ}C$), they are blended with polyvinyl chloride for some applications.

Neoprene. This family of dry rubbers and lattices was introduced in 1932, called *Duprene* by Du Pont at that time. The material is made by the free-radical-initiated polymerization of chloroprene in emulsion systems. As with most synthetic rubbers, a variety of neoprenes is made possible by variation of the polymerization conditions and ingredients. Neoprene is particularly good for its fire-retardant, solvent-resistant, and high-temperature stability properties. The chlorine in each segment deactivates the adjoining carbon-carbon double-bond, thus making it less sensitive to oxidative attack. Metal oxides, such as zinc oxide and magnesium, serve as curatives rather than sulfur.

Polyurethanes. Polyethylene in solution is treated with chlorine and sulfur dioxide to introduce approximately 1.3% sulfur and 29% chlorine into the polymer. Most of the chlorine is attached directly to the carbon atoms in the backbone of the polymer. The remainder is in the form of sulfuryl chloride groups, $\cdot SO_2Cl$, through which crosslinking occurs in the curing step with metal oxides. The material has good oxidation and ozone resistance and thus overall excellent weather resistance. Calendered stocks are used for lining ditches and ponds, for example.

Thiokol® Rubbers. These are polysulfide rubbers and are prepared by the condensation polymerization of sodium polysulfides with a dichloro (sometimes blended with a trichloro) organic compound. Type A, the first family of rubbers, was made from Na_2S_4 and ethylene dichloride. Thiokols are known for high resistance to organic solvents.

Polyacrylate Elastomers. These are made in emulsion or suspension systems involving the copolymerization of ethyl acrylate with the acrylate esters of higher-molecular-weight alcohols. These materials have excellent solvent-resistant properties and stability at elevated temperatures. A major use is for automatic-transmission gaskets for automobiles.

Silicone Elastomers. These materials have alternating Si and O atoms for a backbone and the members differ mainly in the nature of the organic substituents on the Si atoms and the degree of polymerization. Because of the absence of double bonds in the backbone, the numerous forms of stereoisomers found in unsaturated hydrocarbon rubbers do not have counterparts in the silicone rubbers. The chemical combination of organic and inorganic materials gives the silicone rubbers useful properties over a wide temperature range (-70 to $+225\,^{\circ}C$). These rubbers are well known for excellent dielectric stability and high resistance to weathering, oils and chemicals.

Fluoroelastomers. These materials are prepared by emulsion copolymerization of perfluoropropylene and vinylidene fluoride; or of chlorotrifluoroethylene and vinylidene fluoride. Also there are fluorosilicones in this family. Useful at temperatures up to and over $300\,^{\circ}C$, the fluoroelastomers have excellent resistance to aromatic solvents, acids, and alkalies. They are also among the more costly of the available commercial elastomers.

Ethylene-Propylene Elastomers. Known as EPR, this material is of limited use because it cannot be vulcanized in readily available systems. However, the rubbers are made from low-cost monomers, have good mechanical and elastic properties, and outstanding resistance to ozone, heat, and chemical attack. They remain flexible to very low temperatures (brittle point about $-95\,^{\circ}C$). They are superior to butyl rubber in dynamic resilience.

E-LAYER. A division of the ionosphere, usually found at an altitude between 100 and 120 kilometers in the E-region. It exhibits one or more distinct maximums and sharp gradients of free electron density. It is most pronounced in the daytime but does not entirely disappear at night. Also called *El-layer*, *Kennelly-Heaviside layer*, or *Heaviside layer*. There is some evidence to indicate a second layer above the normal E-layer located at about 150 kilometers, and called the *E2-layer*.

ELDER TREES AND VIBURNUMS. Of the family *Caprifoliaceae* (elder or honeysuckle family), the elder is a small tree, frequently a shrub, which is found in Europe and North America. The box elder (or ash-leaved maple) is a member of the family *Aceraceae* (maple family) and is not directly related to the other elders. Elder trees are of the genus *Sambucus*. These plants are deciduous, considered hardy, with odd, pinnately compounded leaves. There are from 5 to 11 ovate, pointed, fine-toothed leaflets. The flower is small and may be pink or creamy white in color, occurring in flat clusters. The fruit is a small berrylike drupe and may range in color from red, through blues and purples, and black, depending upon the species. There are about 12 species commonly found in North America. The more important include: American elder (*Sambucus*

canadensis), which has black-to-purple-to-blue berries, well known as the source of elderberry wine; the blueberry elder (*S. glauca*), which has a blue fruit; the Mexican (*S. Mexicana*) and the velvet elder (*S. velutina*), both of which have black fruits; and the Pacific red elder (*S. callicarpa*), which has a red fruit. There are also some essentially local species, including the blackhead elder (*S. melanocarpa*), and the Florida elder (*S. simpsonii*). See Table 1 for record elder trees.

The American elder is found from Nova Scotia and New Brunswick westward across Canada to Manitoba and south and westward in the United States through Kansas and into Texas and Arizona. The tree tends to become larger as it is found in the west. The elder can be found in the Allegheny Mountains to an elevation of about 3500 feet (1070 meters). It thrives in rich moist soil.

The common elder of Europe, north Africa, and western Asia is the *S. nigra*, which has yellowish flowers and lustrous black fruit. The pithy new wood of this shrub or tree is known for its rather disagreeable odor, which is alleged to even repel flies and other insects.

Closely associated with the elders and also members of the elder family are the viburnums, which also are deciduous, but sometimes evergreen shrubs and trees. These plants have fragrant, clustered white flowers and fruits of fleshy consistency and bright colors. The *Viburnium prunifolium* is commonly referred to as the blackhaw or stag-bush. Usually an erect bush, but frequently a tree ranging in height from 10 to close to 30 feet (3 to 9 meters), the plant normally will have a trunk diameter up to 10 inches. The bark is rough and gray-brown and in earlier years was used as a tonic and medicinal. The leaves are dark green, from 1 to 3 inches (2.5 to 7.6 centimeters) in length. The flowers are quite small and white and occur in large clusters approaching 5 inches (12.7 centimeters) in breadth. The fruit is bluish, edible, and sweet. The southern or rusty blackhaw (*V. rufidulum*) is a somewhat smaller species, but quite similar to the stag-bush. Record blackhaws also are listed on the accompanying table.

There are numerous species of the viburnums, just a few of which include: The wayfaring tree (*V. lantana*), very popular in Europe as a hedgerow plant; *V. opulus*, also known in Europe and north Africa as the Guelder rose or cranberry shrub, and particularly well adapted to wet areas. (Incidentally, this shrub is not related to the common cranberry, which is of the family *Ericaceae* (heather family).); the *V. alnifolium*, also known as hobble bush, witch hobble, and wayfaring tree; V. opulus var. *americanum*, commonly known as the pimbina, crampbark, cranberry tree, or highbush cranberry (these berries are sometimes used as substitutes for common cranberries); *V. pauciflorum*, known as the squashberry bush or squashberry pimbina; *V. acerifolium*, the dockmackie or arrowwood; *V. pubescens*, the downy arrowwood; *V. molle*, the soft-leaved arrowwood; *V. venosum*, similar to *V. molle* ; *V. dentatum*, the arrowwood shrub; *V. cassinoides*, the withe-rod Appalachian tea shrub; *V. nudum*, the naked withe-rod; and *V. lentago*, the nannyberry, sheepberry, or wild raisin tree.

ELECTRET. A permanently polarized piece of dielectric material; the analog of a magnet. Barium titanate ceramics, preferably containing a small percentage of lead titanate, can be polarized by cooling from a temperature above the Curie point in an applied electric field. Electrets are also produced by solidification of mixtures of certain organic waxes in a strong electric field.

ELECTRICAL BREAKDOWN. The sudden decrease of resistivity of a substance when the applied electric field strength rises above a certain threshold value (the substance's dielectric strength).

For air at normal pressures and temperatures, experiment has shown that the breakdown process occurs at a field strength of about 3×10^6 V m^{-1}. This value decreases approximately linearly with pressure, and is dependent upon humidity and traces of foreign gases. In the region of high field strength just ahead of an actively growing leader in a lightning stroke, breakdown occurs in the form of a rapidly moving wave of sudden ionization (electron avalanche). The dielectric strength in a cloud of water drops is less than that in cloud-free humid air.

ELECTRICAL CONDUCTIVITY. The measure of a material's ability to carry an electric current. An electric conductor is a material which, when placed between terminals having a difference of electrical potential, will readily permit the passage of an electric current. Different materials have different degrees of conductivity, and their effectiveness in this respect is computed as the conductivity. The best conductors are the metals, such as silver, copper, aluminum, platinum, and mercury, but nonmetallic substances such as carbon, saline solutions, and moist earth also are sufficiently conductive so that this property becomes of significance under

certain circumstances. By virtue of their cost-conductivity characteristic, copper and aluminum are widely used conductors. They will usually be found as wires or buses. Copper is used more commonly than aluminum, the use of which is preferred for high-voltage transmission lines, where its lighter weight is of definite advantage. Steel as a conductor is inferior to the other two materials mentioned. but its greater strength and resistance to wear have led to its adoption as a conductor of special purposes, such as that of power rail service on electrified railways, and as an inner core of copper or aluminum cables. The resistance of a conductor is its resistivity multiplied by its length and divided by its cross-sectional area.

Commonly Used Electrical Conductors. For practical comparative purposes, the commonly used metals are compared with the International Annealed Copper Standard (IACS). A value of 100% conductivity is assigned to annealed copper. The standard may be expressed in terms of mass resistivity as 0.15328 ohm-grams/square meter, or the resistance of a uniform round wire 1 meter long weighing 1 gram at 20 °C. Useful equivalent expressions of the annealed copper standard in terms of various units of mass resistivity and volume resistivity, include:

Value	Units at 20 °C
0.15328	ohm-grams/square meter
875.20	ohm-pounds/square mile
1.7241	microohm-centimeters
0.67879	microohm-inches
10.371	ohm-circular mils/foot
0.017241	ohm-square millimeters/meter

All of the foregoing values are equivalent to $\frac{1}{58}$ ohm-square millimeters/meter. Thus volume conductivity can be expressed as 58 ohm-square millimeters/meter at 20 °C. See Table 1.

TABLE 1. CONDUCTORS — ELECTRICAL CONDUCTIVITY AND RESISTIVITY[a]

Material	% IACS (Volume) 20 °C	Volume Resistivity (Microohm-Centimeters) 20 °C
Annealed copper	100.00	1.7241
Copper alloy (B187–62)	98.40	1.7521
Copper alloy (B188–61)	97.80	1.7629
Copper alloy (B47–64; B116–64)	97.16	1.7745
Copper alloy (B355–65T, nickel coated)	96.00	1.7960
Copper alloy (B246–64, tinned hard)	92.72	1.8595
Copper alloy (B355–65T, nickel coated, soft)	88.0	1.9592
Aluminum	64.94	2.6548
Aluminum alloy (B233–64)	61.5	2.8035
Aluminum alloy (B317–64)	59.0	2.9222
Aluminum alloy (B396–63T)	52.5	3.2839
Copper-clad steel	40	4.3971
Aluminum-clad steel	20	8.4805
Iron (pure)		9.78
Commercial galvanized iron		16–20
Silver	108.4	1.59
Gold		2.3

[a] Representative metals and alloys. There are hundreds of metal combinations used. Frequently, electrical conductivity is not the sole criterion in selecting a conductor. Other factors include density (weight), strength, ductility, and corrosion and abrasion resistance.

Fundamentals of Electrical Conductivity. The conductivity σ of an isotropic material in a steady direct-current electric field E is defined by

$$j = \sigma E$$

where j is the current density (charge transported per unit time across unit area perpendicular to the current flow). In meters-kilograms-seconds (mks) units, j is measured in amperes per square meter and E in volts per meter, so that σ is in (ohm-meters)$^{-1}$ or ohms per meter. The reciprocal of the conductivity is the electrical resistivity, $\rho = 1/\sigma$. The electrical resistance R of a sample is the ratio of the potential drop across the sample to the total current through the sample. The resistance of a cylindrical sample (with the current flow parallel to the axis of the cylinder) is

$$R = \rho l / A$$

where l is the length of the cylinder and A is its cross-sectional area. If the dimensions are measured in meters and ρ is in mks units, the resistance is given in ohms. The reciprocal of the resistance is the electrical conductance.

Many homogeneous solids and liquids obey Ohm's law for sufficiently small electric fields. Ohm's law states that the current through a sample is proportional to the potential drop across the sample, and thus R, ρ, and σ are independent of the impressed electric field. Samples which do not obey Ohm's law are called *nonlinear* ; gases fall into this category, as do many important circuit elements, such as transistors and vacuum tubes. Most metals obey Ohm's law for field up to at least 10^8 volts/ meter, though under certain conditions, semiconductors have shown deviations from Ohm's law for fields as low as 10^{-2} volts/meter.

The existence of a finite resistance means that the energy delivered by the electric field to the current carriers is dissipated, being converted to heat (mostly energy of atomic vibrations). The rate of dissipation per unit volume is given by

$$\tfrac{1}{2}\rho j^2 = \tfrac{1}{2}\sigma E^2$$

and is called the Joule heat.

In some solids, the conductivity is *anisotropic*, i.e., the magnitude of j depends upon the direction of E as well as its magnitude, and j and E are not necessarily parallel. If Ohm's law is obeyed, it becomes

$$\mathbf{j} = \boldsymbol{\sigma}\mathbf{E}$$

where σ is a second rank tensor. Anisotropic solids include single crystals of materials which do not have cubic crystal structures, and polycrystalline aggregates of such materials in which there exists some preferred orientation such as can be produced by extrusion or cold rolling.

If the applied electric field varies sinusoidally in time (alternating current), the conductivity generally depends upon the applied frequency v. Appreciable deviations from the dc value may appear for microwave frequencies or greater. In the microwave and optical range, it is common to identify $-\sigma/2\pi\in_0 v$ as the imaginary part of the *dielectric coefficient*, where $\in_0$ is the permittivity of free space $\frac{1}{4}\pi\in_0 = 9 \times 10^9$ newton meter^2/coulomb^2. Thus, σ is closely related to the absorption of electromagnetic energy.

Solids are usually classified as metals, semiconductors, or insulators. Metals are characterized by an increasing resistivity with increasing temperature. Resistivities of metals at room temperature range from about 10^{-8} to 10^{-6} ohm-meters. Behavior at extremely low temperatures is covered under **Superconductivity**. Semiconductors are characterized by a decreasing resistivity with increasing temperature (impure semiconductors may show this behavior only at high temperatures). Resistivities of semiconductors at room temperature range from about 10^{-5} to 10^{+7} ohm-meters. Insulators share the same temperature behavior of resistivity as semiconductors, so the difference between the two classes of materials is a simple one of degree only. Generally, materials with room-temperature resistivities greater than 10^7 ohm-centimeters are called insulators. Resistivities as high as 10^{18} ohm-meters have been observed. There are some materials intermediate between metals and semiconductors. For example, the resistivity of manufactured carbon decreases with increasing temperature at low temperatures, and increases at high temperatures. The room-temperature resistivity is also intermediate, varying from 10^{-5} to 10^{-4} ohm-meters, depending upon the conditions of manufacture.

Except in the case of some insulators, the current in solids is carried by electrons. Quantum mechanics has shown that not all the electrons in a solid are free to carry current. The conductivity depends upon the number of free carriers and their ease of motion. The latter factor is expressed by the mobility μ, which is defined by

$$v_d = \mu E$$

where v_d is the drift velocity (average velocity of the free carriers produced by the action of the electric field). The drift velocity is usually very much

smaller than a typical carrier velocity v (the average of the magnitude of the carrier velocities). The conductivity is then given by

$$\sigma = ne\mu$$

where n is the density of free carriers (in meters^{-3}), e is the magnitude of the electronic charge (1.6×10^{-19} coulomb), and μ is in square meters per volt per second. If more than one group of carriers is present, the total conductivity is the sum of contributions from each group. Quantum mechanics has also shown that the mobility in a pure, perfectly regular crystal would be unlimited. The mobility is limited by the scattering of the carriers by deviations, such as the thermal vibrations of the atoms, impurity atoms, or irregularities in the crystal structure, such as vacancies and dislocations. A simple approximate theory of the mobility allows it to be expressed as

$$\mu = e\tau/4\pi\in_0 m^* = e\lambda/4\pi\in_0 mv$$

where τ is the relaxation time (roughly, the average time between the collisions which a carrier makes with the scattering centers), λ is the mean free path of the carriers, and m^* is the effective mass of the carrier (a concept which comes from the theory of energy bands in solids). If more than one scattering process is involved, the reciprocal of the relaxation time (scattering rate) is approximately the sum of the contributions from each process. At room temperature, mobilities range from very small values (such as 10^{-4} meter^2/volt-second) to 10 meter^2/volt-second; relaxation times range from about 10^{-14} second to about 10^{-12} second, and mean free paths range from about 10^{-9} meter to about 10^{-6} meter. One of the early triumphs of quantum mechanics was the explanation of why the mean free path can be so much larger than the distance between neighboring atoms (of the order of 10^{-10} meter).

In good metals, n is the density of valence electrons, and is thus independent of temperature (except for very small temperature dependence due to the thermal expansion). Because the electrons follow the *Fermi-Dirac* distribution law, the typical velocity v is the velocity at the Fermi surface, which is large (usually about 10^6 meters/second), and independent of temperature. The temperature dependence of the conductivity is that of the relaxation time τ, and the approximate additivity of scattering rates due to different processes results in *Matthiessen's rule*, which states that the resistivity is approximately the sum of a temperature dependent part R_T, due to scattering by lattice vibrations, and a part R_I proportional to the concentration of impurities and lattice defects. As the amplitude of the lattice vibrations increases with increasing temperature, the scattering effect and R_T increase. Above the Debye temperature θ (given by $k\theta = hv_m$, where k is the Boltzmann's constant and v_m is the maximum frequency of the lattice vibrations), R_T is proportional to the absolute temperature. At low temperatures, R_T is proportional to the fifth power of the absolute temperature, and at all temperatures it is well approximated by the *Bloch-Gruneisen formula*. At very low temperatures (1 to 18 °K), some metals become superconductors and all measurable resistance disappears.

Pure semiconductors at absolute zero temperature have no free electrons. As the temperature is increased, some electrons are excited to current-carrying states (in the *conduction band*). The states that are left unoccupied (in the *valence band*) are also free to carry current, and are called *free holes*. The concentrations of electrons and holes increase very rapidly with temperature, causing the resistivity to decrease. The carrier concentration may be expressed as

$$n = f(T)\exp(-\Delta E/2kT)$$

where T is the absolute temperature, ΔE is the energy gap between the valence and conduction bands, and $f(T)$ is a slowly varying function of temperature. Extra carriers may also be provided by impurity atoms, *donors* contributing electrons, and *acceptors* trapping electrons and producing holes. Very small impurity concentrations may make very large changes in resistivity. If most of the free carriers come from impurities, the semiconductor is called *extrinsic*; it is n (negative)-type if electrons predominate, or p (positive)-type if holes predominate. If most of the carriers come from thermal excitation, the concentration of electrons and holes are about equal, and the material is called *intrinsic*. The rate of change with temperature of the mobility of a semiconductor is generally less than the rate of change of the carrier concentration. The mobility is often represented by $\mu = cT^r$, where r varies from about -2.2 to $+1.5$, depending upon the particular material, concentration, and type of defects. The conductivity of intrinsic material can also be expressed as

$$\sigma = g(T)\exp(-\Delta E/2kT)$$

where $g(T)$ is another slowly varying function of T. This equation is often used to analyze experimental data and find ΔE.

Insulators may be thought of as semiconductors with such large energy gaps that n is very small and the resistivity is very high. In addition, the ions in some insulating solids (such as the alkali halides) are free to move and carry a measurable current. The ions move by "hopping" into vacant lattice sites. As they must cross a potential energy barrier, the ionic mobility is proportional to an activation factor $\exp(-\in/kT)$. The resistivities of such solids are of the order of 10^2 to 10^8 ohm-meters at room temperature, but are as low as 10^{-3} to 1 ohm-meter at elevated temperatures.

Another mechanism for electronic conductivity seems to operate in certain oxides and perhaps in some organic semiconductors. In this case, the electrons are localized and move by "hopping" in the same way as the ions in ionic solids.

Because the resistivity depends upon the state of crystalline order, it is used as a tool in studying phase changes, such as solid-liquid, order-disorder, magnetic, and crystal structure transitions. The resistivity of some materials is affected by pressure and mechanical strain. Many insulators and semiconductors exhibit the phenomenon of photoconductivity, in which the absorption of light produces free carriers and increases the conductivity.

Many conductors show the phenomenon of *magnetoresistance*, which is the increase in resistance when the conductor is placed in a magnetic field. (A very few materials exhibit negative magnetoresistance, which seems to be related to an inhomogeneous structure of the conductor.) The basic cause of the magnetoresistance is the Lorentz force, which causes the electrons to move in curved paths between collisions. Even for isotropic materials, the conductivity and resistivity must be taken as tensors in the presence of the magnetic field, called the *magnetoconductivity tensor* and the *magnetoresistivity tensor*. The off-diagonal elements of the magnetoresistivity tensor are related to the *Hall effect*. The on-diagonal elements for isotropic materials or for the magnetic field parallel to a crystal axis are usually called the longitudinal magnetoresistance (for the current parallel to the magnetic field) and transverse magnetoresistance (for the current perpendicular to the magnetic field). For small values of the magnetic field, the change in resistance is proportional to the square of the magnetic field strength. For large magnetic fields, the resistance may saturate (approach a constant value), continue to increase as the square of the magnetic field strength, or follow a more complex behavior. The magnetoresistance ratio (change in resistance divided by the zero-field resistance) reaches only a few percent for most materials, but at low temperatures for some materials, such as bismuth, approaches 10^6. In general, the transverse effect is larger than the longitudinal one; the effect is larger in high-mobility materials, and is largest for materials with more than one type of charge carrier. The magnetoresistance may be used in conjunction with the Hall effect to deduce the type, density, and mobility of charge carriers, and to obtain information about the Fermi surface.

Electrolytes. The conductance of an electrolyte has the same general definition as that given for any conductor. The same unit is used, the reciprocal ohm (mho). The term conductivity also has the same significance for electrolytes as for solid conductors, being conductance per unit length of path. Another term applied to electrolytes is *equivalent conductance*, which is the product of conductivity and the volume (in cubic centimeters) of solvent containing 1 gram-equivalent weight of solute at a specified concentration, measured when placed between electrodes 1 centimeter apart. The *molar conductance* is defined similarly, except that the weight of solute is 1 gram-molecular weight instead of 1 gram-equivalent weight. The *ionic conductance* is the amount contributed by each characteristic ion to the total equivalent conductance in infinite dilution. Thus, in the mathematical expression of the law of independent migration of ions:

$$\lambda_0 = \lambda_+ + \lambda_-$$

in which λ_+ and λ_- are the ionic conductances of cation and anion, respectively, and λ_0 is the total equivalent conductance of the electrolyte. The *conductance ratio* is the ratio of the equivalent conductance of a given ionic (electrolytic) solution to its equivalent conductance at infinite dilution.

See also **Electrolytic Conductivity and Resistivity Measurements**; and **Superconductivity**.

ELECTRICAL CONDUCTORS. See **Electrolytic Conductivity and Resistivity Measurements**; **Semiconductors**; and **Superconductivity**.

ELECTRICAL DISTANCE. The distance between two points expressed in terms of the duration of travel of an electromagnetic wave in free space between the two points. A convenient unit of electrical distance is the light microsecond or approximately 983 feet (300 meters). In the use of this unit, electrical distance is numerically equal to transmission time in microseconds.

ELECTRICAL GROUND FAULT CIRCUIT INTERRUPTERS (GFCI). A ground fault circuit interrupter (GFCI) is an automatic protection device that protects individuals from electrical shock. If one should contact a GFCI-protected circuit conductor or energized surface while part of the body is grounded, the GFCI will respond by cutting off power before shock or serious injury can occur. Before the GFCI became available, the only circuit protection was from circuit breakers, or fuses, which essentially only protects equipment and buildings from higher current damage. It is in only the past couple of decades that GFCI protection has been required by the National Electrical Code (NEC) in many situations.

Ground Faults

Ground faults occur when current-carrying parts of a circuit accidentally contact any grounded conducting material. GFCIs provide electric shock protection against this type of accident.

High-current ground faults cause an immediate massive current flow to ground and are normally interrupted by over-current devices such as fuses or circuit breakers, usually within 10 milliseconds.

Low-current ground faults can cause current to flow to ground. This current, being lower than the rating of the fuse or circuit breaker, will not cause overcurrent devices to cut off the circuit power. Low-current ground faults of 60 cycles (AC) can be extremely dangerous. Just 0.01 of an ampere (10 milliamperes) can freeze a victim to a power source until the amount of current received reaches lethal proportions. If the current passes through the heart, breathing may become arrested at 18 milliamperes. If the current increases to 60 milliamperes, ventricular fibrillation of the heart can occur. A house current of 60 milliamperes can kill a person in seconds. See also **Electric Shock**.

GFCI Operation. This device monitors both the current flowing to the load (hot wire) and the current flowing from it (neutral wire). Under normal circumstances, these should be equal. When a ground fault occurs, the GFCI senses an in balance between the hot and neutral wires, caused by the leakage of current to ground, and trips out, cutting off the supply of current. The GFCI has a transformer with neutral and hot primary windings wound in opposite directions, and has a secondary winding which will produce a voltage when there is an imbalance. The voltage is applied to a solid-state amplifier whose output is applied to a relay coil. The relay interrupts the current. Most GFCIs are designed to trip within 30 milliseconds after a current imbalance of only 5 milliamperes or more has been detected. Although harmless, even the common 5-milliampere trip-level shock can have hazardous secondary effects caused by reflex actions of the body (for instance, falling off a ladder). The GFCI is a serious and very important addition to safety equipment in the electrical industry and has saved countless lives.

There are several different types of GFCI units. The first is a combination circuit breaker and GFCI, which is installed in the service panel instead of a regular circuit breaker. This type usually has a small test button on it, and it protects that entire circuit. This type of GFCI will shut off power to that entire circuit even when a very slight and harmless internal leakage to ground occurs. The GFCI circuit breaker is set to interrupt current at 20 milliamp to account for leakage in the branch circuiting. The second type of GFCI is the receptacle type, which is installed instead of a conventional receptacle outlet. This type of GFCI has a reset and a test button, usually placed between the two outlets, and it protects anything plugged into that particular outlet. Depending upon the GFCI model, it may also protect all other outlets that are downstream (come after) it, but not upstream outlets (between it and the fuse box). The third type of GFCI is the portable type that merely plugs into an existing three-prong grounded outlet and converts that receptacle to a ground fault protected receptacle. Some models even come with extension cords for use around the outlet, or in damp locations. These are both handy, but they are not "permanent" solutions or installations. The GFCI plug in or receptacle is set to interrupt currents from 4 milliamps to 6 milliamps.

Protection not provided by GFCI's. GFIC's will not provide protection if one should contact the hot and the neutral wire while one is not grounded (line-to-line short). As the current through the body is not flowing to ground, the GFCI will not operate, one is then at the mercy of the system's overcurrent protection devices. These will trip only if the current is high enough (overload) and serious damage may occur before they go into operation. However, should some of the current passing through the body also flow through a grounded object to the earth or ground (simultaneous fault) the GFCI will trip the circuit open as with a normal ground fault.

The GFCI also will not work if faults in another line circuit occur. If a saw or drill penetrates wiring of a circuit other than the one supplying its own power, the operator can be aided only by the protective devices in the penetrated circuit. GFCIs or overcurrent devices in the circuit supplying the tool cannot stop this flow of current.

GFCIs have proved so efficient, in a variety of applications, that there is a tendency to place undue reliance on them as a source of protection. It should be emphasized that this device, while extremely reliable, is not designed to be failsafe should an internal failure develop. The installation of a GFCI does not obviate the need for recognized practices and procedures developed through the years to insure safe electrical work.

Were should GFCI circuit breakers or portable ground-fault interrupting receptacles be used? Electricity is not limited to following the path of least resistance; it will take every other route to ground open to it. Operators of equipment can be subjected to shock hazards due to fault grounding, worn insulation, or bypassed isolation methods. GFCIs can minimize the hazards caused by these conditions, and they must be used as follows:

- Underground installations, concrete slabs or masonry in direct contact with the earth.
- Locations exposed to weather.
- Partially exposed areas (under canopies or roofed open shelters) and locations subject to a moderate degree of moisture.
- Outdoor receptacles or any receptacles that are used by an operator standing on the ground.
- All electrical equipment mounted in or on tow tanks, pools, docks, or in any body of water where the possibility of human contact with water and leakage current exists.
- On all receptacles within 10 to 15 feet of the preceding items.
- In all damp or wet locations, such as basements, or in rooms where water pickup using powered water vacuums or electric cleaning equipment (as in showers) is required.
- In conductive locations (inside metal tanks, ducts, or boilers) or in any area where a person can be easily grounded.
- In vehicle repair or washing areas.

Ground-Fault Circuit-Interrupter Protection for Personnel specifies that GFCIs must be installed in the following locations:

- For residential occupancies all 125-volt, single-phase, 15-ampere and 20-ampere receptacles shall be installed within 6 feet of a sink in bathrooms and kitchens and must have approved ground fault circuit protection.
- All outdoor receptacles located between 10 and 15 feet of the inside walls of a swimming pool must be protected by GFCI's.
- Dwellings where 125-volt single-phase, 15-ampere and 20-ampere receptacles are installed outdoors.
- Garages and crawl spaces below grade.
- Unfinished basements.
- Whirlpool tubs.
- Light switches in bathrooms within reach of the lavatory, tub or shower.

ELECTRICAL INSTRUMENTS. The basic electrical analog instrument can be traced to Oersted's discovery (1819) of the relation between current and magnetism. Faraday (1821) learned that a current-carrying conductor would rotate in a magnetic field. Ampere (1821) demonstrated that a current in one conductor attracted or repelled another current-carrying conductor. Sturgeon (1836) wound the current-carrying wire into a coil and suspended it in a magnetic field. Kelvin (1867) placed a soft iron core in the center of the coil, shortening the air gap, increasing the sensitivity, and improving the scale characteristics of the device. D'Arsonval (1881) patented an instrument of this type. Weston (1888) discovered the factors required to produce a permanent magnet system, added soft iron pole pieces, devised current-carrying control springs and produced the first commercial double-pivoted permanent magnet moving coil instruments as such. From Oersted's and Kelvin's work also stem the principles on which polarized iron vane and electrodynamic type instruments evolved through the work of Ayrton and Perry (1881), Bruger (1886), Weston (1889) and many others.

Traceability

Electrical instruments are calibrated in terms of the prime standards of the quantity measured. These prime standards are established and maintained by various government standards organizations throughout the world — sometimes referred to as legal standards. The national caretaker of standards in the United States is the National Bureau of Standards. The method of tracing the accuracy of voltmeters, ammeters, and wattmeters to prime standards is outlined schematically in Fig. 1. Sophisticated standards and calibration services are also available from a limited number of private firms. Government laboratories generally calibrate only primary standards

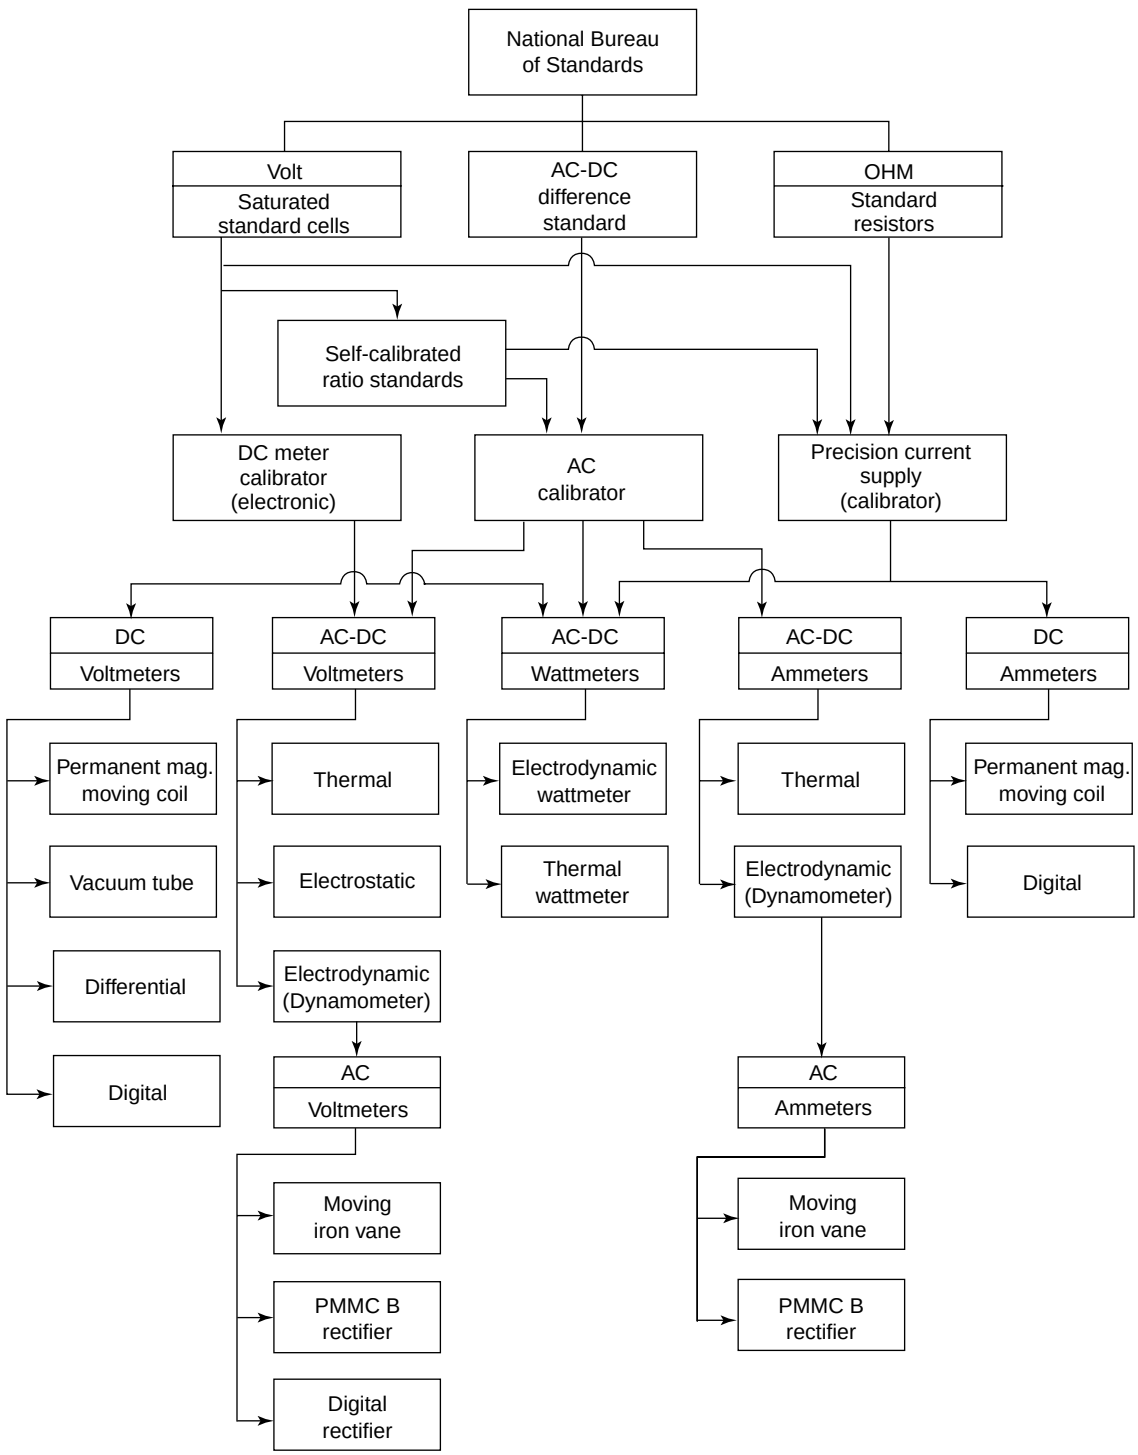

Fig. 1. Traceability of electrical instruments back to prime standards maintained by the National Institute of Standards and Technology and by similar standards organizations in other countries.

in selected areas; private firms generally must be relied upon to calibrate instruments, test equipment, or standards in other areas. A directory of standards laboratories is available from The National Institute of Standards and Technology (NIST), Physical Measurements and Services Program, Gaithersburg, Maryland 20899.

Manufacturers of standard cells and precision electrical instruments and systems usually maintain their own standards laboratories. These contain local standards that are calibrated or recalibrated on a periodic scheduled basis by an official organization, such as NIST; secondary standards and the working standards used in various stages of manufacturing and assembly are, in turn, calibrated against these local standards.

Various types of ratio devices are used to extend the standard-cell voltage (approximately one volt) to cover many ranges of commercial instruments and in terms of current in amperes in addition to voltage through the use of standard resistors. Extension of voltage values is accomplished through the use of what is commonly referred to as a volt box. Effectively, this is a high-valued resistor, accurately tapped at exact proportions of its total value. If the total voltage is applied to the total resistance, then the value at the tapped points is low enough to compare accurately with the standard-cell voltage.

Extension of current values is accomplished through the use of very low-valued resistors; passing the unknown current through them results in voltage which, in turn, can be compared with the standard-cell voltage, and through the use of Ohm's law and the resistance value, the value of the current can be established. Such low-valued resistors are called *shunts* and standard units of this kind are maintained with much care. These shunts can be calibrated — as by the National Bureau of Standards.

The direct voltages and currents established at this level are used to calibrate electronic calibrators which, in turn, are used to calibrate dc voltmeters, ammeters, and ac-dc voltmeters, ammeters, and electrodynamic wattmeters. Also shown in Fig. 1 are ac-dc difference or transfer standards. These are high-accuracy instruments, such as the thermaland electrodynamic-type voltmeters, ammeters, and wattmeters, which are sent to the NIST for calibration. In this case, NIST does not perform an accuracy check, but rather determines the difference between the ac calibration at various frequencies and that on direct current. These standards then are used for determining the performance of AC-DC instruments when used on alternating current.

Alternating-current voltmeters and ammeters usually are calibrated against electronic AC calibrators, which have been calibrated against direct current standards by using thermal transfer standards.

Voltage Standards. The cadmium cell, developed by Dr. Edward Weston in 1893 and universally known as the Weston Standard Cell, was used as a world standard of emf from the time of its acceptance by the International Committee on Electrical Units and Standards in 1908 until the advent of Josephson voltage standards in the 1970s. Standard cells are still the prevalent primary voltage standard in industry. The unit of voltage at the International Bureau of Weights and Measures and the legal voltages of most industrial nations are now maintained through the ac Josephson effect. The Josephson effect is realized through weak connections (commonly through a dielectric tunnel barrier a few nanometers thick) between superconductors. Such connections are referred to as Josephson junctions. For a wide range of frequencies, the current-voltage characteristics of a Josephson junction that is irradiated with electromagnetic radiation of frequency f will exhibit zero-resistance parts (constant-voltage steps) at voltages given by

$$V = nhf/2e$$

where n is an integer, h is Planck's constant, and e is the magnitude of the charge of an electron. The units of voltage are defined through the equation above by assigning a value ot $2e/h$. For the United States legal volt, V_{NBS}, the assigned value is $2e/h = 483\ 593.42\ \text{GHz}/V_{NBS}$; for the international volt, V_{69-B1}, the assigned value is $2e/h = 483\ 594.0\ \text{GHz}/V_{69-B1}$. In general, the ac Josephson effect is used periodically to determine the emf of a group of standard cells that then embody the unit of voltage between determinations.

A standard cell is made in two types: (1) the normal cell, containing a saturated cadmium sulfate solution; and (2) a type used as a working standard, in which the solution is less than saturated above 4°C. The saturated cell is the basic standard for maintaining the value of the volt, and is used in this manner in all national laboratories. Its rather high temperature coefficient must always be taken into account.

The emf of the unsaturated cell is within 1.0188 and 1.0198 abs volts, the exact voltage of each cell being established by comparison with the normal or saturated cell. This cell is a useful working standard because of its negligible temperature coefficient.

Electrochemical cells of the type described have a relatively high internal resistance and thus should be used under zero load conditions. The cells should not be short-circuited because several weeks may be required for full recovery of a stable reference voltage, i.e., if the cell has not been permanently damaged.

Highly precise reference signals are available from electronic standards, which employ temperature-compensated zener diodes. A wide variety of precision black box instruments, arranged for flexibility and convenience of use, is marketed.

Standard Resistors. The hermetically sealed, wire-wound one-ohm resistors designed by J.L. Thomas of then National Bureau of Standards are among the highest-quality resistance standards ever produced. The United States legal ohm, Ω_{NBS}, is the mean four-terminal resistance of a group of Thomas-type standard resistors immersed in oil at 25°C under a power dissipation of 0.01 watt. In the Thomas-type standard, the container is made of coaxial cylinders only slightly different in diameter with the space between the cylinders sealed. The resistance element (carefully annealed Manganin™ wire) is mounted in this space in good thermal contact with the smaller cylinder, which serves as the inner wall of the container.

A subgroup of five Thomas one-ohm resistors, together with resistors of different values and/or different design, are used as working standards at NIST. These standards enable calibrations to be made over a wide range in resistance values (10^{-4}–10^{15} ohms) and under conditions differing from those under which the legal unit is maintained. Examples of the latter are standard resistors especially designed for stable characteristics at very high currents.

Anatomy of Electrical Measuring Instruments. Although analog-type indicating instruments still are found on machines and in the laboratory, digitalization of circuitry and displays, permitting better readability and portability, created a sharp demand during the last few decades, and, as of the early 1990s, most catalogs featured the digital variety of meters. It is very helpful in understanding electrical measurements to review briefly the chronology of electrical measurement concepts.

Polarized Iron-Vane Mechanism

The polarized iron-vane system was the first current measuring mechanism to be reduced to practice. Originally dependent upon the earth's magnetic field to provide the control torque, it was later made both more sensitive and more convenient in use by the use of a permanent magnet. In the form shown in Fig. 2(e), the mechanism came into use in large quantities as an automobile dashboard ammeter. Better suited to mass production in relatively crude form than to greater refinement, this mechanism has lost its position in the field of electrical instruments and has, instead, made a place for itself in the "indicator" field where precision is not demanded.

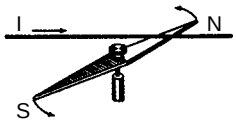
Moving Iron-Vane Mechanism

In an early magnetic vane mechanism of the suction type the opposing force or restoring torque is provided by gravity instead of the presently used conventional spring. This method was widely used in older instruments. All gravity-controlled instruments had the major disadvantage of being subject to serious position errors.

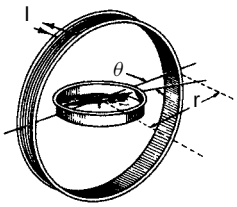
With reference to Fig. 3, if two similar adjacent iron bars are similarly magnetized, a repelling force is developed between them which tends to move them apart. In the moving iron vane mechanism, this principle is used by fixing one bar in space and pivoting the second so that it will tend to rotate when the magnetizing current flows. A spring attached to the moving vane opposes the motion of the vane and permits the scale to be calibrated in terms of the current flowing.

In the concentric vane mechanism shown in Fig. 4, vanes slip laterally under repulsion. This design has only moderate sensitivity and has square-law scale characteristics. The short magnetic vanes result in small direct-current reversal and residual magnetism errors. With this mechanism, it is also possible to shape the vanes to secure special characteristics, thereby opening the scale where needed.

The radial vane mechanism, shown in Fig. 5, opens up like a book under repulsion. Of the polarized iron-vane mechanisms, this is the most sensitive, has the most linear scale, and requires better design and better magnetic vanes for good grades of instruments. An aluminum damping



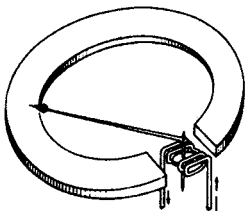
(**a**) The original electrical indicator—Oersted—1918



(**b**) Tangent Galvanometer.

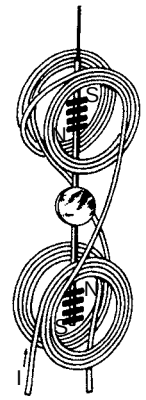
$I = \frac{10H}{2\pi N} \tan\theta$ amperes.

r = radius of coil.
H = horizontal component of earth's field in gauss.
N = number of turns



(**c**) Simple polarized iron vane mechanism. Pointer is driven by an iron vane governed by the resultant field of the permanent magnet and that of the current in the coil.

(**d**) Early type astatic galvanometer —Kelvin—1858. Used on early trans-Atlantic cable circuits. Note lower set of needles has reversed magnetic polarity from upper set, thus reducing the restoring force of the earth's field land increasing the sensitivity.



(**e**) Complete polarized iron vane mechanism. Soft iron core adds to sensitivity, requiring fewer turns of wire and improves scale characteristics. Weston prototype ——Model 354 (now obsolete).

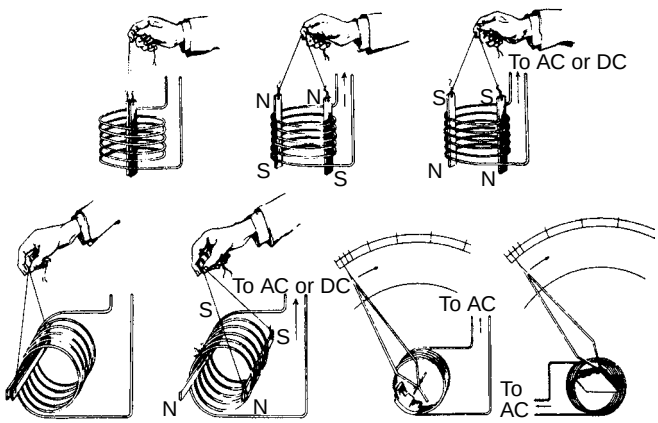

Fig. 3. Principle used in moving iron-vane mechanism.

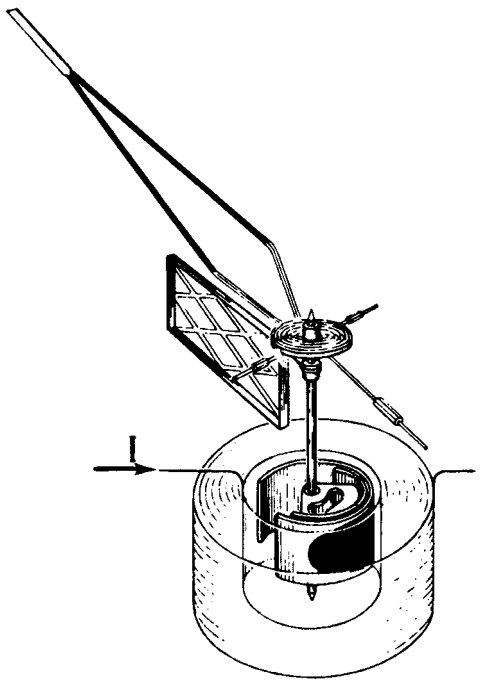

Fig. 4. Concentric vane mechanism.

vane, attached to the shaft just below the pointer, rotates in a close-fitting chamber to bring the pointer to rest quickly.

The Electrodynamic Mechanism

Electrodynamic mechanisms are the most fundamental of all of the indicating devices presently used. Form factor variations do not occur because of the complete absence of magnetic materials, such as iron, and the indications are of true RMS values. This mechanism is current sensitive — the pointer moves because of current flowing through turns of wire. It is the most versatile of all of the basic mechanisms since the single-coil movement can be used to indicate current, voltage, or power, ac or dc. Crossed-coil movements can be used for power factor, phase angle, frequency, and capacity measurements.

An early version of this basic principle was the current balance of Lord Kelvin (1883) and shown in Fig. 6.

Perhaps the most important use of this mechanism is as a transfer instrument between the basic standards of E, I, and R, all of which are defined for direct current only, to alternating current, in which form most of the power of the world is generated, sold, and used. The torque produced in the moving coil of an electrodynamic instrument is proportional to the product of the in-phase components of the currents in the field and moving coils; this mechanism measures products.

The electrodynamic mechanism used in wattmeters, voltmeters, and ammeters is shown in Fig. 7. With a longer pointer and other minor changes, the mechanism is used in a laboratory standard. With the further modification of crossed-moving coils, fundamentally the same mechanism is used for measurements of power factor, phase angle, and capacity. In this form or with crossed field coils, this mechanism measures a ratio by balancing two torques.

Damping vanes similar to those used in moving iron instruments (Figs. 4 and 5) rotate in close-fitting chambers and provide proper damping for the pointer motion. If two complete field coil systems are arranged one above the other, each including and acting upon its own moving coil, and if the two moving coils are attached to a common shaft which carries the pointer, the mechanism can be used to measure the total power in a polyphase A.C. system.

The Electrostatic Mechanism

The electrostatic mechanism resembles a variable condenser. Of all the mechanisms used for electrical indications, it is the only one that measures voltage directly rather than by the effect of current. The torque resulting

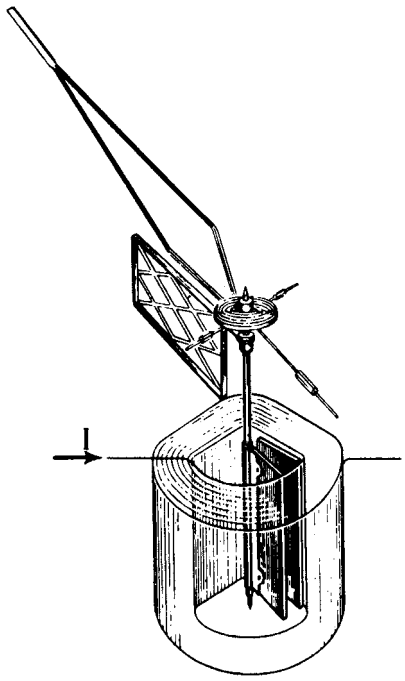

Fig. 5. Radial vane mechanism.

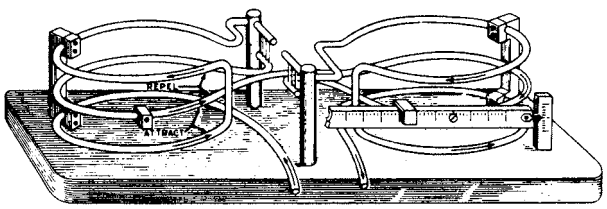

Fig. 6. Current balance of Lord Kelvin.

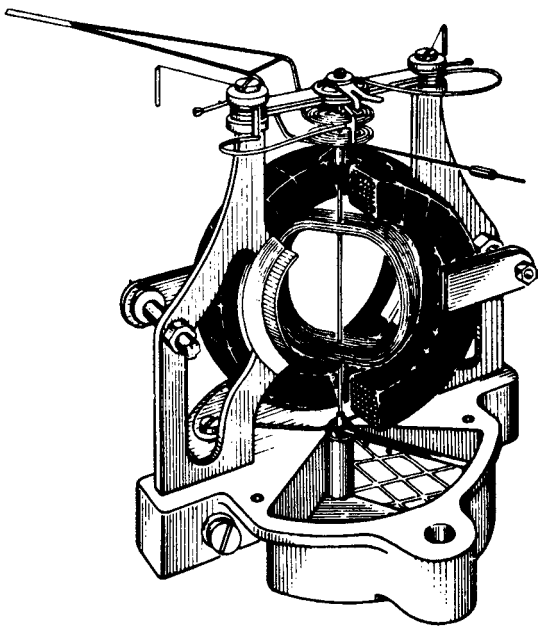

Fig. 7. Electrodynamic mechanism used in some voltmeters, ammeters, and wattmeters.

from the attraction between fixed and moveable plates is a function of the voltage between the plates, the plate area and, inversely, the distance between the plates. For greater sensitivity, this distance must be reduced, clearances permitting, or the plate area (and thus the weight) must be increased. Greater weight, in turn, calls for still greater plate area if a sufficient torque is to be developed to overcome pivot friction in most industrial applications. This limits the use of the instrument to certain special applications, particularly in ac currents of relatively high voltage, where the current taken by other mechanisms would result in erroneous indications. A protective resistor is used in series with the instrument to limit current flow in the event of a short between plates.

A gold leaf electroscope is shown in Fig. 8. Like charges on the ends of the leaf cause a separation of the ends. This is very sensitive as an indicator, but not characterized as an instrument per se. A form of the attracted-disk electroscope as devised by Sir William Snow Harris (1834) is shown in Fig. 9. Guard ring around the disk served to prevent nonuniformity in the electrostatic lines of force. A very large example of the attracted-disk electrometer mounted in a shielded cage and using quartz pillar supports is used at the National Bureau of Standards for voltage standardization up to 300,000 volts. Using this high voltage electrometer, the ratio of transformation of high voltage potential transformers has been checked for the first time by an independent method.

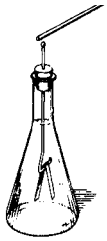

Fig. 8. Gold leaf electroscope.

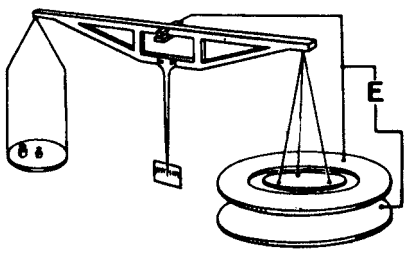

Fig. 9. Attracted-disk electroscope.

Figure 10 illustrates the principle of an early electrostatic mechanism devised by Lord Kelvin in 1887. Moving and fixed plates attract each other causing the moving plate to rotate against the torque of a control spring (not shown). Position of balance thus becomes a measure of the potential applied. In industrial form (Fig. 11), such instruments are made with multiple sets of plates in ranges from 150 to 3,500 volts.

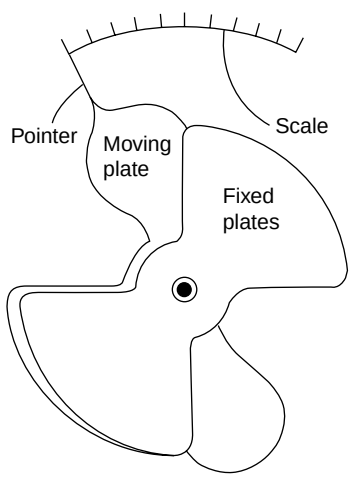

Fig. 10. Early electrostatic mechanism devised by Lord Kelvin.

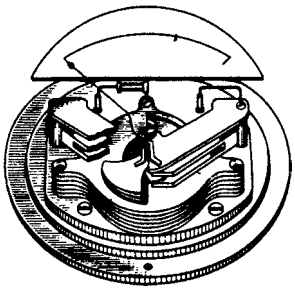

Fig. 11. Moving-and-fixed plate-type electrostatic instrument.

Permanent-Magnet Moving-Coil Mechanism

The design shown in Fig. 12 offers the largest magnet in a given space and is used where maximum flux in the air gap is required in order to provide an instrument of lowest possible power consumption.

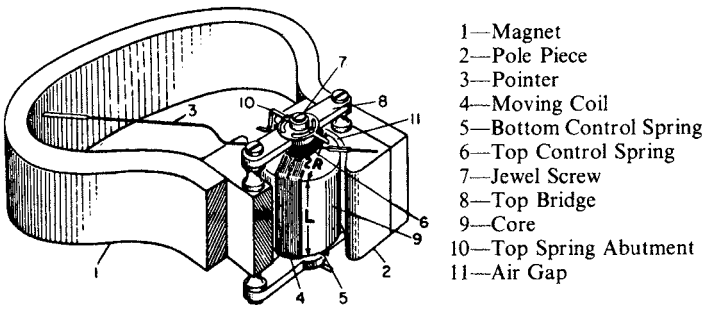

Fig. 12. Permanent-magnet moving-coil mechanism with external magnet.

With the advent of improved magnetic materials, it became practical to design a magnetic system in which the magnet serves as a core. Such magnets operate at their highest energy product with minimum lengths, thereby making the core magnet mechanism a practical reality. These mechanisms have the advantage of being relatively resistant to external magnetic fields, therefore allowing for the elimination of magnetic shunting effects in a panel or the need for magnetic shielding in the form of iron cases. See Fig. 13.

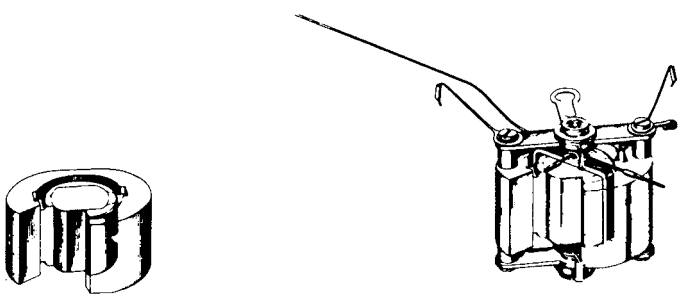

Fig. 13. Core magnet and moving-coil mechanism.

The advantage of the self-shielded feature makes the core magnet mechanism particularly useful for aircraft and aerospace applications, especially where a multiplicity of mechanisms must be mounted in close proximity to each other, as exemplified by cross-pointer indicators wherein as many as five mechanisms are mounted in one case to form a unified display.

End-Pivoted or Off-Center Coil Type. The end-pivoted permanent-magnet moving-coil mechanism is a variation of the more common center-pivoted type. In this arrangement, the coil rotates in a single air gap, allowing a full-scale deflection as high as 270°. The concept is not new. Meters of this type were made as far back as 1900, but with low magnetic flux and poor performance. An improved instrument has a scale deflection of 250°. The magnet extends into the soft iron core, thereby minimizing leakage flux and achieving a high flux density.

The off-center coil type is also used extensively in edgewise panel and aircraft meters. The deflection is usually limited to 60° or less with the magnetic flux concentrated over the smaller angle.

Taut-Band Instruments. The suspension type mechanism has been known for years. Until recently, the device was utilized for laboratory equipment where high sensitivities were required and available torques were extremely low so that it was desirable to eliminate even the low friction of pivots and jewels. The device had to be used in the upright position since the sag in the very low torque ligaments caused the moving system to come in contact with stationary members of the mechanism in any other position. The taut band instrument enables one to obtain the advantage of the absence of friction of ribbon suspension while also eliminating the sag by placing the ribbons under sufficient tension. This tension is provided by a tension spring so that the instrument can be used in any position. Generally speaking, taut band suspension instruments can be made with higher sensitivities than those using pivots and jewels and can be utilized in virtually every application which is presently served by pivoted instruments. See Fig. 14.

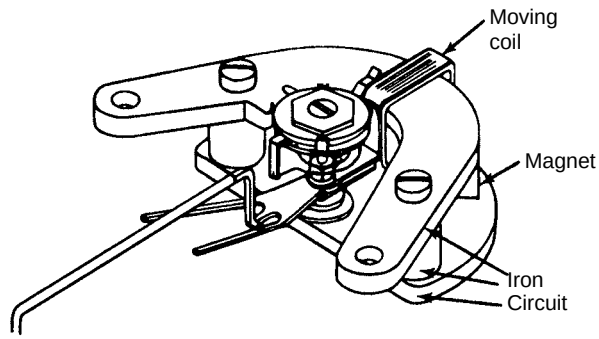

Fig. 14. Taut band suspension.

A permanent-magnet moving-coil mechanism is not insensitive to temperature by itself but may be made so by the appropriate use of proper series and shunt resistors of copper and manganin. Magnets and springs decrease in strength and copper increases in resistance with increase in temperature. The changes in the magnet and the copper tend to make the pointer read low on fixed voltage impressed, while the spring change tends to cause the pointer to read high. The effects are not identical, however, with the result that an uncompensated mechanism tends to read low by approximately 0.2% per degree centigrade. For purposes of specification an instrument is considered compensated when the change in accuracy due to 10 degrees change in temperature is not more than one-fourth of the total allowable error.

Wattmeters, thermal watt converters, watthour meters, power factor meters, var meters, and instrument transformers are described in the entry on **Electric Power and Energy Measurement**.

Check Alphabetical Index for other electrical instruments described in this Encyclopedia.

ELECTRICALLY SCANNING MICROWAVE RADIOMETER (ESMR). See **Nimbus Satellite Program**.

ELECTRICAL POWER QUALITY. Power quality has become a more important technology as new and more complex electrical and electronic equipment has entered society. High speed, micro-sized devices have made 60 cycle power a bull in a china closet. Along with this, the electronic equipment itself, has become the source of noise, spikes, and harmonics that are harmful to other equipment. Also radio frequency interference has become more of a nuisance. These problems present themselves in all segments of our society from industry to the home environment. Motors, panels, and transformers overheat, circuit breakers trip, computers lock up and their hard drives crash. Catastrophes occur such as, electric wheelchairs turning in the wrong direction, entire assembly lines stopping, and stock exchanges crashing.

Problems

The susceptibility of electronic equipment to certain problems can be shown by the ITIC (Information Technology Industry Council) voltage

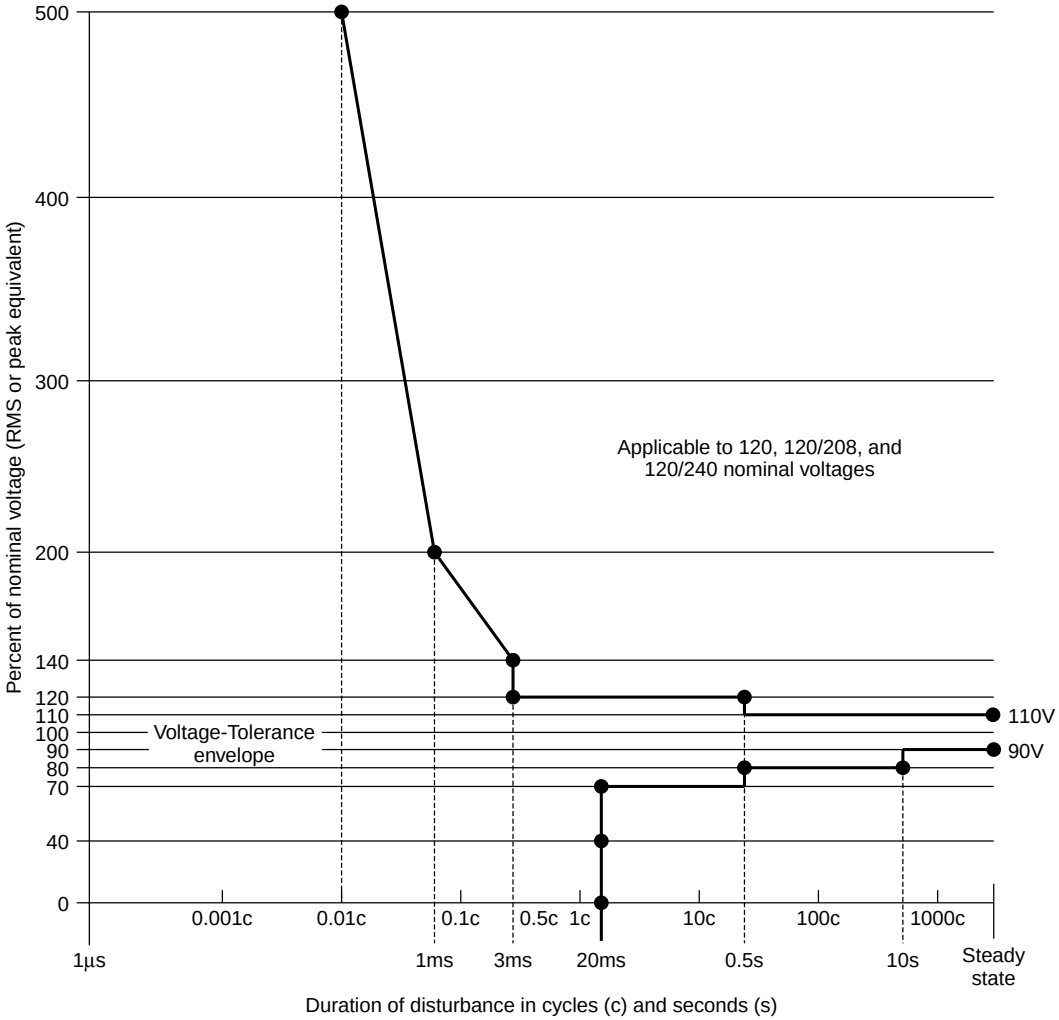

Fig. 1. ITIC Curve.

susceptibility curve. See Fig. 1. Problems could occur outside of this curve. The left part of the curve from 0 to about 1 cycle represents surges and transients caused primarily by lightning and switching of loads. The high voltage surge will deteriorate solid state components, and their high frequency component will capacitively couple across transformers to conductors carrying digital logic. The center part of the curve, from several cycles to about 60 cycles, represents momentary voltage sags and swells caused primarily by local starting loads and distant utility disturbances. This will cause the necessity to reset and reboot computers. The right side of the curve represents long term voltage drop or outages caused primarily by utility problems or heavy load usage.

Other problems for electronic equipment can come from noise, harmonics, and electrostatic discharge. Noise can come from radio frequency interference that can couple itself to electronic equipment anywhere that the equipment can act as an antenna, or it can come through the ground connections in the form of anything that the world can produce. Noise primarily affects signaling circuits and can couple itself capacitively or inductively, depending on circuit parameters ($Xc = 1/2\pi fC$, $XL = 2\pi fL$). Harmonics are multiple frequencies of the fundamental (60 cycles) and are produced primarily by nonlinear loads such as computer power supplies or electronic ballasts. Harmonics will overheat transformers and motors and will distort sine waves creating problems with circuit breakers and computer power supplies. Electrostatic discharge, or static, is caused by friction between different materials. The effect of static is similar to surges.

Solutions

Surge protection: The TVSS or Transient Voltage Surge Suppressor protects equipment from lightning and switching surges and is installed anywhere from the service entrance of a building on down to the load or protected equipment. They operate by using MOVs (metal oxide varistors). They are solid state devices that will conduct current at a certain voltage level placed across them. The voltage is determined by the gap distance between plates. The total amount of current or energy conducted is determined by the number of these devices in parallel. The best performance is obtained by networking the suppressors in three stages. A higher energy rated device would be located at the service entrance. The next device with a lower energy rating would be located at a distribution panel. The final line of defense would be a plug in device located at the equipment. The devices located within the building would also protect equipment from internally generated surges. The TVSS offers the most protection for the dollar and should be a part of most power distribution systems.

Isolation: The isolation transformer protects equipment from common mode (or ground) noise and electrical magnetic interference. Isolation transformers can be small units located at the equipment or they can be the distribution transformer used to feed panels or equipment rooms. They operate on the principal of isolation of transformer windings through an iron core, and have the added benefit of having a new ground established at the transformer. The performance of these transformers can be enhanced by the addition of shielding between windings for better isolation of noise and ferroresonant technology to offer voltage regulation, up to 1 cycle of power outage ride- through. A third coil can also be added that can cancel odd harmonic currents that are generated by power supplies or nonlinear loads. When surge suppression is added, this is sometimes called *Power Conditioning*. Isolation transformers are “middle of the road” in cost but can be very beneficial in areas with noisy or dirty power.

UPS systems: The Uninterruptible Power Supply can protect equipment from almost all power problems and is the state of the art in power protection. UPS’s serve the needs of the most critical loads and they are the most expensive protection. The UPS is one of the only systems to protect

against total power lose or brownouts. They come in many variations but the two basic types are the *on-line* and the *off-line* or *standby* UPS.

The *on-line* works as follows: A rectifier/charger is continually powered by the utility that charges a battery, which supplies an inverter, which supplies the load. The output is usually conditioned and isolated. The *on-line* is the most expensive and is used for the most critical applications. They range in size from about one KVA to about one MVA and can be paralleled for redundant protection.

The *off-line* works as follows: A rectifier/charger is continually powered by the utility that also feeds the load. The rectifier feeds a battery, which feeds an inverter, that is normally off. The load source is switched by a transfer switch when the utility is lost. The output is not usually conditioned or isolated. The *off-line* is the least expensive and is used on smaller loads. The transfer switch can also be a source of problems. If the *off-line* UPS has conditioning and isolation it is sometimes called a "Line Interactive" type.

Proper Electrical Distribution System Design and Wiring: By far the greatest cause of power quality problems lay in the distribution system itself. Some of the problems are as follows: Loose connections cause arcing noise. Sensitive equipment will be affected, if on the same circuit as noisy equipment such as copiers. Incorrect grounding methods, such as neutral to ground connections downstream of service location, or grounding electrodes at more than one location, will cause ground loop currents at the equipment. Data wires, run next to power circuits or fluorescent lights, will have noise inductively coupled to it. Equipment fed from panels having noise generating equipment connected to it, such as welders and motors will generate voltage drops and noise. High ground resistance (above 25 ohms) to ground at building grounding electrode will cause common mode noise from outside of building to find paths to ground inside of building.

As computers and electronic equipment become more complex, then more complexity is required to protect the equipment. The protection is never perfect and it becomes a matter of how much money one wants to spend. If problems are life threatening or equipment shutdown will cost millions of dollars, then the amount of money spent does not matter.

Times have changed since the advent of computers. As one rural utility supervisor pointed out, it used to be that the power would go off and it would take an hour before the telephone would start ringing, but today, if there is just a power flicker, the phones will start ringing off the hook.

ELECTRICAL STORM. 1. Popular term for thunderstorm.

2. Sometimes applied to a relatively rare condition of disturbed atmospheric electric field in the lower atmosphere that arises when strong winds are blowing and much dust is in the air, but there is no thunderstorm activity.

Triboelectrification due to the blowing dust may charge fences and other metallic objects to such an extent that slight shocks are felt upon touch.

ELECTRIC CARS. The tempo of research and development engineering for mass production of battery-operated highway vehicles has undergone a marked increase during the past decade. Experts in the field have predicted that substantial numbers of electric cars will be registered as early as 1998 and that these cars will constitute 5% of all cars on the road in the United States, and of other advanced countries of the world, by the early years of the twenty-first century. Electric cars will reduce air pollution, particularly troublesome in large metropolitan areas, and ultimately will dramatically reduce the petroleum consumption demanded by internal combustion engines.[1] Although trial runs of car and truck fleets have been conducted for several years, to date these have been essentially regarded by the general public as curiosities. Although much further progress in battery and power train design is required to build and market electric vehicles to attract buyers, some professional people in the field believed that the mid-1990s and following years would witness a marked increase in public interest and certainly of awareness.

A Matter of Energy Balance. A key objective in designing the power package for an electrically powered vehicle has been that of finding a *high-density* power source, coupled with the objective of creating *zero emissions* into the atmosphere. The energy density problem is well illustrated by the case of using lead–acid batteries. A 20-gallon (75.7-liter) tank of gasoline can provide about 2.4 million Btu (0.6 million Calories). Lead-acid storage batteries, weighing about the same as that quantity of gasoline, can provide only about 7700 Btu (1940 Calories), or about $2\frac{1}{4}$ kilowatt-hours. The ratio of energy in a tank of gasoline to the energy in the same weight of conventional storage batteries (before they are fully discharged) is more than 300 to 1. However, an automobile engine can convert only about 20% of the energy in the gasoline into driving power, while the electric motor can produce motive effort from nearly all of the electricity delivered by a battery. This reduced the margin to 60 to 1, still a very marked disadvantage for lead-acid batteries as compared with the internal combustion engine.

Prior to briefly describing current battery research, it is in order here to review the lead-acid battery situation further — because there are parallels even though, with the more promising batteries, the situation becomes much more favorable for the battery power source. If it is first assumed that lead-acid batteries are used to power passenger cars, experience indicates that an electric car in city traffic at speeds up to 35 miles (56 kilometers) per hour uses about $\frac{1}{4}$ kilowatt-hour per 10 miles (16 kilometers) traveled. If it is further assumed that the car weighs 3000 pounds (1361 kilograms), half of that weight must be allowed for the battery. The very best lead-acid batteries currently available can deliver 15 watt-hours per pound if discharged over 20 hours. Thus, the battery can deliver, at the maximum, 22.5 kilowatt-hours. However, the battery will be discharged over a 1- to 2-hour period and thus its capacity will be about halved. Thus, the useful available output at most will be 11 kilowatt-hours from a 1500-pound (680-kilogram) battery pack. Inasmuch as the car is assumed to weigh $1\frac{1}{2}$ tons (1361 kilograms), thereby using 0.375 kilowatt-hour per mile, the car will have a maximum range of 30 miles (48 kilometers) at 35 miles (56 kilometers) per hour with a fully charged battery. If, instead of 35 miles (56 kilometers) per hour, the operator elects to travel at 55 miles (88 kilometers) per hour, the range would be cut in half, or approximately 12 to 15 miles (19 to 24 kilometers) per charge.

The foregoing model depends upon certain assumptions that, through the use of available lighter materials of construction and improvements in motor and drive systems now underway, can improve the case of the battery somewhat. But, needless to say, the internal combustion engine trips the energy balance by a wide margin. Thus, in connection with new battery designs, energy density is a major design target.

Battery Types. Batteries with several differing components for their cells currently are under intense study. They range in the degree of perfection attained to date.

Lead–Acid Battery. It is of interest to note that General Motors (GM) selected a pack of 32 lead–acid batteries for the power supply of the Impact car announced in late 1991. It is claimed that this car, equipped with two 57-horsepower alternating current motors can achieve a top speed of 100 mph (161 kph), but is equipped with a governor to limit its speed to 75 mph (121 kph). The vehicle is claimed to accelerate from 0 to 60 mph (97 kph) in 8 seconds. The two motors, operating together, develop 114 HP at 6600 rpm. A range of 120 mi (129 km) is estimated. Details on lead–acid battery are given in the article on **Battery**.

Nickel–Iron Battery. Although the Ni-Fe battery dates back to Edison, who first constructed it, the battery has not been mass-produced and, consequently for use in electric autos, much more manufacturing experience will be required. The battery was used in U.S. Navy submarines for a number of years prior to nuclear power. One negative factor is that it produces hydrogen gas, which is explosive at certain air-gas ratios. Engineers inclined toward the Ni-Fe battery are impressed by its ruggedness, and they project that the battery would last for the whole life span of a vehicle. It is reported that Chrysler, in cooperation with EPRI (Electric Power Research Institute), is designing a van to be powered by 30 such batteries having a total weight of 1800 lb (816 kg). The Ni–Fe battery features 50% more energy density than its lead–acid counterpart.

[1] This observation immediately poses the question, "Since fuel is required to create the electricity that will charge the batteries of electric cars, will this not simply increase the petroleum consumption of the electric generating plants?" There will be increased need for electric power, but power plants do not depend heavily (6–7%) on petroleum to fuel their boilers, whereas the internal combustion engines of autos consume some 63% of total petroleum in the United States.

Nickel–Cadmium Battery. The Ni Cd battery has enjoyed some favor among European car manufacturers, such as Volkswagen and Mercedes-Benz in Germany. Mercedes is testing six Ni Cd powered 190 models. BMW has built ten battery-powered model 320s.

Lithium Alloy–Metal Sulfide Battery. This battery, a cross section of which is shown in Fig. 1, is based on a relatively simple and safe technology that has made it attractive in the past for use in military equipment and other products for which performance and reliability are critical. The battery has a specific energy capability of 100 watthours/kilogram. This represents a tripling of the range estimated for vehicles that use improved lead–acid types.

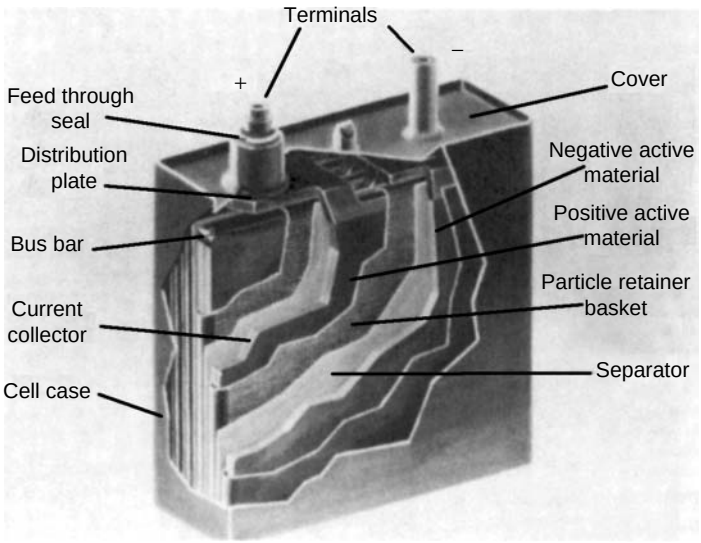

Fig. 1. Lithium alloy/metal sulfide cell in late stage of development and testing in the late 1980s. This is one of several new battery designs considered to have excellent potential for use in the electrical vehicles of the future. (*Electric Power Research Institute*.)

Sodium–Sulfur Battery. A Ford Aerostar has been converted to battery power through the use of sodium–sulfur batteries that provide about three times the range of lead–acid batteries of the same weight. One negative factor is that these batteries must be maintained at very high temperature, estimated at about 600 °F (316 °C) for maximum efficiency. It is claimed that normal driving and charging activities keep the batteries at that temperature. An additional negative is their inoperability after about three days of no use, thus creating problems in connection with long-term parking. Designers are attempting to overcome permanent chemical changes that may occur when the batteries are cold. It has been reported that 100 sodium-sulfur equipped European Escort vans, with a top speed of 70 mph (113 kph), will be tested soon.

Comparison of Battery Performance. A rough comparison of performance estimates is given as follows:

Lead–Acid	Up to 1000 charges	250 mi	(400 km) range
Nickel–Iron	1100	300	480
Nickel–Cadmium	2000	325	525
Lithium–Aluminum/ Iron sulfide	600	470	755
Sodium–Sulfur	600	500	800
Lithium–Aluminum/ Iron Disulfide	600	680	1095
Lithium polymer	700	740	1190

Power Trains. Much research is being directed toward improving the power trains of electric vehicles. These divide between the use of alternating current and direct current motors. One AC program involves the use of an advanced power transistor and integrated circuit technology. It has been claimed by some researchers to be superior to DC systems and competitive with other AC systems in cost, weight, and performance. In an electric van fleet tested, the AC power train, when compared with superior DC power trains, showed a decrease in initial costs by about 5% and increased driving range by about 10%.

Battery-charging Methodologies. Several schemes have been suggested pertaining to how the electric car user will be able to retain a sufficient charge in the batteries to assure reasonable usage of the vehicle. The charging problem related to city driving, short-distance commuting, and the like is much simpler than for traveling long distances. For the former, it has been proposed that the user would maintain a charging facility in the residence and recharge the batteries during periods of low, general power consumption, a desirable off-peak situation for the utilities. Or, during the day, charging facilities would be available at the office building or factory, wherever the user works during the day. For long trips, it has been suggested that there would be charging stations along the highway, probably facilities added on to the normal service station that dispenses gasoline and diesel fuel. The other major battery recharging problem is designing a perfectly safe system that can be used in all kinds of weather, and, of course, a system that would charge the batteries quickly.

Not much has been said recently, but another system would exchange a fully charged battery for one that needs charging. This approach would require an additional design problem for the car manufacturer.

General Motors has announced a proprietary "inductive coupler" charging unit that is claimed to be safe and economic for "fueling" electric vehicles. With the Hughes-developed system, it is claimed that drivers will be able to recharge their vehicles simply by inserting a 5-inch (12.7-cm) round, plastic-covered paddle into a slot in the car. The system "transfers electricity through a magnetic field rather than a direct metal plug-to-metal socket connection. A spokesman for the firm has stated that the car's charging system can be accomplished safely and without fear of shock in rain and very moist conditions.

Hybrid Systems. A typical hybrid vehicle is equipped with a small generator that is powered by a small internal combustion engine. This engine-generator, which provides the vehicle's average power requirement, lengthens the mileage over which the battery's energy is expended. Coupled with any of the newer battery designs, the engine-generator concept could provide a cost-effective way to increase vehicle range when long-distance travel is occasionally needed. Routine, shorter-range travel would be powered by the propulsion battery alone.

Incentives and Projects. Although car manufacturers have displayed numerous earnest efforts to develop an electrically powered vehicle that will attract buyers, an underlying incentive is legislative. This is exemplified by a current law on the books in California, which requires any auto maker selling more than 5000 cars annually, commencing in 1988, to include within the total at least 2% of "no emissions" vehicles. Progress has been made with solar-powered vehicles, but the technology would be far short in targeting for such an early deadline. Hydrogen-fueled systems (which emit water vapor only) will require development extending well into the next century. Thus, the battery-operated vehicle is the only viable candidate in view.

Most of the research in this field has been conducted by the large auto makers in the United States, Japan, and Europe, battery manufacturers, and universities working on grants. Most vehicle makers have supplemented their central research in recent years with impressive electronics capabilities, which include programs for developing electric vehicles. Because batteries require electric power for their maintenance, some of the electric utilities also have been active in the electric vehicle area. For example, EPRI (Electric Power Research Institute), an organization sponsored by over a hundred electric utilities in the United States, has included in its recent annual research budgets over $1500 million for research on batteries and their infrastructure. The goal: "In cooperation with the auto and utility industries, focus on developing batteries and infrastructure that could result in the development of more than 2 million electric vehicles by 2002, with an intermediate step that could deploy over 200,000 electric vehicles by 1998." If fully developed, this will result in electric power sales increases of 10 billion kilowatt hours/year; a carbon dioxide (CO_2) reduction of 220,000 tons/year; a nitrogen oxides (NO_x) reduction of 37,000 tons/year; a carbon monoxide (CO) reduction of 8 million tons/year; and a volatile organic compounds (VOC) reduction of 22,000 tons/year.

Long-Term Potential. Among many other concepts for improved urban and suburban travel of the future is the Electrified Roadway. These roadways would be suitable for use with electric cars, trucks, and buses. An electric cable buried beneath the road surface would provide electricity through inductive coupling to a pickup on the vehicle. This would simultaneously propel the vehicle and charge its battery. Automated vehicle

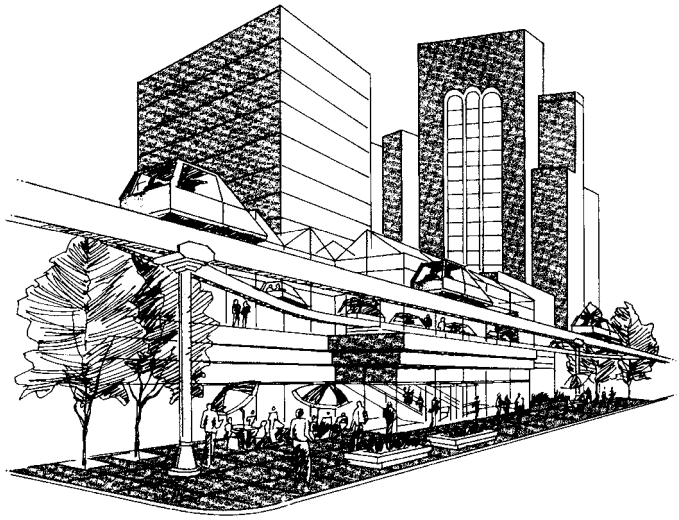

Fig. 2. Personal rapid transit system designed as an alternative to private automobiles. A test segment of the system is scheduled for testing in a midwestern city in the United States during the late 1980s. (*Electric Power Research Institute*.)

Fig. 3. The Electrified Roadway concept is scheduled for testing in a West Coast city prior to 1990. Shown here is a prototype bus that will operate over a one-mile segment of electrified road. The propulsion battery is designed to be recharged as the bus travels over the electrified road segment. This will enable the bus to operate all day on both electrified and nonelectrified segments of the proposed three-mile route. (*Electric Power Research Institute*.)

control schemes could also be integrated into the electrified roadway system. See Figs. 2 and 3.

Historical Perspective. Records show that 1575 electric automobiles were built in the United States in the year 1900, while only 939 cars equipped with gasoline engines were manufactured. The feasibility of the electric car was established well over eight decades ago. Electric automobiles were particularly popular with women during the early part of this century because of the difficulty in starting piston engines with a crank (prior to the self-starter). See Fig. 4. Coupled with gross improvements in gasoline-powered engines, the self-starter eclipsed the future of the electric car for many years. By 1930, the electric automobile was largely regarded as a museum piece. The principle of electric propulsion has been applied over the years and to the present, however, in the form of hundreds of thousands of electric trucks, fork lifts, etc. used in numerous materials handling operations. Because these off-road vehicles operate at low speeds and frequently only during one shift out of 24 hours, the standard lead-acid storage battery was adequate.

ELECTRIC CIRCUITS. Electric charges, at rest and/or in motion, are the fundamental sources of electric and magnetic fields. Broadly speaking, there are three more or less distinct situations involving the

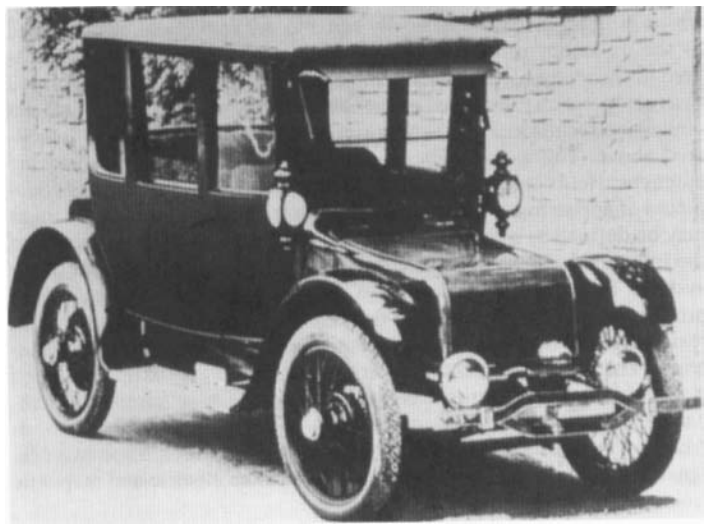

Fig. 4. The concept of the electric automobile dates back many years. Vehicle shown here was popular during the early part of the 20th century. Electrical vehicles offer numerous advantages in terms of economy, reduced air pollution, lower cost of maintenance, and longer useful life — provided that battery and powertrain improvements presently underway can be achieved. Among other programs, as of the late 1980s, a fleet of GM Griffon electric vans is undergoing tests in selected regions of North America. (*Electric Power Research Institute*.)

spatial distribution of the fields produced by distributions of charge and current. Many important instances arise where these fields are distributed throughout a region of space of vast extent and differ accordingly at separated points in the region. The fields produced by a radio antenna come under this category. On the other hand, important applications are made of devices in which the electric and magnetic fields are confined to a much more limited region of space although the fields still undergo a significant variation in magnitude from point to point throughout the region. A transmission line connecting a television antenna on a roof to its associated receiver is an example of this type of situation. Here the fields are confined to the immediate vicinity of the line conductors but the fields vary significantly as one moves along the line. Finally, however, there are applications utilizing pieces of apparatus in which the electric and magnetic fields are confined to regions of space so restricted in spatial extent that one may speak of an electric or magnetic field as having an essentially constant value, in the immediate region of the device, that is very much greater than at all other points of space. As an example, it is noted that if a large number of turns is wound on a small circular core to form an inductance through which a direct current passes, a magnetic field will be created which is concentrated in the immediate vicinity of the coil and vanishes rapidly as one recedes from this location.

It is found, however, that when one deals with changing currents (charges in motion with varying velocity), the spatial dimension alone is not an adequate measure to establish which of the three situations suggested above is involved in a particular application. For sinusoidally varying currents one can define a quantity known as the wavelength which in free space is numerically equal to the velocity of light divided by the frequency of the sinusoidal variation. If spatial extent is measured in wavelengths, then an assemblage of apparatus which is confined to a region which is less than about one tenth of a wavelength in greatest dimension results in a good approximation to the third situation considered above. This possibility, one in which the electric fields and the magnetic fields may be considered to be concentrated in individual pieces of apparatus, is the domain of electric circuits. An electric circuit may be defined as a characterization of an electrical system in terms of the integrated effects of the electric and magnetic fields present in the system. The characterization is an approximation to the actual field problem in which one replaces the actual system by elements having resistance, capacitance, and inductance and by sources of electric potential and electric current. Systems in which the approximation cited is permissible are sometimes called “lumped constant” circuits. Antennas and transmission lines, on the other hand, are often referred to as “distributed constant” circuits. The distinction between these two designations comes from the spatial variation of the electric and magnetic fields as outlined above.

As may be inferred from their definitions, the parameters of resistance, capacitance, and inductance are not necessarily independent of the currents and voltages impressed upon the elements of an electrical system. Whether the resistance of an element is a function of the current through it or not, the relation $e = Ri$ (R is resistance in ohms) is still valid for the connection between the voltage across an element and the current through it. On the other hand, corresponding relations for the coil and the capacitor become more involved if their parameters are dependent on current or voltage. For constant parameters of inductance (L in henrys) and capacitance (C in farads), the voltages and currents in pure inductive and capacitive components assume the form

$$e = L\frac{di}{dt} \text{ or } i = \frac{1}{L}\int e\,dt$$

and

$$i = C\frac{de}{dt} \text{ or } e = \frac{1}{C}\int i\,dt$$

respectively. If the parameters $L$and Cvary with impressed voltage and current, the above relations are not valid and recourse must be made to the basic law of electromagnetic induction when coils are involved and to the expression for electric current as the rate of change of charge (derivative of charge with respect to time) for circuits containing capacitors.

Whether elements with constant or variable parameters are involved, one may employ Kirchhoff's Laws of Networks to formulate equations representing conditions of equilibrium between the applied voltages and/or currents and the quantities that result. See also **Kirchhoff Laws of Networks**. The equilibrium equations may be formulated on the basis of voltages as independent variables and currents as dependent quantities, the system of equations being known as the mesh equations for the circuit. Alternatively, they may be written on the nodal basis, where the sources are current generators and the dependent quantities are nodal voltage differences with respect to a reference node. As an example of the process involved, consider the simple series circuit shown in Fig. 1 and the simple parallel circuit shown in Fig. 2. The single mesh equation characterizing the series circuit and the single nodal equation describing equilibrium in the parallel circuit are, respectively

$$E(t) = Ri(t) + L\frac{di(t)}{dt} + \frac{1}{C}\int i(t)\,dt$$

and

$$I(t) = \frac{1}{R}e(t) + \frac{1}{L}\int e(t)\,dt + C\frac{de(t)}{dt}$$

The mesh and nodal equations for more complicated circuits have a form similar to these equations with added dependent variable terms and, in general, additional independent variable terms. The equations may be solved by various mathematical means to yield the desired unknown quantities, currents for mesh equations and voltages for nodal equations.

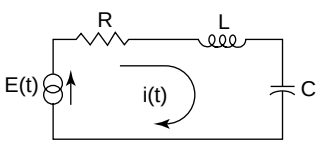

Fig. 1. Simple series circuit.

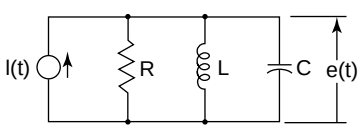

Fig. 2. Simple parallel circuit.

If the applied voltage sources are batteries or alternative sources of electric potential which are constant with time, the solution to the network equations described above will consist of constant terms (including zero as a special case) plus terms which decay exponentially with time. The latter terms are called the transient terms or the transient solution. They correspond to the solution of the homogeneous differential equations. The constant terms represent the steady state solution of the problem. These particular solutions may be obtained by the means that are considered in the section on Direct-Current Circuits where only networks of pure resistances are involved. (In the computation of the steady state response for circuits with constant potential applied, inductors may be replaced by elements of zero resistance and capacitors by resistors of infinite resistance.)

ELECTRIC CLOCK. A clock that employs electric current. Most automobile clocks use current from a battery to automatically rewind a mainspring. In other electric clocks, the mainspring is usually eliminated — the battery current driving the balance wheel through electromechanical contacts. An early line-current system used an auxiliary mainspring that was kept fully wound by the current for use should the line power fail. Later, a synchronous motor controlled by alternating current replaced the balance-wheel system in electric plug-in clocks.

Other types of electric clocks represent developments of the pendulum. See also **Pendulum Clock**. An electromechanically driven pendulum system, developed in 1843 by Alexander Bain in Scotland, was probably the first electric clock. At a considerably later date, the so-called Western Union clock used two 1.5-volt cells to wind a mainspring that maintained a pendulum while accepting an hourly time-pulse signal by telegraph line to synchronize its time display on the hour with a remote master clock system. The time-pulse signal, in effect, corrected for accumulated errors from all sources.

The later consumer cordless electric clocks use a 1.5-volt dry cell to drive the balance wheel electromagnetically, by means of an electronic circuit. By utilizing a transistorized electronic circuit as a switch to drive the balance wheel equipped with a tiny magnet, these clocks eliminate electromechanical contacts. In another clock, the frequency standard is an electromagnetically driven 360-Hz tuning fork, powered by a single aspirin-size 1.3-volt mercury oxide cell. An electronic control circuit is required to drive the tuning fork. The accuracy of this clock averages plus-or-minus two seconds a day. If three tuning fork systems are electrically interconnected, as in a marine navigation clock, the daily deviation in rate drops to less than one second. See also **Tuning Fork**.

In the United States, plug-in electric clocks usually use self-starting shaded-pole synchronous motors, controlled by the 60-cycle alternating line current. Their accuracy, therefore, is dependent upon the line frequency. Throughout the United States, however, line frequency is normally both properly stabilized and corrected several times daily, eliminating accumulated error and permitting an accuracy of up to plus-or-minus four seconds. Where line frequency is not corrected at least once a day, the resulting error displayed by plug-in electric clocks can be far greater. In many locations elsewhere in the world, where line voltage is not normally stabilized, plug-in clocks are less reliable. Where power line shutoffs are routine or frequent, plug-in clocks can represent a major inconvenience.

During the last few decades, the cost of manufacturing timing mechanisms has been reduced drastically. This has been coupled with the availability of very low cost crystal oscillators. A majority of table-top clocks today feature digital readouts, plus additional features for alarming. Even though these instruments do not depend upon line frequency, some models require power line current. Others utilize battery power. For those instruments, depending on power line current, power interruptions are a very serious source of inconvenience because loss of power for even a fraction of a second will require resetting. Most instruments are equipped to "blink" to indicate that the line source has been interrupted and that resetting is needed. A combination of line and battery power can eliminate the foregoing inconvenience when there is a power line interruption. Table-top electric clocks commonly are offered as a clock-radio combination. See also **Clocks**.

ELECTRIC DIPOLE. A pair of equal and opposite charges an infinitesimal distance apart.

In electromagnetics, the term dipole is often applied to two equal and opposite oscillating charges an infinitesimal distance apart; in this sense, it is synonymous with an electric-current element.

ELECTRIC DISCHARGE. The flow of electricity through a gas, resulting in the emission of radiation that is characteristic of the gas and of the intensity of the current. Also called *discharge, gaseous electric discharge*, or *gaseous discharge*.

ELECTRIC EEL. See **Gymnotid Eels**.

ELECTRIC FEEDBACK. In magnetic amplifier terminology, feedback through an electrically conductive network, as differentiated from feedback produced by currents in windings having coupling to the control windings (magnetic feedback).

ELECTRIC FIELD. 1. A vector field, usually denoted by **E**, defined as follows: at a given time and at each point in space the force experienced by a positive charge (sometimes called a test charge) at that point divided by the magnitude of the charge, taken to be sufficiently small that it does not affect the positions and velocities of all other charges. The set of all vectors thus obtained is the electric field, although this term is often used for its value at any given point. The magnitude of the vector is the electric field intensity and the direction of the vector is parallel to the lines of force.

2. Same as electric field strength.

ELECTRIC FIELD STRENGTH. The magnitude of the electric field vector. This term is sometimes called the electric field intensity, but such use of the word intensity is deprecated in favor of field strength, since intensity connotes power in optics and radiation.

ELECTRIC FIELD VECTOR. At a point in an electric field, the force on a stationary positive charge per unit charge. Under conditions in which the ratio of force to charge is not constant, the field vector is defined as the limit of the ratio as the change approaches zero. This may be measured in newtons per coulomb, in volts per meter or in corresponding units in systems other than the mksa system.

ELECTRIC FLUX DENSITY. At a point, the vector whose magnitude is equal to the charge per unit area which would appear on one face of a thin metal plate introduced in the electric field at the point and so oriented that this charge is a maximum. The vector is normal to the plate from the negative to the positive face. The term electric displacement density or electric displacement is also in use for this term. In an isotropic medium of permittivity $\in$, the flux density is $D = \in E$ is rationalized mks units, where **E** is the electric field vector.

ELECTRIC INDUCTION. See **Induction (Electric/Magnetic)**.

ELECTRICITY. An isolated atom consists of a small nucleus, itself composed of protons and neutrons, surrounded by a cloud of electrons. The proton and the electron are the ultimate stable particles of electricity. Their charges are equal and opposite, the proton being regarded, by convention, as positive. A normal atom with its full complement of electrons is thus uncharged.

Electrostatic phenomena arise when bodies (or parts of bodies) have an excess of electrons or protons, a state usually produced by transferring electrons, e.g., by means of a battery or by rubbing two dissimilar materials together. Between two positively charged bodies (or two negatively charged ones) there is a repulsive force; between positive and negatively charged ones, an attractive force.

If two bodies at different potentials are connected by a conductor, such as a metal wire in which there are free electrons, the electrons in the wire drift under the influence of the electric field. Such movement of electrical charges gives rise to further phenomena and we speak of an electric current. The current may be one of electrons only, as in a metal, in semiconductors, or in electron tubes. Or the current may be of positive nuclei, as in an isotope separator; or of both positive and negative charges, as in the conduction by ions (atoms that have gained or lost an electron) in liquids or in gaseous electrical discharges.

Electrons flowing in the positive direction give rise, by our convention of signs, to a negative current. In a metal, semiconductor, or conducting liquid, the velocity at which the electrons or ions drift is quite slow, less than one centimeter per second even for current densities in a metal as high as 10^4 amperes per square centimeter. In vacuum devices, such as cathode-ray tubes, the speed of the electrons approaches that of light. If a wire joins two electrostatic charges, the current persists for a short time only, but it may be maintained by means of some source of energy, such as a battery, a generator, a thermocouple, or a solar photoelectric cell.

When a current flows under the influence of a potential difference, the moving charges — electrons in metals, ions in solution — are impeded by collision with the atoms in the conducting metal or liquid. The charges give up to the atoms the energy they acquired as they moved in the electric field, and electrical power is converted into other forms — for instance, into heat in the case of a metal wire. Electric fields are also produced by time-changing magnetic fields, and this principle is extensively exploited, as is motional electromotive force (emf) to generate electric power. Electromotive force and voltage drop are usually regarded as synonymous. When an emf is impressed on a closed metallic circuit, current results.

The electrification of amber by rubbing with wool or fur was observed many centuries ago. Not until the work of Volta, late in the eighteenth century, was electricity recognized through any but electrostatic phenomena, and investigations on the properties and applications of electric currents, were among the most brilliant features of nineteenth-century physics. Even in the 1890s physicists were still asking, "What is electricity?" It had then long been known that an appropriate application of energy will separate electricity into two components, designated as positive and negative; that bodies charged with these components attract each other; and that the energy of separation is yielded upon the reunion of the two components. It remained for J.J. Thomson to recognize the electron, and for the subsequent analysis of atomic structure to identify the proton, and to explain their relations.

Hundreds of entries in this volume deal with electrical fundamentals, equipment, and applications.

ELECTRIC LENGTH. The physical length of a transmission line or its equivalent, corrected for any nonhomogeneities that may affect the speed of propagation, and expressed in wavelengths, radians, or degrees.

ELECTRIC MOTOR. See **Motor (Electric)**.

ELECTRIC POTENTIAL. The electric potential at a point is the work done in moving a unit positive charge from the datum point (sometimes at an infinite distance from the region of interest) to the point in question. The earth's surface has also been used as the datum of potential. From the definition, it can be seen that the potential at the datum is zero. The unit of potential is the volt. The difference of potential between two points is the work done in moving a point charge from the first point to the second. It is equal to the difference in the values of the potentials at the respective points.

ELECTRIC POWER. Electric power is the product of electric current and electromotive force; that is, multiplication of current flowing by voltage forms the basis of the calculation of electric power. In a DC circuit, the current measured in amperes, multiplied by the voltage between wires, is the power in watts. A thousand watts constitute the kilowatt, a larger and more frequently employed unit of electric power.

The voltage and current may not be in phase with each other in an A.C. circuit and, while the instantaneous power is the product of the instantaneous voltage and current, this out-of-phase relation causes the power to fluctuate between positive and negative values. Hence for the average power (which is usually what is desired) this factor needs to be taken into account in determining electric power is an AC circuit, for it is only that component of the current which is in phase with the voltage that contributes to the average electrical power. The out-of-phase component produces the "wattless power." The power factor measures the fraction of the current that is in phase and available for true power. It is equal to the cosine of the phase difference between voltage and current. In a single-phase ac circuit having current of I amperes, voltage of E volts, and power factor f, the true power is EIf watts. In a balanced three-phase circuit, it is $\sqrt{3}EIf$ watts.

ELECTRIC POWER AND ENERGY MEASUREMENT. Over the years, the term *power*, in association with electricity, has tended to lose its true meaning. Thus, *power* is often found used in nontechnical literature where actually the correct term energy should be used. By definition, power is the rate at which energy is transformed or made available and is measured in *watts*. Energy may be defined as the time integral of power, or as the total energy supplied and is measured in *watt-hours*.

From an economic viewpoint, the most important of all electrical measurements is the measurement of energy. The watt-hour meter in various

forms can be found in nearly every home, factory, highway billboard, and other locations where electrical energy is being purchased. Metering, installation and wiring have been governed by national, industrial, and local codes for so many years that at least in the United States, a particular type of installation is nearly identical everywhere.

For homes or small stores where energy demand is low and fractional horsepower motors are used, the common supply is single-phase, 3-wire. Two voltage levels are available, 120 and 240 volts, depending upon which pair of wires is selected. Electric ranges and heavy-duty home air conditioner motors can take advantage of the high voltage to reduce line currents, which reduces losses and permit smaller-size wiring.

Measurement of energy is almost always by means of fixed-installation metering. This provides safety through grounding of the meter enclosure and ease of reading through proper location and mounting. Tamperproof housings, which are also weatherproof where necessary, are common practice to insure the integrity of readings.

On the other hand, the measurement of power (watts) follows no such set of rigid rules. Very often considerable planning must go into a watt measurement to properly use existing metering or to purchase new equipment so that the test will be valid and results will be within the expected accuracy limits.

Whereas the measurement of energy is almost entirely restricted to 60 Hz, power measurements range from direct current to alternating current, including distorted waves, chopped waves, and missing pulses. A variety of circuits for connecting wattmeters to single-phase and poly-phase systems have been developed over the years. Basic connection diagrams appear in many electrical engineering textbooks. However, the user of a wattmeter is hard pressed to find diagrams covering practical or unusual situations. Wattmeter manufacturers usually offer an instruction book or a bound set of connection diagrams with their instruments. Basic wattmeter connection diagrams appear later in this article.

Power Theory. Since energy is simply the total power over a time period, an understanding of the power equations will provide some background into both power and energy terminology. A direct current circuit under steady-state conditions will produce power, computed as the production of the voltage across the circuit and the current in amperes in the circuit. This will also apply to alternating current circuits as long as instantaneous values of volts and amperes are used. The product of volts and amperes at any instant will give the instantaneous power in watts. However, such a measurement is unusual, difficult to make, and the resulting information is of limited use. Instantaneous power is of interest, of course, in the study of transient phenomena.

Average power in an ac circuit is of far more interest since it is equivalent to DC power and is a measure of mechanical work being done or heat liberated. Wattage or average power has an exact mathematical relation to horsepower or Btus or calories.

The most basic equation for power, relating voltage, current, power, and the phase angle between the voltage and current, is derived as follows. If both voltage and current are sinusoidal, the average power over a cycle is:

$$P = \frac{1}{T}\int_0^T ei\,dt$$

$$P = \frac{1}{2\pi}\int_0^{2\pi} E_m \sin\theta \cdot I_m \sin(\theta - \phi)\; d\theta$$

where E_m and I_m are maximum values and ϕ is the phase angle by which the current lags behind the voltage.

From $\sin(\theta - \phi) \sin\theta \cos\phi - \cos\theta \sin\phi$,

$$P = \frac{E_m I_m}{2}\left(\int_0^{2\pi} \sin^2\theta \cos\phi d\phi - \int_0^{2\pi} \sin\theta \cos\theta \sin\phi\; d\theta\right)$$

$$P = \frac{E_m I_m}{2\pi}\left[\left(\frac{\theta}{2} - \frac{\sin 2\theta}{4}\right)\Bigg|_0^{2\pi} \cdot \cos\phi - \left(\frac{1}{2}\sin^2\theta\right)\Bigg|_0^{2\pi} \sin\phi\right]$$

$$P = \frac{E_m I_m}{2}\cos\phi$$

The RMS values of sinusoidal voltage and current are:

$$E = \frac{E_m}{\sqrt{2}} \text{ and } I = \frac{I_m}{\sqrt{2}}$$

Substitution in the previous equation yields:

$$P = EI\cos\phi$$

An immediate concern is what happens to the indications of a wattmeter if the voltage or current or both are not sinusoidal. Since it is possible to synthesize an odd wave shape with higher harmonics of the fundamental frequency, a wattmeter will give correct indications if it is frequency compensated over the span of harmonics. It is to be noted that if a particular harmonic is present in either the current or the voltage but not the other, it does not contribute to the average or active power. Frequency compensation of the wattmeter is still necessary for an accurate measurement.

Wattmeter Construction

Dynamometer. All wattmeters of this type contain a fixed coil (usually divided into two coils), which carries the current, and a moving coil having series resistance connected for voltage, turning within the fixed coil. The torque on the moving system is proportional to the product of the currents in the fixed and moving coils:

$$\text{Torque} = K_1 i_m i_f \frac{dM}{d\theta}$$

where M is the mutual inductance between the two sets of coils and remains constant over the usable scale angle.

The period of the instrument is very long compared with the period of the alternating voltage. Since the instrument movement cannot follow the rapid variations in torque, it will take up a balance position where the driving torque will equal the spring-restoring torque. Deflection represents the average torque:

$$\text{Deflection} = \frac{K_2}{T}\int_0^T ei\,dt$$

which is identical to the average power equation:

$$P = \frac{1}{T}\int_0^T ei\,dt$$

multiplied by a constant.

It follows then that a dynamometer wattmeter is a "true RMS wattmeter" and will take into account the magnitudes of voltage and current as well as the phase angle between them. Furthermore, meter indication will reverse when the flow of power reverses.

Thermal Watt Converter. As with the dynamometer, this type of instrument dates back to the early days of electricity. Heat produced by the voltage and current directly heats thermocouples that are arranged in a network to provide a dc output directly proportional to the wattage input. Figure 1 shows the essential parts of a thermal watt converter, namely, the potential transformer, which is connected to monitor voltage, the current transformer, which has a double-wound, center-tapped secondary, and the two sets of thermocouples.

The quantity of heat in $R1$ is proportional to $R1(I_{T1})^2$ and in $R2$ is equal to $R2(I_{T2})^2$. A vector diagram can be drawn for the sum and difference of I_p and I_c. From this diagram, equations can be developed which yield the difference in wattage in resistance $R1$ and $R2$ as $4RE1\cos\phi$. The variable part of this term is $EI\cos\phi$ which is the expression for ac power.

Some early thermal wattmeters used bimetallic elements or liquid filled thermometers to measure the difference in heat between resistors $R1$ and $R2$. Thermocouples were used in more recent designs. In one design of a thermal wattmeter (Weston), the resistors and the thermocouples are one and the same. They act both as the heating resistors and as the temperature-sensing elements and show a very fast response to power changes. Also because the impedances of the several parts of the circuit are inherently balanced, there is little tendency for interchange of currents or potentials between the AC and the DC portions of the network.

Used mostly by the power industry, especially in totalizing of electric system loads, the watt converter has also found widespread use for measuring the power taken by very large motors where a remote readout is needed. Classed as a true RMS wattmeter, this device will respond to magnitude of voltage and current as well as the phase angle between them. Converter output will also reverse if the flow of power in the system reverses.

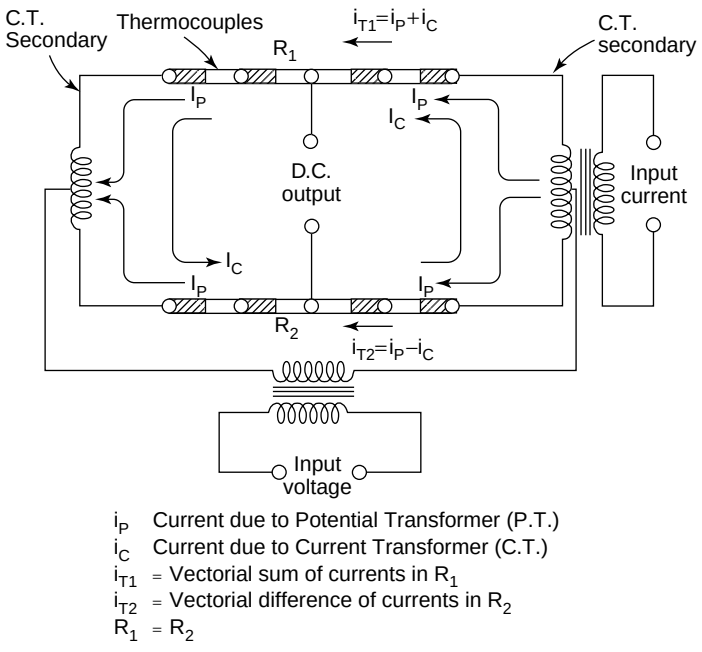

Fig. 1. Basic circuit of single-element thermal watt converter.

Specific Design Considerations. For clarity, it is believed best to comment pertaining to design factors pertaining to a few specific commercial instruments, realizing of course that other designs are also available commercially. Available single-element and 2-element watt converters have a response to 99% in 0.7 second. Due to this rapid response, some protection of the thermocouples is necessary during overload conditions. Converters made by Weston use transformer cores which will saturate at moderate overload and minimize thermocouple burnout or other damage. If repeated overloads occur, the current circuit is usually operated below the 5-ampere normal level. Output is 50 millivolts open circuit per element when connected to a 500-watt load. An available 2-element watt converter has an output of 100 millivolts for 1,000 watts of circuit load. Provision is made for adjusting resistors in the output network so that the output can be reduced to achieve a particular ratio between input wattage and output millivolts.

Since a thermal watt converter has no moving parts to wear, it has been made very rugged by potting the entire circuit in a steel case. Poly-phase wattmeters are easily made by assembling two or more single-element wattmeters and providing for a common output signal. An available 3-element wattmeter was designed for use on military motor-generator sets having 3-phase, 4-wire distribution systems. Such systems can be expected to operate under unbalanced conditions and to correctly read system power, a 3-element wattmeter must be used.

If the internal potential and current transformers are of good quality, the thermal watt converter can be used on frequencies extending to 20,000 Hz. A high-frequency type meter has a working frequency span of 180 to 20,000 Hz. In general, all thermal watt converters use internal transformers, which excludes their use on direct currents.

The Low Power Factor Wattmeter

All of the so-called true RMS wattmeters will operate over the full range of power factor from zero to unity. Many low power factor examples can be found in the laboratory, such as motor or transformer testing, core loss tests, and power supply circuits. At zero power factor, a wattmeter will indicate zero watts even with rated voltage and current flowing. It quickly becomes apparent that the major difficulty in making a low power factor measurement is the low indication obtained on the meter. For example, if a wattmeter indicates full-scale with a unity power factor load, it will indicate half-scale with a 50% power factor load for the same level of voltage and current. At 20% power factor, the pointer will move only one-fifth the distance up-scale.

Special wattmeters are available for use on low power factor circuits. They are commonly called 20% power factor meters since the full-scale wattage is equal to the maximum voltage times the maximum current times 0.2. Both the accuracy and readability are improved through the use of this type of instrument. Since the 20% power factor wattmeter is designed to develop five times the torque of a unit power factor type instrument, care must be taken not to apply voltage or current above the maximum values shown on the instrument rating. Large overloads will soon burn out the resistors, fixed coils or moving coils. Small overloads continuously applied will cause deterioration of the overheated insulation. A wattmeter designed for low power factor can be used on higher power factor circuits provided either the voltage or current is sufficiently reduced to keep the pointer on the scale. Likewise, normal unity power factor meters may be used at low circuit power factors provided maximums are not exceeded.

Power Measurement

Power in an ac or dc circuit may be determined indirectly by making appropriate measurements of voltage, current and, where necessary, power factor. Power factor is usually expressed as a decimal value ranging between 0 and 1 and is derived from the cosine of the angle between the voltage and current. Power factor is further designated lead or lag, depending upon whether the current vector is ahead or behind the voltage vector based on counterclockwise rotation of the vectors. When making power calculations, it is not necessary to know if power factor is lead or lag.

Therefore, calculated power is a valid procedure, but with some reservations. Results are accurate only if all quantities of voltage, current, and power factor are correctly measured. The most elusive quantity is power factor. It is rare that a single-phase power factor meter can be used on other than 60 Hz. Even the 3-phase power factor meter has the requirement that the load must be balanced, although some designs have covered several thousand hertz. Modern electronic phase-angle voltmeters give excellent results on good sine waves over a wide frequency span. However, when distorted waves are encountered, results are questionable since many instruments of this type operate on the zero crossing principle. Further, the power factor of a distorted wave has little meaning since by definition it is based on a sine wave. The conclusion is soon reached that the only way to measure power accurately is through the use of a wattmeter.

In recent years, the phrase “true RMS wattmeter” has been reserved for the description of the ultimate in wattmeters. This is because some of the types of wattmeters available today will be accurate at only one frequency, must operate over a narrow voltage span, will not operate on dc, or must be worked at a high power factor. Although more descriptive than technically correct, the phrase will probably remain in the literature.

The original, basic, true RMS wattmeter was the dynamometer. Even until recently, this type of instrument was used as the standard wattmeter at the U.S. Bureau of Standards. A dynamometer wattmeter can be calibrated very accurately on dc and then used on ac. It is often the standard used to check other wattmeter devices because it can be made to a high accuracy, is a passive device, and will retain its accuracy for many years.

Probably the most important theorem in electric power measurement is that proposed by Blondel. In essence, it states that to correctly measure total system power, it is permissible to use one less wattmeter than current-carrying conductors. Also, the common point for the potential circuits is the conductor without a wattmeter current connection. The circuit being so measured may be operated at any power factor or condition of current or voltage unbalance. Strict adherence to Blondel’s theorem would require the use of three wattmeters or a 3-element type meter to correctly measure a 3-phase, 4-wire system. Since large commercial systems strive to maintain good voltage balance, a less expensive wattmeter of the $2\frac{1}{2}$-element design may be used and still achieve good accuracy.

Many questions often arise as to the proper wattmeter connections for various types of loads. For example, in a 3-phase, 3-wire circuit, the load can be delta, wye, or some other configuration. The wattmeter is only concerned with the three wires. This leads to a simple pictorial concept for the connection of a wattmeter. Visualize a laboratory bench with an unknown power supply on the left, the connecting wiring across the bench, and an unknown load to the right. Without knowledge of source or load, a true measurement of total system power can be made by following Blondel’s theorem. Assume four wires are present and that all may be carrying current. Provide three wattmeters, making the wire without a meter the potential common. It is to be noted that one terminal of the meter current circuit and potential circuit carries an instantaneous

polarity marking (usually plus or minus). That means that if (+) of a direct current supply is applied to each of these terminals, the meter will deflect upscale. Likewise if (−) were so applied, the meter will still go upscale. If one terminal is made the opposite polarity, the meter will move down scale. In a multi-meter correction, the (±) current terminals should all be toward the source. Even so, due to load reactance, one wattmeter may produce a reversed indication. Total power then will be the algebraic sum of all meter readings. The measurement has been made without any knowledge of the source or the load. Voltage and current levels must be within the range of the meter to avoid overheating damage.

If more knowledge of the load can be obtained, the immediate benefit would be reduced metering costs. If we still have a 3-phase, 4-wire system, but know that the neutral wire carries no current, then only two wattmeters are needed to give a true reading.

If we further know that both voltage and currents are balanced around the phases, then metering costs can be further reduced by using a single wattmeter and a wye box. When combined with the meter, the two arms of resistance in the wye box form a wye having a neutral point. The wattmeter will then measure a phase power which is a known fraction of the total power. The scales of switchboard meters are usually direct reading, but the indication from a portable wattmeter must be multiplied by the wye box multiplying factor.

If only voltages in this 3-phase, 4-wire example are balanced, then a so-called $2\frac{1}{2}$-element wattmeter is satisfactory.

Adherence to Blondel's theorem will always provide a true power measurement regardless of circuit conditions. A knowledge of the circuit will often point the way to less expensive metering which can provide adequate results.

For the measurement of power in a 2-wire circuit, Figs. 2 and 3 show the possible connections. The connection shown in Fig. 2 indicating the wattmeter potential circuit connected on the load side of the current coils is most often used. Readings taken on small wattage loads may easily be corrected for meter loss by opening the load and reading the wattmeter. Although not truly correct under varying loads, this "tare" reading will much improve the accuracy of the measurement.

If the wattmeter current coils are wound for low currents, such as 0.1 ampere, there is sufficient voltage drop across them under load to make the connection shown in Fig. 3 and thus yield a more accurate result.

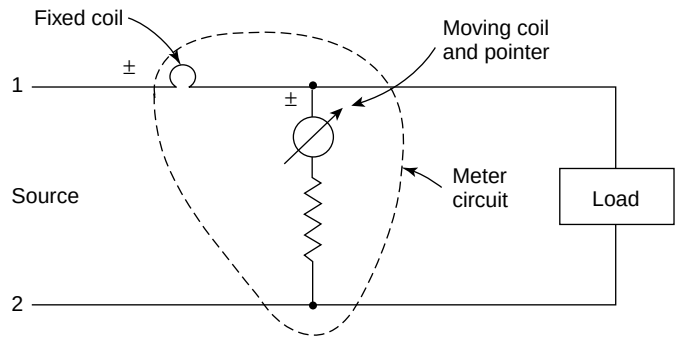

Fig. 2. Single-element wattmeter with potential circuit connected on load side. This connection is most often used.

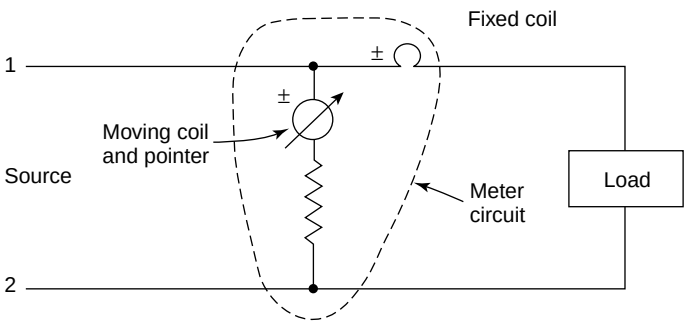

Fig. 3. Single-element wattmeter with potential circuit connected on source side. Usually used when fixed coil has a low current rating and a high voltage drop.

Figure 4 clearly demonstrates Blondel's theorem of two wattmeters in a 3-wire circuit where the common potential circuit connection is made in the line without a current coil. There are some 2-element wattmeters available which connect the two moving coils into line 2. Such an arrangement is adequate for moderate voltages and accuracy, but the mechanical force set up between the fixed and moving coil due to the electrostatic effect precludes the use of this connection where high accuracy is needed.

The $2\frac{1}{2}$-element wattmeter of Fig. 5 will monitor all the current flowing and so is capable of a correct wattage measurement where current unbalance exists. Line to line voltages should be nearly balanced and it is assumed that they are 120° from one another in vector rotation.

Power Factor

Whenever the voltage and current are not in phase, a third term called power factor must be introduced. The formula is expressed by:

$$\text{Power Factor} = \cos\left(\tan^{-1}\frac{Q}{P}\right)$$

where Q = reactive power, P = active power.

This basic formula may be used on simple, 2-wire circuits as well as a 3-phase system as long as the poly-phase system is balanced in both voltage and current.

When a poly-phase system is unbalanced in any manner, the system power factor will no longer have any specific physical meaning. A numerical ratio can be obtained and is defined as the interval power vector. This is not, in general, equal to the average value of the power factor during the interval.

Power factor is not usually one of the measured quantities when testing low power circuits under laboratory conditions. Commercial users of bulk power very often monitor power factor so as to be able to make adjustments of condenser banks or synchronous motors to keep the power factor as high as possible. This, in turn, usually reduces the cost of the power purchased.

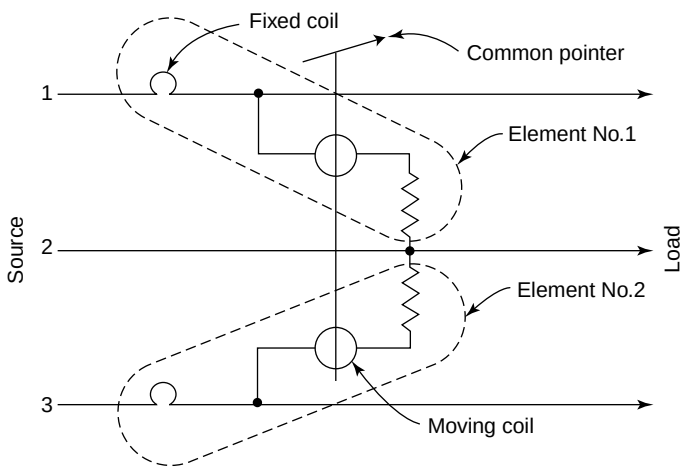

Fig. 4. Two-element wattmeter connected to a 3-phase, 3-wire system.

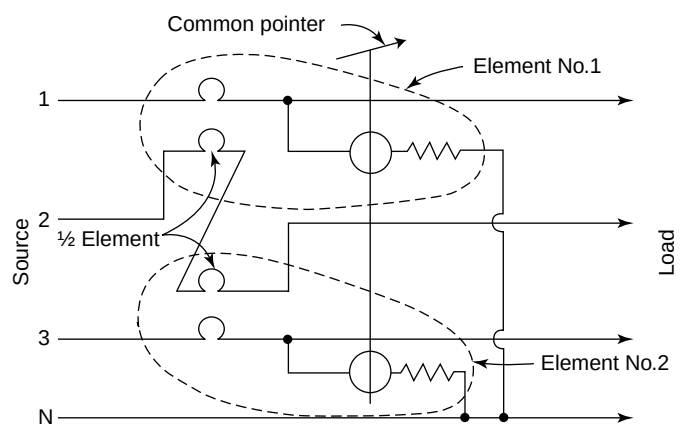

Fig. 5. A $2\frac{1}{2}$-element wattmeter connected to a 3-phase, 4-wire system.

Power Factor Meter. Since the power factor meter can show at a glance the operating condition of a power system, it is most often found on the switchboards of both consumer and supplier of power.

Ratio type movements are commonly found in both single phase and poly-phase power factor meters. The single-phase power factor meter measures the ratio of vars to watts which corresponds to the tangent of the power factor angle when the voltage and current are sinusoidal. A scale can then be drawn for the power factor, which is the cosine of the angle.

The poly-phase power factor meter also uses the same basic ratio mechanism as the single-phase meter and is connected 3-phase, 3-wire. This instrument will indicate vector power factor by measuring the angle between line current 2 and line voltage 3-2 and 1-2. The indication is the poly-phase power factor only for balanced voltages and currents when both are sinusoidal. Some years ago, Weston offered a poly-phase power factor meter for use on unbalanced systems. However, due to limited acceptance because of the high cost resulting from the complexity of construction, it was discontinued. It is doubtful that such a meter can be purchased today from any manufacturer.

Single-phase instruments can be scaled in a variety of combinations, such as 0-1 P.F. lag or lead, or 0.3-1-0.3 P.F. Due to the principle of the instrument, not every range combination is possible in the poly-phase power factor meter.

When compared to the other electrical quantities, the var is a relatively new term, having been recognized by international agreement in 1930. The letters were taken from volt-ampere-reactive and represent power incapable of producing work. Voltages used in this form of metering are always 90° in vector rotation from that used in wattage measurement. In any alternating current system having sinusoidal voltages and currents operating at other than unity power factor, the real power is less than the volt-ampere-product and is related by the familiar right triangle. See Fig. 6.

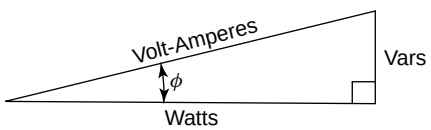

Fig. 6. Real power is less than volt times amperes. ϕ = power factor angle.

Since more iron and copper are required to deliver a given amount of power at a low than at a high power factor, design allowances must be made for any reactive volt-amperes in addition to the designed load power. Line losses are higher and voltage regulation poorer when the power factor is low. Any customer contributing to a low power factor must be expected to pay for this added loss in addition to the actual energy consumed. Var metering is generally used to obtain an estimate of the average power factor of a fluctuating load over a period of time. A recording type meter would be used for this measurement.

$$\text{Var} = EI \sin\phi = EI \cos(90^\circ - \phi)$$

A wattmeter can be converted to a varmeter if the voltage is shifted into quadrature with the line voltage at the load. In single-phase varmeters, this voltage shift is done by means of added reactance. In poly-phase systems, the voltage shift is most easily done by reconnection if all necessary points are available. On 3-phase, 3-wire systems, a var connection may be made to wye-connected resistors forming an artificial neutral. A special poly-phase, phase-shifting autotransformer, also called a potential converter or phasing transformer, is available for var service. When a varmeter is purchased from the manufacturer, the proper scaling, instrument adjustment (watts), and connection diagrams are provided. If it is desired to convert an existing wattmeter to a varmeter, several problems must be avoided (or at least understood).

Varmeter indication can be either up or downscale, depending upon whether clockwise or counterclockwise rotation is selected for the new var voltages. Either is correct, but it should be determined that up-scale indication will occur for a leading or lagging power factor. Another more serious problem is that of voltage level. If the new var voltages differ from those used by the basic wattmeter, then, for the same power supplied to the load, the full-scale value and therefore all scale points will be in error. In order to correct this, the meter series resistance would have to be changed (a task for a meter shop with wattmeter calibration equipment).

Varmeters are usually arranged to deflect to the right (up-scale) on leading power factor circuits with phase rotation 1-2-3. Zero center varmeters also have the words IN at the left and OUT on the right. The OUT refers to the flow of power from a source, considered to be located at the left of a diagram, to a load somewhere to the diagram right.

Instrument Transformers

For reasons of personnel safety and good instrument design, it becomes impractical to connect meters directly to circuits having voltages above 1,000 volts and currents above 50 amperes. Furthermore, instruments tend to become inaccurate when directly connected to high voltage because of electrostatic forces that act on the moving system. Shunts are often considered for large ac currents, but have the disadvantages of large power loss at high current ratings and no voltage isolation. Unless a shunt is especially designed for ac use, its inductance, nonuniform split of current in the blocks, skin effect, proximity effect, and nonuniformity of the material all contribute to ac shunt error.

By contrast, potential and current transformers offer a practical and safe means of reducing voltage and current by an exact ratio for instrument use. All instrument transformers have the following basic design objectives: (1) careful attention to an exact primary-to-secondary ratio; and (2) as small a phase angle as possible. Instrument transformers by design have small load (burden) capability because meters do not need large amounts of power and a low burden will enhance the design for best possible accuracy.

In a power station, the instrument transformers which are used for station metering, relay operation, and control services are often several feet tall (a few meters), resulting from a design to withstand very high voltages. For laboratory and shop testing at low distribution voltages, both potential transformers and current transformers are very small in comparison. They weigh perhaps 15 pounds (~7 kilograms) and can be hand carried. Quality potential transformers for laboratory use will support a 25-volt-ampere burden, have a ratio accuracy from 0.1 to 0.5%, and a phase angle of 10 minutes. A core-type design in which the winding surrounds the iron provides the necessary insulation for a high range of 2,300/1,150 or 115 volts. The iron is usually grain oriented silicon steel from 0.012 to 0.025 inch (0.3 to 0.6 millimeter) thick, depending upon the quality of the transformer and frequency range. Current transformers of the toroidal type, using tape-wound, high nickel-iron cores, have phase angles of less than 2 minutes and a ratio error of plus or minus 0.02%. Burden capability is up to 25 VA. Primary-to-secondary insulation is difficult to provide in a toroidal transformer. A rating of 2,500 volts is common for stock transformers with 5,000 working volts pushing the practical limit for this construction in custom designs.

Automated, Remote Meter Reading. The concept of using meter-mounted sensors connected to an information network, such as the telephone system, was initially suggested in the 1960s. However, little progress has been made until recently, and this is in connection with selected industrial/commercial users of a large amount of power. As of 1993, this program had passed the field testing stage. In the mid-1980s, a pipeline company complained to a large southeastern U.S. electric utility that the utility's billing cycles, which had different start and end dates in different locations, were not synchronized with the user's monthly pumping cycles. As a consequence, the pipeline firm had difficulty in managing the cost of electricity required to move petroleum products through its vast pipeline network. With energy costs representing 40% of the company's annual operating expenses, this was no small concern. The solution was *advanced metering*.

Through this new program, known as ROCS™ (Read-Only Central Station), large commercial and industrial customers can access, by computer, real-time information from their electric meters. With such data, users can take advantage of cheaper rates while monitoring and managing energy consumption. In the system, each customer provides its own personal computer and a telephone line to connect the PC to the meter. A video display monitor, a modem, and proprietary software also are required. Users may examine their data privately at any time, without involving the utility. Security is maintained through multiple password protection, hardware security keys, and the limited read-only functions of the software, which ensures the operating integrity of the recorder. Users can monitor and audit daily energy use at multiple locations and predict their energy billings.

Additional information can be found in the Timberman reference list at the end of the article on **Electric Power Production and Distribution**.

ELECTRIC POWER PRODUCTION AND DISTRIBUTION. Few people would disagree that an abundant, reliable, and comparatively low cost electric power supply is fundamental to the maintenance and growth of the world economy, especially in the case of the advanced, industrialized nations.

Over the years, since the beginnings of centrally produced and distributed electric power (1880s), the major problem facing electric utility managers, whether investor or publicly owned, was simply that of *keeping up with the demand*. Utility managers were among the first industrialists to establish long-term planning, required because of the long lead times imposed between the design phase and putting a new plant or expanded facility onstream. Lead times became even longer in the case of nuclear power plants, ranging from 5 to 8 and even 10 years from blueprints to delivery of power.

Today, electric power planning has become even more complex as the industry grapples with the problems of environmental protection. The introduction of effluents into the air as the consequence of combusting fossil fuels to create steam and hot gases to operate the electricity-generating turbines poses severe technical complexities, either in terms of (1) treating and neutralizing the undesirable effluents (principally sulfur dioxide (SO_2), nitrogen oxides (NO_x), and carbon dioxide (CO_2), as well as solid particulates), or (2) essentially treating or transforming the raw fuels used. Coal, in particular, is implicated in connection with SO_2, but nitrogen oxides and CO_2 are natural products of combustion, thus implicating all fossil fuels. By comparison, it is interesting to note that these problems are not present when nuclear fuels are used.

Because of the technologies needed to cope with environmental problems, electric power planning today is additionally faced with selecting one solution for a given problem out of a choice of several proposals. (Although the results desired from technology can be legislated, the actual achievement of results is not precisely programmable.) The complex politico-scientific formulas currently applying to coal-fired power plants in the United States are described in the article on **Coal Conversion (Clean Coal) Processes**.

With an expected doubling of world population sometime in the 21st century, electric power planners are also greatly concerned with how the supply can keep up with what appears to be phenomenal demands if current standards of living are to be maintained in the present industrial nations and improved in the developing nations. This latter topic is beyond the scope of this article, but reference is made to an excellent scholarly article by Robert Fri (listed at end of this article).

Emphasis on Research

If any nation is to assure a reliable electric power supply now, within the next few decades, and beyond, the answers must derive from advanced technologies, some of which are on hand and are being implemented, some of which still are essentially in their infancy, and some of which are as yet unknown. Thus, electric power planning now must include inputs from costly research and development programs that not only tackle the near-term problems, but also peer far into the future. This is a task that is national (and international) in scope and far beyond the capability of any one electric utility. Thus, it was a laudable exercise of logic when a few years ago over a hundred electric utilities joined together to form the Electric Power Research Institute to concentrate on finding and developing technical solutions to present and future problems. Similar but smaller efforts of this nature also have been undertaken by some of the other very advanced industrial countries. These concerted research efforts are described later in this article.

Electric Power Statistics

Global statistics of electric power production are difficult to compile and thus are not fully reliable. For example, statistics from the former Iron Curtain countries were always subject to question. For general purposes, however, the percentages shown in Fig. 1 should suffice.

According to a forecast (1991) made by NERC (North American Electric Reliability Council), the electrical peak demand in the United States will grow at a rate of 1.9% per year from 551,500 MW (megawatts) in 1991 to 651,100 MW in 2000. In the United States, peak demands occur in summer. See Fig. 2. The United States is anticipated to continue to be summer peaking through 2000. The summer peak demand is about 11% greater than the winter peak.

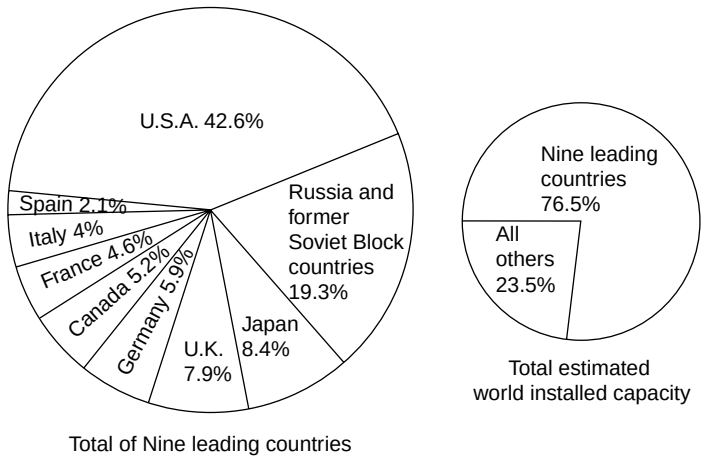

Fig. 1. Distribution of electric generating capacity among leading countries.

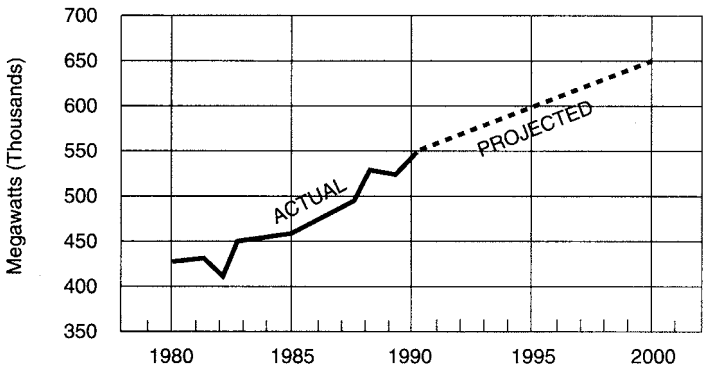

Fig. 2. Actual and forecasted summer peak electric power demands in the United States. (*Adapted from North American Electric Reliability Council*.)

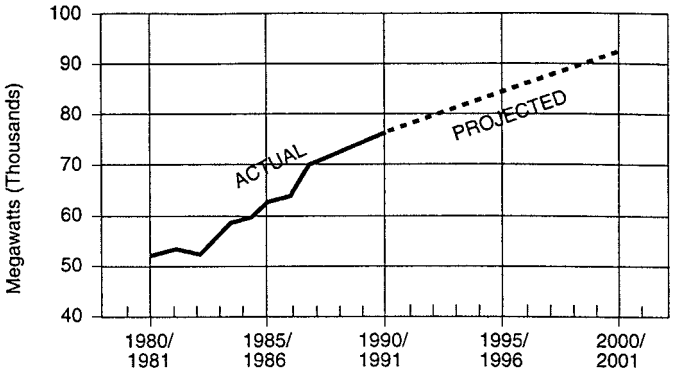

Fig. 3. Actual and forecasted winter peak electric power demands in Canada. (*Adapted from North American Electric Reliability Council*.)

The peak demand in Canada, which occurs during winter, was 80,900 MW in 1991 and is projected to be 97,100 MW in 2000, representing a growth rate of about 2% per year. Canada's winter peak is projected to exceed its summer peak by about 40%. See Fig. 3. The peak demand and annual net energy for load projections for the United States and Canada are given in Table 1.

A typical peaking curve for a U.S. utility (summer peaking) is shown in Fig. 4.

The electrical power requirements or load placed upon a specific power-generating facility may, at times, be greater than or less than the optimal rate in terms of economy, profit, and other operating factors. Within the upper and lower limits of capacity of any facility, operating adjustments are made, cutting in generating equipment or cutting out units, as may be required. But it may be more economical for a facility to buy power from another generating facility or, depending upon the direction of the demand, to sell power to another facility. This can be accomplished smoothly by

TABLE 1. PEAK DEMAND AND ENERGY FORECAST
Electric Power in United States and Canada

	1991	2000	Growth (%/yr)
Peak demand (thousands of MW)			
United States (summer)	552	651	1.9
Canada (winter)	81	97	2.0
Net energy for load (millions of MWh)			
United States (annual)	2951	3513	2.0
Canada (annual)	446	548	2.3

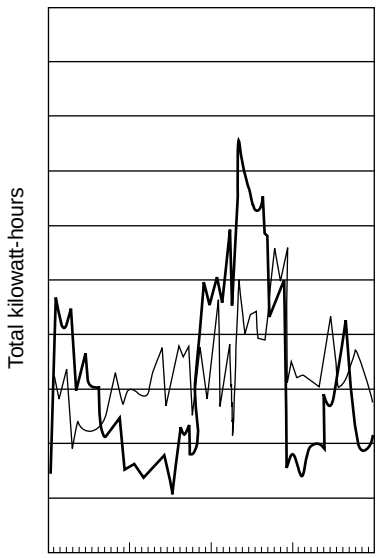

Fig. 4. Annual peaking curve for a typical U.S. electric utility. Heavy line is total as reported. Fine line is seasonally adjusted.

means of a tie-line, or, if large numbers of facilities are so connected, the system may be part of an *interconnecting network*. In the latter situation, not only are individual facilities connected, but whole utility systems may form a vast network encompassing very large geographical areas. In some countries, all or nearly all facilities are so interconnected. In the case of North America, there are interconnections between two countries — the United States and Canada.

Fundamentally, networks are established in the interest of maximizing operating economy and for providing extra power when required, as may be caused by any number of factors, such as storms, which may affect one or two generating facilities in a given area quite seriously. In fact, the public is made aware of such interconnections in times of emergencies. Power from other sources is conveniently available, too, to handle scheduled maintenance shutdowns.

T.J. Nagel has described the situation succinctly: "The purpose of interconnections is to expand the scope of the individual power systems so as to enhance both reliability and economy of the power supply. In terms of reliability, interconnections provide assistance during generation outages, assist in distributing excessive generation at times of major load outages, and provide support in times of transmission outages. In economic terms, interconnections allow the full exploitation of economies of scale in both generation and transmission. Savings thus can be realized without compromising reliability, through the sharing of risk. Interconnections allow the interchange of power to reduce generation costs". With reference to a 1991 report prepared by NERC, it is observed that, in the 100-year history of the electric utility industry in North America, utilities have grown from isolated systems supplying their customers from local generating sources to a highly interconnected system of generating stations and high-voltage transmission lines encompassing large geographic areas and many individual utilities. As shown by Fig. 5, in NERC, there are four major interconnection areas: (1) the Eastern Interconnection, (2) the Western Interconnection, (3) the Texas Interconnection, and (4) the Québec Interconnection.

Within each interconnection, individual utility systems are operated in synchronism with each other. Within the limits of the transmission systems,

Fig. 5. Four major interconnection regions. (*North American Electric Reliability Council*.)

TABLE 2. GENERATING CAPACITY PROJECTIONS
Aggregate 1991–2000 Forecast — United States and Canada (Additions, Changes, Facility Retirements)

	United States		Canada		NERC-Total[1]	
Type	Thousands Of MW	% of Total	Thousands of MW	% of Total	Thousands Of MW	% of Total
Nuclear	5.9	6.6	2.6	11.5	8.6	7.5
Coal	15.1	17.0	1.9	8.3	17.7	15.6
Hydro	1.1	1.2	12.7	55.0	13.9	12.3
Oil/gas	34.2	38.3	2.3	9.9	36.8	32.5
Pumped storage	2.5	2.8	0	0	2.5	2.2
Other (utility)	12.8	14.3	1.1	4.8	13.9	12.2
NUGs (net additions)	17.7	19.8	2.4	10.5	20.1	17.7
Additions	**89.3**	**100**	**23.0**	**100**	**113.4**	**100**
Changes	10.6		0.4		11.0	
Retirements	−4.3		−0.5		−4.8	
Net Total	**95.7**		**22.9**		119.6	

[1] Includes additions in WSCC-Mexico.
Utility oil-fired (4300 MW) and gas-fired (29,900 MW) units account for 38.3% of the total 89,300 MW of planned additions in the United States. The second largest additions in the United States are the nonutility generators, at 17,700 MW, or 19.8%, nearly half of which are gas-fired. A significant number of nonutility generators (NUGs) exist in California, Texas, and New York. The foregoing projections show major increases from NUGs in NPCC, SERC, WSCC, and MAAC.
In Canada, hydro units account for 55%, or 12,700 MW, of the 23,000 MW of total planned additions over the forecast period.
(*Source*: North American Electric Reliability Council.)

demand at any point in an interconnection can be supplied by generation located at any other point. Transfer of electricity from one point to another will, to some extent, flow over all transmission lines in the interconnection, not just those in the direct path of the transfer.

The ability to transfer electricity *between the interconnections* is very limited and depends on the capacity of the tie-lines, the ability to deliver electricity through the network to the tie-points, and the amount of generating capacity available at the time of the transfer.

Generating Capacity within NERC. New unit capacity additions of 113,400 MW are planned in NERC over the 1991–2000 period. A summary of these generator unit additions, changes, and facility retirements is given in Table 2.

Some major interconnections are comprised of two or more subregional bodies, as indicated by the map in Fig. 6. Recent forecasts indicate that the period through 2000 may experience relatively small margins for contingencies, or are likely to need capacity resources in addition to those currently planned. Regional-specific contingencies and concerns include

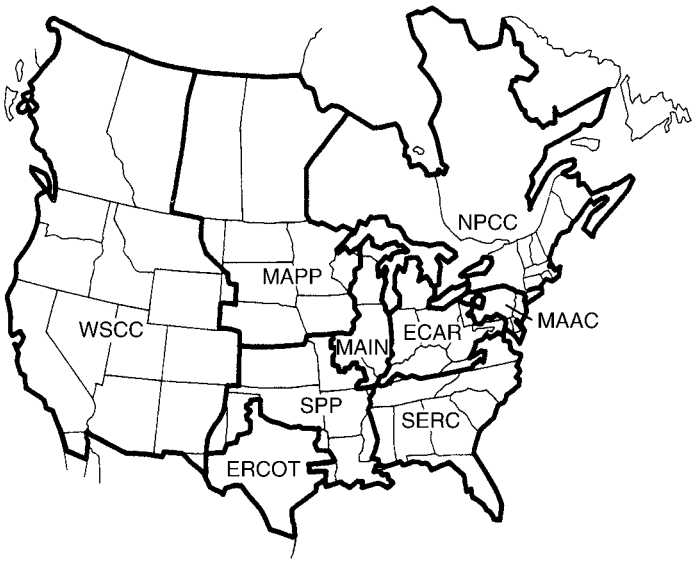

Fig. 6. Regional reliability councils that make up the total NERC network. Legend: ECAR (East Central Area Reliability Coordination Agreement); ERCOT (Electric Reliability Council of Texas); MAAC (Mid-Atlantic Area Council); MAIN (Mid-America Interpool Network); MAPP (Mid-continent Area Power Pool); NPCC (Northeast Power Coordinating Council); SERC (Southeastern Electric Reliability Council); SPP (Southwest Power Pool); and WSCC (Western Systems Coordinating Council. Also, not shown, is an affiliate, ASCC (Alaska Systems Coordinating Council).

risks of higher-than-expected peak demand growth, lower generation availability, or the inability to improve it, especially during peak periods, or the reduced effectiveness of projected demand-side management programs. Areas with the smallest amounts of capacity available for contingencies are in the Eastern Interconnection. This interconnection also is the most susceptible to potentially adverse effects from the U.S. Clean Air Act Ammendments of 1990. In addition, a series of Clean Air Programs has set tight goals to drastically cut emissions.

Electric Power Network Research. From a fundamental standpoint, the great bulk of instantaneous support to make up a generating deficiency in some part of a network is derived from the inertial energy stored in the combined rotating masses of all generating plants and other electricity resources in the network. Although such a transfer may be accompanied by a slight, very temporary decline in frequency in the network, this is not a critical factor in making the transfer. The much greater role in sustaining continued service and reliability is the capability of the transmission facilities to handle the resulting shift in power flows. Basically, the flows of power on individual elements of an interconnected network are usually uncontrolled. They are distributed in accordance with the impedances of the circuit elements. Consequently, if these elements are overloaded and disconnected by protective equipment, uncontrolled power failures in some parts of the network may occur. Over the years, with particular emphasis since the massive electric power failure that blacked out most of the northeastern United States and parts of two Canadian provinces on the night of November 9–10, 1965, many studies, including sophisticated computer-assisted programs and simulations of emergency situations, have been made. The blackout of 1965 and a subsequent blackout of New York and environs in 1977 were thoroughly investigated and documented. The chain of happenings, including equipment malfunction and network management communications, is beyond the scope of this article.

The transmission system, of course, behaves according to the basic laws of electricity. The amount of power flowing over any one line is determined by Ohm's law (current flow is directly proportional to voltage and inversely proportional to impedance). The principles involved are shown in Fig. 7. The Kirchoff laws of network operation (the voltage around a closed loop must sum to zero, and currents into a node must sum to zero) also apply.

Electric Power Consumption

Some detailed studies of electric power consumption have been made by regional utilities, but the suppliers of power are more concerned with the impact of new users. With so much geographical decentralization of manufacturing firms occurring today, the impact of new industries must be determined well in advance. The information given in Fig. 8 represents an average usage in the United States over a number of years. Generally, this mix will apply to other advanced industrialized countries. Also see Fig. 9.

Raw Energy for Electricity Generation

Numerous raw energy sources have been considered over the past century when conveniently available electric power became commonplace. Wood and coal were used initially, and coal continues to be in demand because of the vast reserves and the number of existing plants that are designed for coal firing. Some of the environmental problems in connection with coal and other fossil fuels were mentioned earlier in this article. Also, there is a separate article on each of these major fuels elsewhere in this encyclopedia. See also **Coal**; **Combustion**; **Fuel Cells**; **Geothermal Energy**; **Natural Gas**; **Nuclear Power Technology**; **Petroleum**; **Solar Energy**; and **Wind Power**.

Intermediate-term Energy Supply Outlook (1990s–2000). The North American Reliability Council observed in 1991 that new issues are emerging regarding the long-term adequacy of the supply and infrastructures associated with coal, natural gas, and fuel oil (petroleum).

Coal. Adequate supplies of low-sulfur coal may not be available in a timely manner to meet the increased demands caused by Clean Air legislation. The increased demand is likely to strain low-sulfur mining capacity in the eastern United States as well as the transportation systems in both the East and West. The mining capacity for low-sulfur eastern coal may not be adequate, and this could lead to significant use of Western coal in the eastern and midwestern NERC regions. Use of low-sulfur western coals in place of eastern coal will pose significant problems of transportation and supply.

Several ways to meet the SO_2 emission limitations of the Clean Air Act are available and include:

Changing the fuel in affected units;
Switching to lower-sulfur coal, lower-sulfur oil, or natural gas;
Removing SO_2 after combustion by scrubbing, or possibly removing sulfur using clean coal technologies; and
Retiring facilities where compliance costs exceed a unit's value.

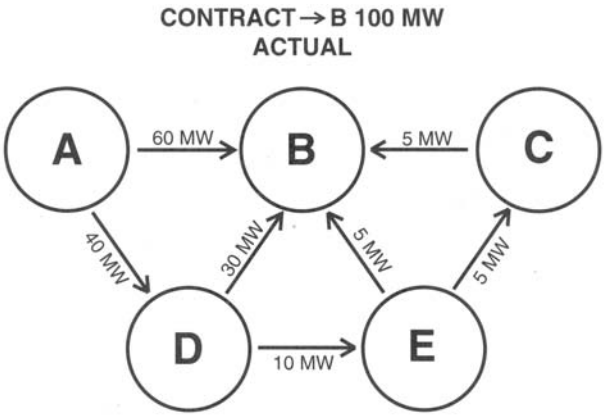
Natural Gas. Limitations currently exist in the natural gas delivery system that constrain the use of gas for electricity generation, particularly during winter. These limitations are likely to become more critical. Some of the developing regions of NERC are remote from natural gas supplies. Efforts are underway to improve natural gas delivery. For example, the import of nearly 400 million cubic feet per day of Canadian natural gas into the northeastern United States has been approved. The gas will be carried by a new 370-mile (596-kilometer) pipeline from Canada into Connecticut and New York. Many electric utilities routinely switch from natural gas to fuel oil in November, as increasing heating demands for natural gas strain the delivery system. Additional concern is expressed where a single pipeline is involved. Although pipelines are highly reliable, a pipeline failure could have a heavy impact on the electric utility industry in the area affected. See Fig. 10.

Petroleum. Two major types of oil are used for electricity generation: No. 6 residual fuel oil, and No. 2 distillate fuel oil. Environmental constraints will require the use of low-sulfur fuel oil. The U.S. refining capacity for low-sulfur residual oil is limited because it is less profitable and the availability is not likely to increase. In some states, regulatory agencies have placed limits on the amount of fuel inventories allowed in utility rate base, usually on the basis of historical consumption. However, inventories are meant to meet needs during supply disruptions that could be more severe than historical occurrences. This is particularly true when oil is used to fuel peaking capacity or as a backup fuel for natural gas. See Fig. 11.

Electric Power Generating Systems

The use of rotating equipment for generating electric power dates back well over a century. See Fig. 12.

The majority of electric power produced in the United States is by 3-phase generators. Advantages of 3-phase generators lie in economy of apparatus, lower transmission losses, inherent starting torque for polyphase motors, and a constant running torque for balanced loading.



Total Current (A)	Increment of Additional Current (A)	Total Losses (A)	Incremental Losses (A)
100	–	10,000	–
200	100	40,000	30,000
300	100	90,000	50,000
400	100	160,000	70,000
500	100	250,000	90,000

In table, A = amperes.

(**b**)

Fig. 7. A large electric power exchange (interconnection) network follows the laws of Ohm and Kirchoff. (**a**) Schematic diagram of an interconnected power system. If Utility A wants to sell 100 MW to B, power may flow to accomplish this transaction as shown. The 100 MW will not flow directly from A to B, but it will divide according to the impedance of the system. The current will not take the single path of least resistance, but it will divide in a way that is inversely proportional to the impedance of all the paths from A to B, thus obeying Kirchoff's network laws. Now, if D wants to sell to E, the two parties must take into account the flows resulting from the transaction between A and B. If the circuit from D to E is loaded to its maximum by the flow introduced from A to B, then D and E cannot complete their transaction. This loop flow limits the use of the transmission system.

(**b**) Large geographical scale network, illustrating a purchase of power by the New York Power Pool of 1000 MW from Ontario Hydro in Canada. Only half of the desired purchase flows directly to New York. Lower network impedance in Michigan, Ohio, and other states causes a significant amount of the power to flow through these states. Loop flow is well known to utility system operators. It registers on their meters and is calculated in advance, but it does limit the ability of systems through which it flows to make additional transfers. (*Electric Power Research Institute*.)

A generator is built with axial slots for armature coils in a stationary hollow cylindrical iron core called the stator. The windings are placed in the slots so that when carrying current they produce a chosen even number of alternate magnetic poles. The coils over each magnetic pole are grouped in three equal bands to give a 3-phase balanced system of terminal voltages.

An inner rotor has coils that carry direct current to give the same number of alternate magnetic poles as on the stator. Rotor current strength is controlled by a rheostat or voltage from a direct-current generator. Voltages are produced in the stator windings by flux cutting as the rotor magnetic flux sweeps by them, and currents flow when the generator terminals are connected to a 3-phase load impedance. The 3-phase stator

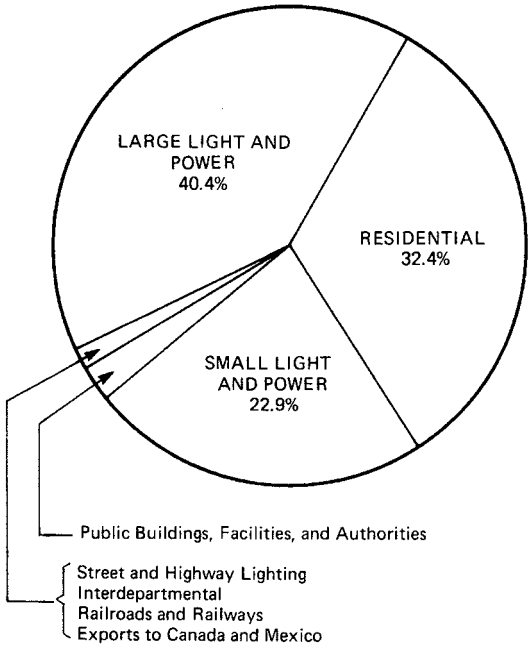

Fig. 8. Distribution of electric power requirements in the United States (average of several years).

line voltages are equal in magnitude and 120 electrical degrees apart in time sequence. So also are the line currents for a balanced 3-phase load. Generator voltages are of the order of 12,000 to 30,000 volts for large machines.

Generator frequency is the product of the pairs of magnetic poles and the speed in revolutions per second. At 60 cycles (60 Hz), a 2-pole generator runs at 3,600 revolutions per minute; a 6-pole generator at 1,200 revolutions per minute. The maximum speed of 3,600 revolutions per minute has been increasingly adopted even for very large machines because high speed means decreased size and weight for a given kilowatt rating and better turbine performance. However, water-wheels and water turbines show best characteristics at much lower speeds, roughly a range of 100 to 600 revolutions per minute. Sixty cycles is the prevailing frequency in the United States. Because of weight and space limitations, 400 cycles is popular in the aircraft industry. Fifty cycles is a common frequency in Europe. See also **Alternator**.

Direct-current generators are built with their de magnetic poles on the stator. Armature conductors on the rotor have AC voltages induced in them as they are rotated; the same principle of flux cutting holds as previously described. An automatic mechanical switching device, called a commutator, is placed on the shaft. It carries fixed brushes, and with its many insulated copper bars connected to the armature coils, it inverts every other alternation of the voltage to give unidirectional, or direct current voltage at the two armature terminals. It is the commutator that requires the rotor to be the armature so that coils and their switching arrangement always move exactly together. Direct-current generators are generally limited to several thousand kilowatts and their application lies mainly in industrial plants of a specialized nature.

Rotating electric generators are driven by a variety of turbines, notably steam, gas, and hydraulic turbines; by gasoline, gas, and diesel engines. These drivers are described under their appropriate alphabetical entries in this volume. The type of driver used is predominately influenced by the type of fuel economically available at a given site as well as local and regional environmental regulations.

Among the major developments within the last few decades are the superconducting turbine generator and the magnetohydrodynamic

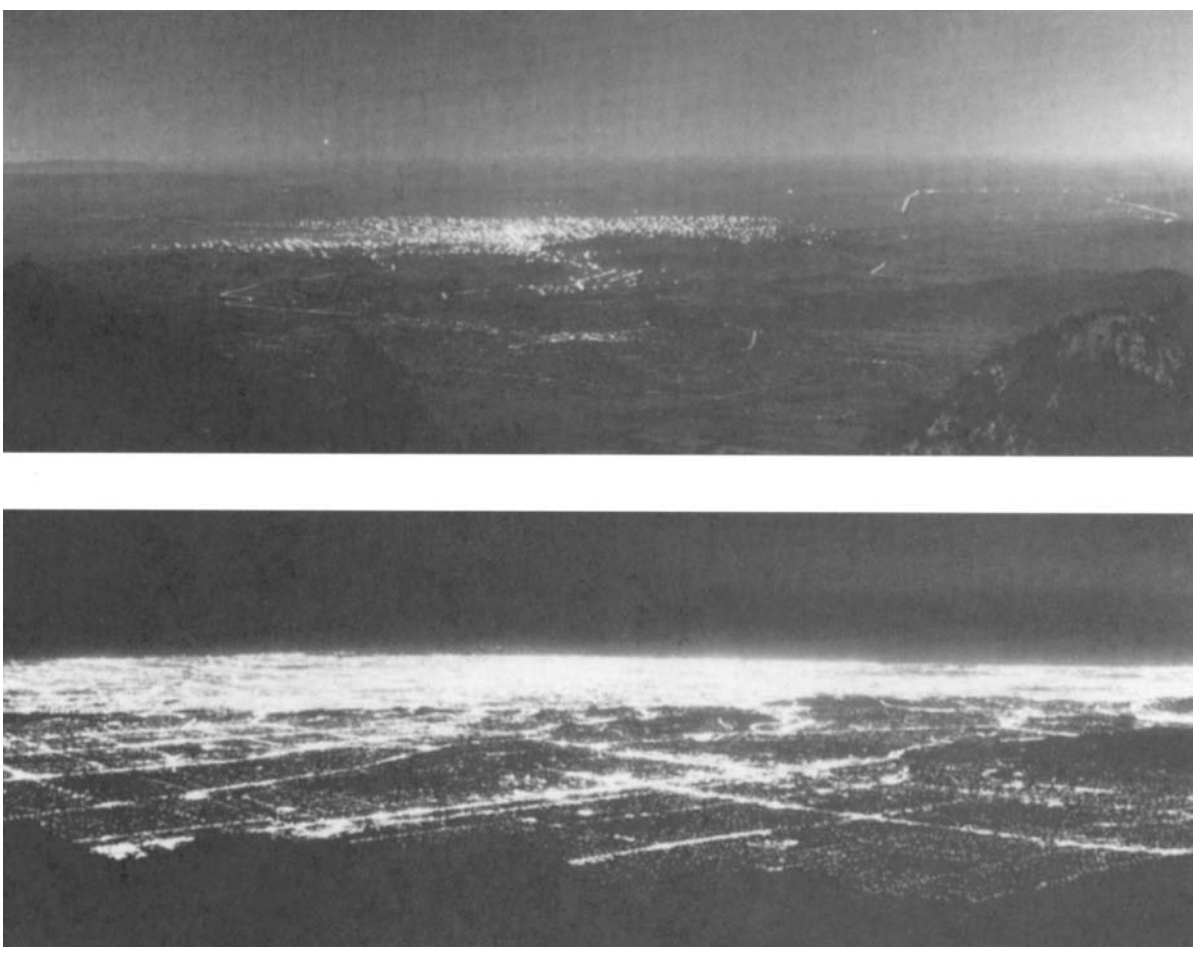

Fig. 9. The fantastic growth of electric power that has occurred during the present century is dramatically illustrated by these two views. They illustrate, of course, only one of the numerous major uses of electric power, illumination. (**a**) View of the Los Angeles basin from Mount Wilson Observatory taken in 1908; (**b**) the same view taken in 1971. Fig. 10. Actual and forecasted consumption of natural gas for generating electricity. NUGs = nonutility generators of electricity. (*North American Electricity Reliability Council.*)

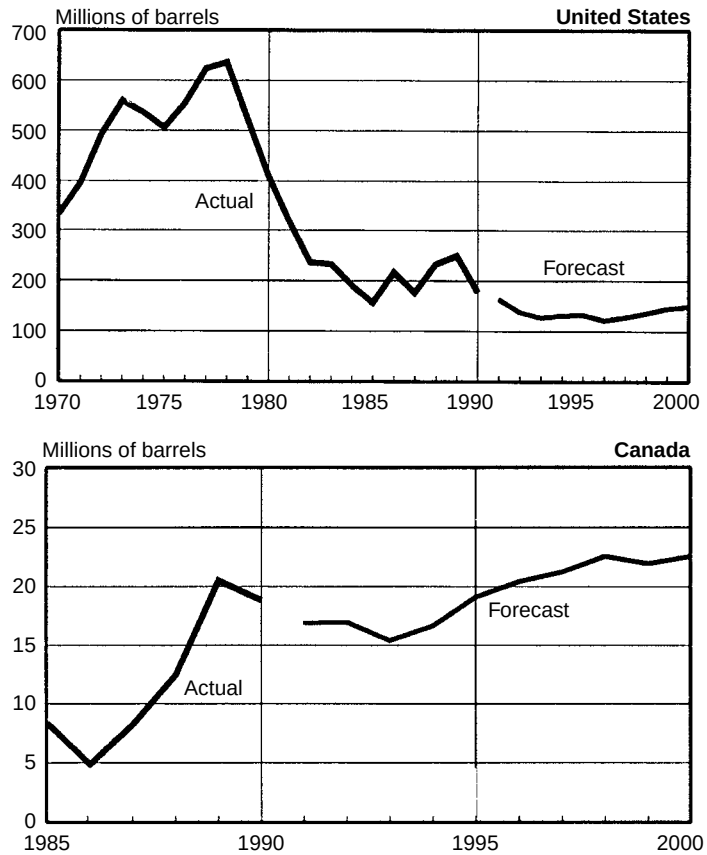

Fig. 11. Actual and forecasted consumption of fuel oil for generating electricity. Nonutility generators of electricity are not included in these charts. (*North American Electricity Reliability Council.*)

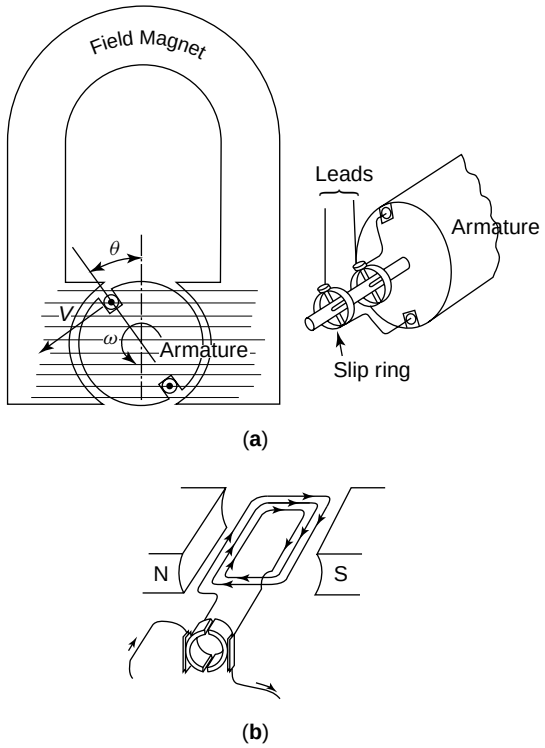

Fig. 12. Simplistic view of electric generator that consists of a soft iron core rotating between the poles of a permanent magnet, and having the slots on the surface, in which is embedded a coil of wire. It is apparent that as the coil rotates, carried by the soft-iron armature, it will cut across the flux lines, extending from pole to pole as shown in (**a**). When this apparatus is connected to stationary leads through the medium of slip rings, and brushes resting thereon, it becomes an elementary alternator. If, instead of slip rings, a split segment, such as that shown in (**b**), is connected to the ends of the coil, the reverse of the current in the coil will occur when alternate segments of the slip ring (an elementary commutator) are opposite one of the brushes. This gives unidirectional current in the exterior leads, although it would be quite variable with only one coil in the armature.

A uniform and unidirectional current is the result of many single-coil armatures so connected that the resultant current is the sum of several individual outputs. With sufficient overlap, the resulting current will be uniform and unidirectional. When the coil is revolving at a speed of ω radians per minute, at the position indicated, the speed of cutting vertically across flux lines is $v \cos \omega t$. The time is measured from the vertical position of the coil, and angle ϕ is ωt. When a wire cuts a magnetic field having a flux density represented by b and has a length and velocity represented by l and v the voltage generated is $blv/10^8$ volts, thus the voltage generated any instant t, t being measured from the point of minimum generated voltage, is $blv/10^8 \sin \omega t$.

The dc generator is an ordinary dynamo machine having a multiple-coil winding, the ends of the coils of which are connected to a multiple-segment commutator. The armature is usually rotating, and the field stationary. The field sets up magnetic lines of force, which are cut by the conductors on the revolving armature, giving rise to a generated voltage, which is led through the commutator to a unidirectional external circuit. The iron core is built of laminations of iron insulated from each other by mill scale, or lacquer, or japanning, so that eddy currents which can be generated in the iron core, will be a minimum. The field windings are usually stationary, and the armature rotating; hence low voltage is the usual condition of use of dc generators.

generator. The application of superconductivity to synchronous machines with rotating field winding was pioneered at the Massachusetts Institute of Technology, commencing in 1967. The development of large superconducting generators for electric utility applications addresses a number of specific needs of the utility industry. By replacing the conventional copper conductor field winding in the rotor of a synchronous generator with a high capacity superconducting winding that virtually has zero resistance at cryogenic temperatures, important benefits are gained. The most obvious advantage is the elimination of rotor I^2R loss. The resulting reduction in excitation power is accompanied by a similar reduction in rotor ventilation power requirements. Increased power density and the resulting elimination

of stator iron at the armature winding are some of the more subtle, but nonetheless beneficial characteristics of the superconducting synchronous machine. See also **Superconductivity**.

The magnetohydrodynamic generator is one in which a thermally ionized gas is forced at high temperature, pressure, and velocity through a duct situated in a transverse magnetic field. An induced voltage appears in the third mutually perpendicular direction (Hall effect), and this voltage may be tapped by electrodes within the duct. If the exhaust gas from the magnetohydrodynamic generator is used to heat steam for a conventional generator, a larger portion of the thermal spectrum can be utilized and the system efficiency may be raised from the tradition value (about 40%) to possibly 50 or 55%. The art of the magnetohydrodynamic generator is not in the high development stage as is the case of the superconducting generator, but active research goes forward. Considerable attention has been given to the potential use of magnetohydrodynamic generator units as infrequently required peaking units. See also **Magnetohydrodynamic Generator**.

Electric Power Transmission

Energy may be transmitted electrically in overhead wires or underground cables as an electronic flow under pressure, the flow being measured in amperes. The voltage is the electric pressure. Electrical energy is proportional to the product of these two quantities. This energy for all practical purposes cannot be transmitted without some losses, the principal one being a resistance loss, which depends upon the current flow and the size of the conductor. In transmitting a given amount of energy, this loss may be reduced by increasing the voltage, with a corresponding decrease in current. Thus, the use of higher voltages increases the efficiency of electric power transmission by decreasing the conductor loss. In addition, there are economic motivations for increasing transmission line voltages. The power that can be transmitted by a line increases with the square of the voltage and decreases directly with the distance. Therefore, for a fixed distance, a doubling of the previous line voltage will permit about four times as much energy transfer. Over the years, the voltages of new transmission overlays have increased progressively.

For several years, AC high-voltage transmission lines have trended toward higher voltages. The lines range from 115 kV to 765 kV upward. The majority of lines installed in the mid 1980s were at voltages greater than 345 kV. A small part of the 350,000+ miles (565,000 km+) of installed line is DC (up to ±400 kV). To meet electric power requirements, the total is expected to be well over 450,000 miles (725,000 km) by the year 2000. Present accelerated research into superconductivity, which feasibly may impact on electric power transmission as it already has done in connection with generators, is indeed difficult to forecast.

Expansion of transmission lines arises from a number of needs, including: (1) to supply load centers from new generating facilities; (2) to provide more interconnections between individual electric utility systems and pools, in an effort to improve the reliability of power supply systems; and (3) to better distribute available generating capacity — in effect, in some instances, delaying need for new capacity for a while. The essential economy or savings derived from ties between power systems is that peak loads can be handled with less plant investment than if each region were to install the required capacity to meet its own peaks.

From the inception of transmission, the increase in voltage was based on technology and economics. Early changes in transmission voltage reveal a doubling of the previous level when a change was made. One exception is the single, unique use of 287 kilovolts (kV) from Hoover Dam to Los Angeles. Generally, transmission remained at a level of 230 kV from 1922 until 1953 when the first EHV, 345 kV transmission lines were placed into service. During the mid-1060s, 500-kV-class transmission came into being, with 765 kV coming onto the scene in the early 1970s. See Fig. 13.

The majority of the EHV lines through the 1980s utilized alternating current. However, because reactive compensation for extra-long high-voltage AC lines is expensive and line losses are very high. HVDC has become an economical alternative. Line losses for DC are approximately 33% lower since DC power, by its nature, is not subject to reactive power losses. The construction of a HVDC transmission line is lower in cost, requiring only two conductors per line as opposed to three per line used in AC three-phase transmission. This allows for lighter towers to be used and consequently ‘narrower rights of way. Less insulation is normally needed on a DC line to deliver the same amount of power. The first attempt at DC transmission in the United States occurred in 1970 when an 800 kV (±400 kV) line known as the Pacific Northwest Southwest Intertie was placed into operation. This bipolar, overhead line permitted an exchange of power at peak load times between two regions 850 miles (1368 kilometers) apart.

Terminal conversion equipment, however, continues to be the major obstacle to widespread use of HVDC. Since a terminal is made up of an AC switchyard plus a valve hall and harmonic filters, size and area requirements are excessive. The development of a solid state thyristor valve, however, enabled the cost of HVDC to remain stable, in addition to simplifying and improving the reliability of the conversion process. See Figs. 14 and 15.

As previously mentioned, the energy loss caused by current flowing through the line resistance is not the only loss of energy in power transmission. The long stretches of parallel conductors have a capacitive effect, causing them to draw a current much as a condenser, even though the switches at the far end of the line are open. Furthermore, at high voltages, the air surrounding the conductors becomes partially ionized, and there exists a brush or corona discharge, which represents a leakage of energy. The latter, as a matter of fact, is a limiting factor in the raising of electrical pressure on the transmission line and on the size of conductor, and tends to offset the savings due to the reduction in current made possible by an increase in voltage. Good transmission line design requires proper coordination of voltage, wire size, and line losses, so that the desired power may be transmitted at a minimum total annual cost.

When current flows on a long transmission line, the inductance and resistance of the line, plus the shunt capacitive effect, cause the voltage at the receiving end to vary with the load, even though the voltage is constant at the sending end. This effect is known as transmission line regulation, and can be calculated quite accurately. From the standpoint of the equipment served, it is desirable that this line regulation be controlled so that utilization equipment eventually supplied from step-down transformers may operate within a reasonable voltage range. Regulators and tap-changing transformers are among the means employed to control transmission line regulation. Furthermore, it can be demonstrated that the economy of power transmission varies as the square of the power factor, making it extremely desirable to operate the transmission line at unity power factor. On account of the induction characteristics of most electrical loads, and the capacitive effect of a transmission line itself, the current on a transmission line will tend to vary from lagging to leading or vice versa with load, although customarily it tends to be lagging. For this reason, a synchronous motor has the advantage of providing some power factor correction. Another method to improve the power factor is to connect static capacitors to the line.

A number of methods have been proposed in past years for VAR (volt-ampere reactance) optimization, but serious shortcomings have prevented them from fully exploiting the VAR and voltage control capabilities of currently available devices. See Fig. 16.

The physical exposure of the ordinary transmission line makes it a likely victim of lightning, and no extensive transmission line could be successfully operated without adequate lightning protection. This may consist of lightning arrestors strategically placed, or an overhead grounded guard wire. Direct strokes are usually immediately dissipated by flashover on the insulators, the lightning then finding its way down the pole to the ground. High-frequency induced waves (2000 to 5000 cycles) may not possess flashover potential, and will travel along the line until discharged by an arrestor, or attenuated, i.e., dissipated in resistance loss. Aside from lightning, a line should be protected against overload and short-circuits. This is commonly the function of transformer fuses, substation circuit breakers, or circuit breakers in general.

In the early 1980s, EPRI established a High Voltage Transmission Research facility, staffed by experts in transmission line research and testing. Located on a large site in Lenox, Massachusetts (near Pittsfield), the facility is well suited to assess the effects of a wide range of weather conditions on high-voltage lines. Surrounding hills shelter the site from high winds and severe vibration, but the facility experiences ample fog, rain, snow, and temperature variations appropriate for electrical and environmental studies. Work at the facility centers on evaluation of insulator performance, corona phenomena, and electric and magnetic fields. Some of the specific studies have included: (1) assessment of the nonbiological field effects of induced voltages and currents on conducting bodies; (2) investigation of ways to reduce radio noise and audible noise emanating from high-voltage lines; (3) evaluation of the electrical strength

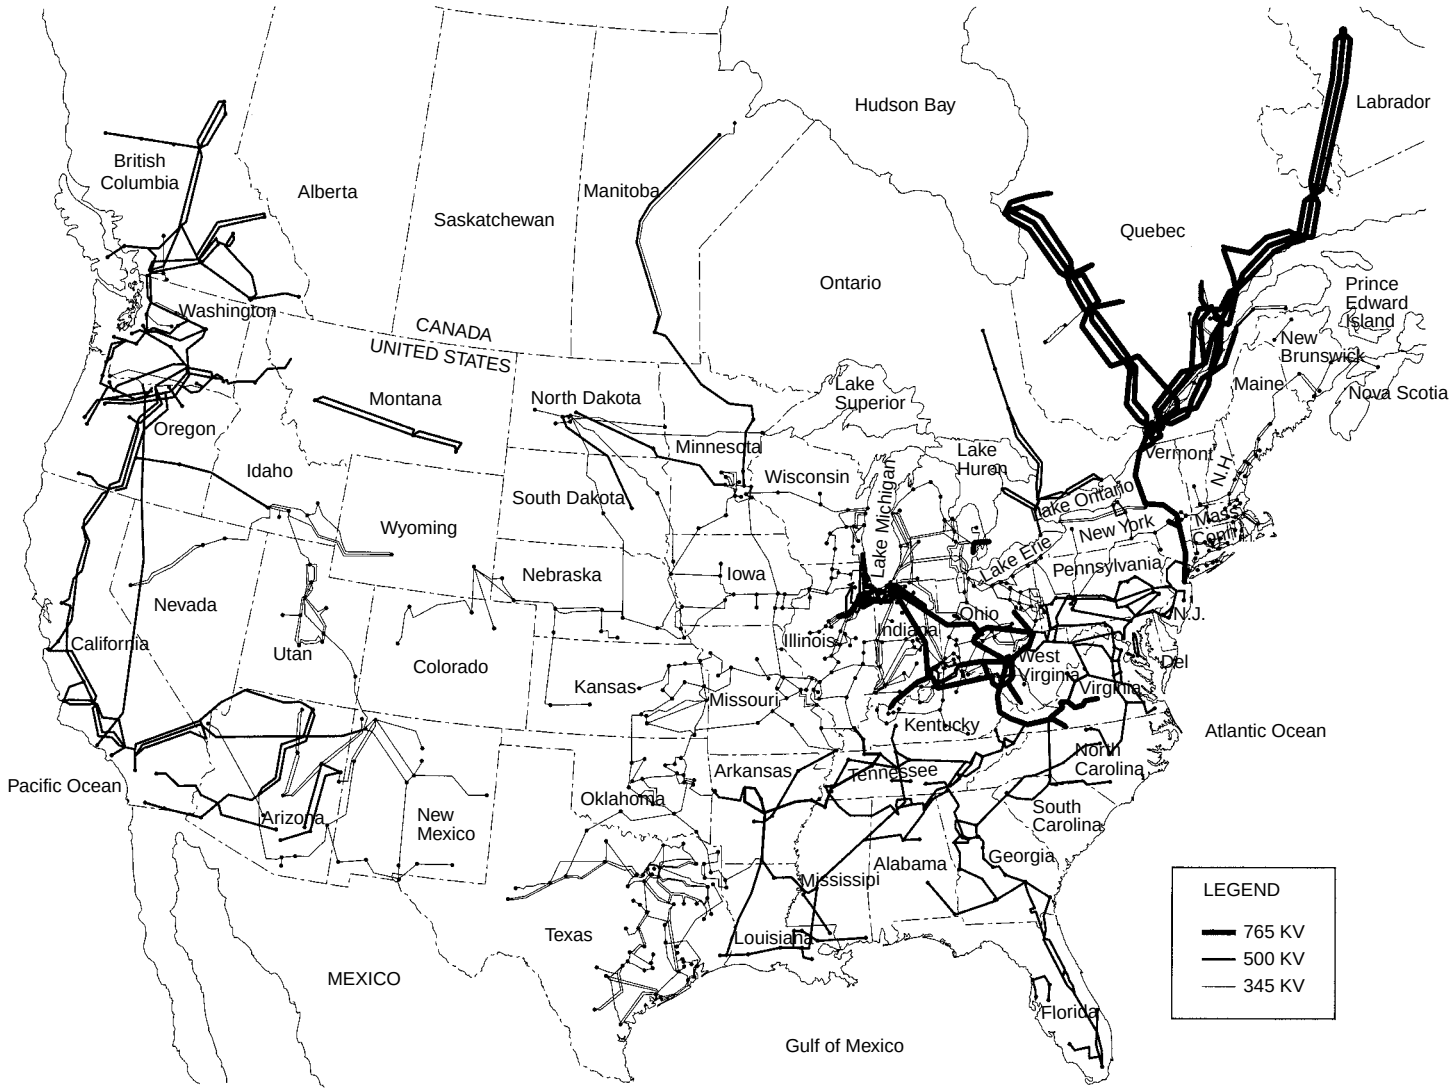

Fig. 13. Transmission networks (extreme-high voltage) and their principal transmission facilities in the United States as of the late 1980s. (*American Electric Power Service Corporation*.)

of insulators subjected to surface contamination; (4) determination of the effect of tower geometry on air gap insulation strength; (5) determination of the effects of switching surge amplitudes on line insulation design; and (6) development of guidelines for hybrid A.C./D.C. lines. See Fig. 17. See also **Lightning**.

Turning from electrical to mechanical characteristics of electric power transmission, the material used as a conductor is generally either copper or aluminum, frequently with a steel core for mechanical strength. The former is used in many cases, but the latter is in use for the very high-voltage lines because the larger diameter is effective in reducing corona loss. It also has low relative cost and high strength-to-weight ratio. Except for very low-voltage distribution network lines, the wires are not insulated, and are carried, mechanically held in position, by insulators of porcelain or glass. Sometimes these insulators are mounted rigidly on the cross arm of the poles, but for the higher voltages suspension insulators are used. On high-voltage lines, each insulator is a chain of separate units, so that the voltage from the line to the pole or tower has a uniform gradient across the insulator.

Galvanized steel, self-supporting towers or poles, or wood H- or K-frame structures traditionally have been used to support overhead transmission conductors. Guyed towers or poles have the least weight, which can be further reduced by the use of aluminum instead of steel. For EHV applications, self-supporting steel towers are most commonly used. The lower voltage subtransmission lines are generally supported by wooden poles using cross arms. A commonly used pole is of southern yellow pine, well creosoted. The towers or poles should be sufficiently high so that, at the middle of the span between them, the bottom of the wire sag has a minimum clearance over the ground, as specified in the safety code.

The spacing of poles must be chosen with due regard for temperature and sag conditions. Larger sags in the wire between poles give lower stresses in the wire, and permit the use of longer spans, but at the expense of the use of taller poles to maintain the minimum clearance. Consequently, the observer may see extremes of design representing individual designers' viewpoints, varying from relatively low, closely spaced poles, with little sag, to long spans where tall poles are spanned by wire having a much greater sag. At the same time, the effects of contraction caused by lowering of temperature in winter, and the loads suffered during storms, particularly sleet storms, must be guarded against.

In the early 1980s, EPRI established a Transmission Line Mechanical Research Facility (TLMRF), which is located near Fort Worth, Texas. The TLMRF has been acclaimed as the world's most advanced facility for transmission systems structural testing and research. As shown in Fig. 18, the facility is equipped to test towers up to 180 ft (55 m) high by means of three longitudinal and two transverse reaction frames. These frames can apply maximum pulls from any level; maximum pulls for all transverse loads, and longitudinal loads at one-half the transverse load for each longitudinal reaction structure. Concrete test pads can support all types of transmission structures, up to and including 1200-kV towers. A unique feature of the facility is that both research testing and proof testing can be performed at the same time. A nonenergized 345-kV prototype transmission line is a part of the facility, thus permitting experiments with respect to total structural system behavior under real-life conditions.

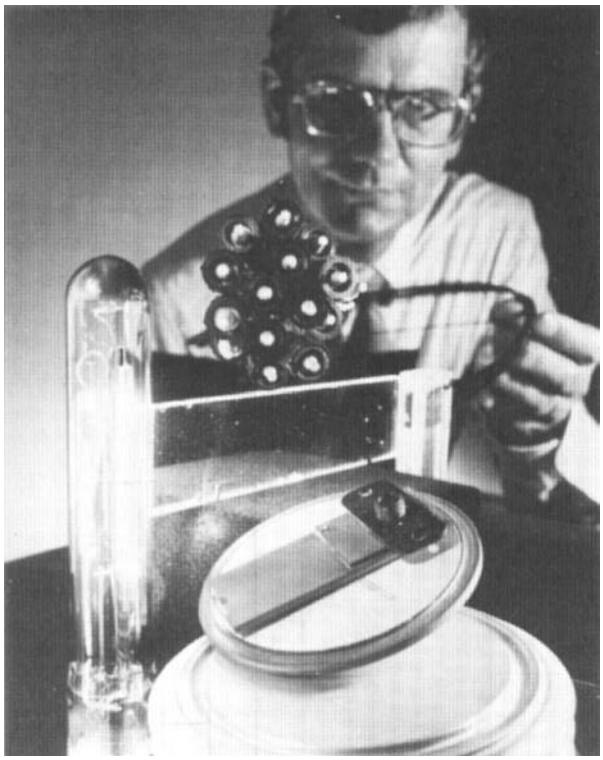

Fig. 14. In the late 1980s, electric utility industry researchers reported that increasing use of solid-state switching systems is being made in phase control and high-voltage dc converters. These systems are composed of a multitude of thyristor (silicon-controlled rectifier) switches connected in series/parallel configurations to provide high-voltage, high-current capabilities. Recently, it has become feasible to trigger high-power thyristor switches by the direct action of infrared (IR) light on a photothyristor. Systems using such thyristors have the advantage that the triggering light signal is carried by electrically insulated fiber optics, and special insulation is not required for the gate circuit. An additional advantage is that the fiber-optic cable is immune to electrical noise pickup and the attendant possibility of destructive accidental triggering. (*Electric Power Research Institute*.)

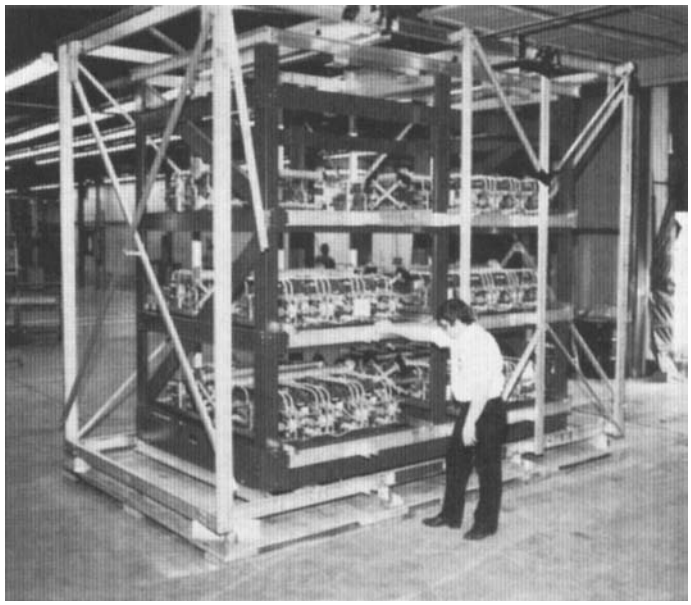

Fig. 15. Since thyristor valves presently account for approximately one-third of the cost of an HVDC terminal, the objective of research has been to develop an advanced thyristor valve that will exhibit improved performance, smaller size, lower losses, and lower cost than traditional thyristor valves. Research targets have included a light-fired, 77-mm-diameter cell, with 5000 V blocking voltage and a low thermal resistance package. Large increases in effective light output intensity have been obtained by advances in the cesium arc lamp design and by using more efficient fiber-optic cables. The new cesium amalgam lamps contain mercury in addition to cesium, and have a reduced bore to increase the arc intensity. As a result of these improvements in the lamp and in the fiber-optic cables, ample light intensity has been obtained at a thyristor gate over an optical path of some 18 meters (59 ft) at moderate pulsing current. For example, 33 times the threshold light intensity has been delivered to an experimental photothyristor by using pulse currents of only 300 amperes. (*Electric Power Research Institute*.)

Growth in Circuit- and Gigawatt-miles. In order to determine transmission system growth patterns, the parameter "total circuit miles" does not account for the disparity that exists in load capability for each of the voltage classes considered. A more meaningful way to measure this growth is in terms of capability of the transmission system to transmit power. Thus, the term gigawatt-mile is an excellent means of expression since it constitutes a measure of transmission capability. The term is analogous to "passenger miles" as used by the airlines, for example, to express the capability to transport people, or of "ton miles" in terms of freight.

Typical load-carrying capacity of circuits operated within the various voltage classes are shown in Fig. 19.

The impact of EHV on the growth pattern of transmission capability is evident from this chart. Until 1960, EHV accounted for less than 10% of the total capacity, while the lower voltage classes were the real work-horses. EHV growth began in 1964, and by 1970 accounted for three-fourths of the doubling in transmission capability that occurred during that period. Capital expenditure postponements by the utility industry on line construction were responsible for the decline shown in the mid-1970s. Although annual additions for 115–230 kV are expected to decline over the next 10 years, EHV is expected to grow at a greater rate for the same period. Future DC capacity is projected to be minimal for both 800 kV and 1000 kV voltage levels.

Trends in Overhead Transmission. While there are economic benefits for three-phase transmission at higher voltages, economic advantages for shifting from very high voltage three-phase transmission to lower-voltage high-phase-order transmission has also been demonstrated. Both six- and twelve-phase systems are being considered developmentally. A prototype of a six-phase line has been built and is currently being tested to obtain data on radio noise and electric field effects. Mechanical testing will be done under various conditions to observe conductor movement. A significant problem to be solved in multiphase transmission (6 or more phases) is relaying and protection.

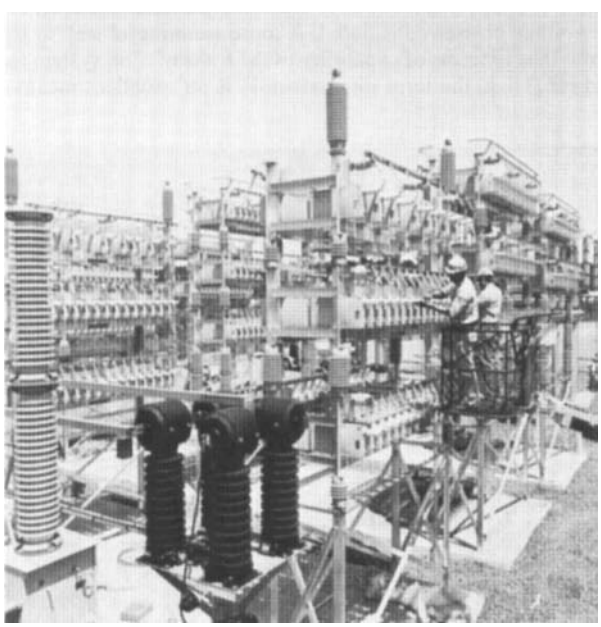

Fig. 16. In the late 1980s, EPRI initiated a project to research methods for improving VAR optimization. The project resulted in a decoupled optimal load flow program suitable for large-scale system analysis. The program has been successfully tested for active power optimization, and the testing of reactive power optimization is in progress. (*Electric Power Research Institute*.)

Reduced rights-of-way and the desire to reduce transmission losses are among the factors that have forced the utility industry to higher-voltage

Fig. 17. A portion of EPRI's research and test facility located in Lenox, Massachusetts. The HVTRF (High Voltage Transmission Research Facility) specializes in research on insulators, corona phenomena, electric and magnetic fields, and all aspects of transmission line design and performance. (*Electric Power Research Institute*.)

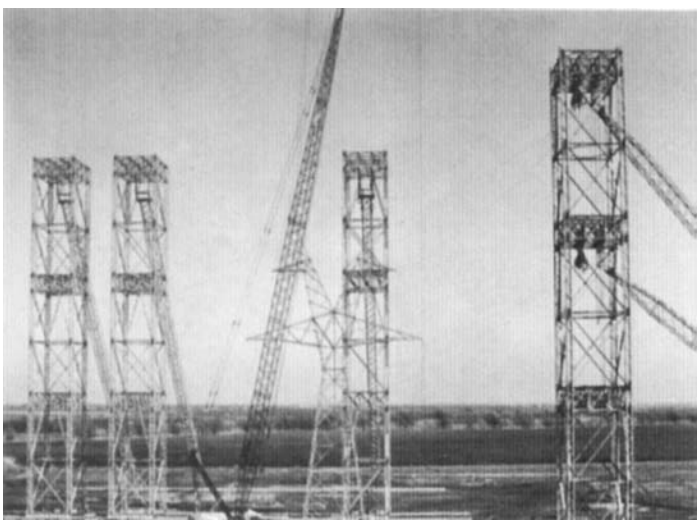

Fig. 18. View of transmission tower testing frames in place at the EPRI Transmission Line Mechanical Research Facility (TLMRF), located near Fort Worth, Texas. (*Electric Power Research Institute*.)

transmission systems. The development of technology for 1200 kV lines and equipment has been in progress in the United States since 1967. Among the problems of ultra-high voltage transmission are radio and audible noise, induction effects, corona and generation of ozone, and mechanical stresses imposed upon the multiple-conductor bundles used. Studies have shown benefits for a single UHV line, compared to two 500 kV lines, when comparing line constructing costs, annual cost of delivered power, and cost of losses. Reliability of a single UHV line is less, however, than two EHV lines, since the single-line probability of outage is greater than that of two lines.

Considerable research and development efforts are underway in the area of DC transmission with concentration on developing more compact, lower-cost terminal converter facilities, increased voltage levels, and

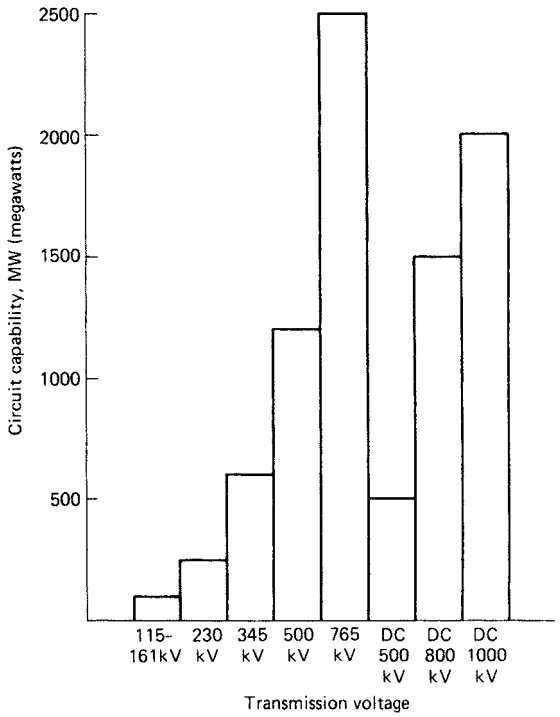

Fig. 19. Typical circuit capabilities.

the expansion of the market to multi-point projects. Specifically, funded projects include HVDC transmission line research, thyristor valve improvement and uprating, HVDC circuit breaker development, and HVDC/HVAC interaction and system studies.

Underground Transmission Technology. Overhead transmission systems are the most logical choice for utilities unless the overhead lines are barred by topography, legislative action, or nonexistent (or extremely expensive) rights-of-way. Cost has now become a strong factor to consider when planning transmission expansion. The generally accepted ratio of installed costs, underground to overhead, that ranged between 10:1 and 20:1 is no longer used. Studies show that no general comparison between system costs is practical due to the different attributes of each new circuit. The various differences include price and availability of land, population distribution, terrain, load size, circuit length, and local regulations. Local input is becoming an ever-larger influence in the transmission planning process.

Although comparisons of the two technologies for rural installations show cost ratios as low as 5:1, cost is still a heavy disadvantage of going underground. In a typical city installation, for example, where the majority of underground circuits are employed, nearly 50% of the circuit cost is incurred in cutting the trench, pulling the cable, backfilling the trench, and reconstructing the surface. Consequently, only 1% of all transmission circuit-miles in service in the United States is installed underground. For this percentage to change, new and improved methods of underground transmission will have to be developed. Research is being sponsored for the development of new cables and more efficient underground installation methods that will result in decreased cost and more reliable systems.

Figure 20 summarizes the new and existing types of underground transmission systems with a time schedule showing their dates of commercial application. A brief discussion of each of these technologies follows.

Pipe. Over 75% of the underground circuits in the United States consist of pipe-type cable systems. This type of system utilizes three oil-impregnated paper-insulated cables enclosed in a single steel pipe with oil under high pressure. This high-pressure, oil-filled (HPOF) cable has been in service since the mid-1970s and designs rated up to 500 kV have been successfully tested. Limitations that still exist with HPOF cables include excessive overload temperature rise, high losses in the insulation, and severe charging currents at higher voltages. In addition, they are subject to occasional failures. High-quality semi-synthetic insulation systems and forced-cooling techniques are being investigated, as are rapid techniques for fault location.

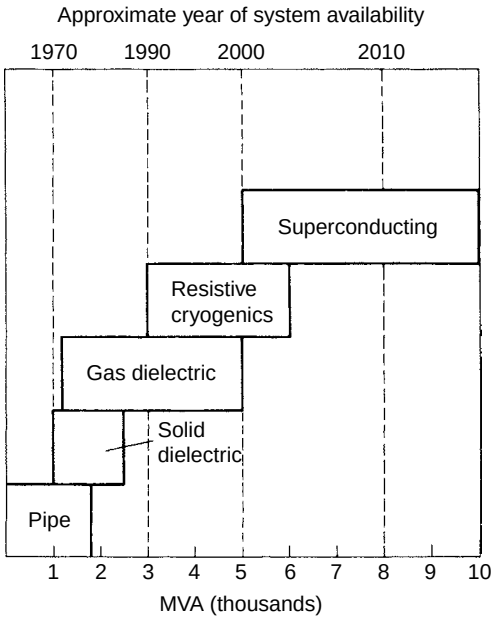

Fig. 20. Comparative capabilities of underground transmission systems.

Fig. 21. Flexible gas-insulated transmission line under test at an EPRI facility. The development of flexible gas cable extends the advantage of SF_6-insulated cable (low losses, inexpensive termination, and no oil handling equipment) to lower power levels (from 2000 MVA to 1000 MVA at 345 kV) and considerably improves the economics and ease of installation. It has been estimated that the flexible system will be about 25% less expensive on an installed basis as compared with the rigid-isolated phase gas cable. (*Electric Power Research Institute*.)

Gas Insulated. Both rigid and flexible gas-insulated cables have been developed. In this system, sulfur hexafluoride gas is used for the insulating and cooling medium. Rigid cables of a single-phase design, while capable of transmitting large quantities of power, are only economical for short runs. To overcome this problem, researchers developed a three-conductor, gas-insulated cable. Overall system size is reduced and a 15–25% reduction in cost is possible. Installation is easier and more efficient, because splicing and field welding are reduced considerably. See Fig. 21.

Solid Dielectric. This system normally utilizes cable of the extruded polyethylene type, where a solid insulation of the synthetic material surrounds the conductor. These cables are easier to handle than the previous types because no insulating fluid is involved. The reliability of these cables, however, is heavily dependent on the purity of the dielectric. Any contaminants can cause electrical discharges that result in failure. Methods have been developed, and are now being perfected, to combat these contaminants and enhance cable reliability. Development and testing is currently being carried out for cable designs at 138 kV. A 230 kV cable has also been produced and will be tested after splice and terminal developments have been completed. A 345 kV cable is under development.

Resistive Cryogenics. Since electrical resistance is a function of the conductor temperature, it is possible to reduce the heat losses in a system if operation is at low temperature. The two conductor metals, copper and aluminum, have electrical resistances at liquid nitrogen temperatures ($-320\,^\circ$F; $-196\,^\circ$C) of one-tenth the magnitudes at normal ambient temperatures. In order for cryogenic systems to be considered efficient, reductions in resistance have to generate savings that match or exceed the cost of refrigeration. Cryogenic systems are currently limited by the high cost and low efficiency of gas expansion-compression refrigerators. Recent attempts to develop a magnetic refrigerator have fallen short of both design goals and what would be needed for a practical refrigerator.

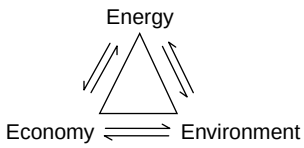
Superconducting. Superconducting systems operate at even lower temperatures, down into the liquid-helium range of $-452\,^\circ$F ($-266.9\,^\circ$C).

Certain metals, such as niobium, lose their electrical resistance at these temperatures with the result that extremely high currents can be transmitted with low losses. Superconducting systems have demonstrated overall efficiency, that is, there is a net gain when savings and costs are compared. Research on superconductivity has been one of the most aggressive areas in both physics and chemistry since the early 1990s. See also **Superconductivity**.

Basis for Electric Power Research

There are several goals that science and advanced technology can target for solving global problems and ultimately achieving a better, more meaningful life for all peoples. Solutions for many problems obviously remain, but within the past decade in particular, technology has accelerated and numerous answers (what might be termed *intermediate* answers) have resulted. For example, science has contributed effectively toward identifying problems and the general application of the principles of physics and chemistry to the economic and sociological aspects of energy-related problems. Further, a lot of background evidence has been collected, much of which has been derived from sophisticated measurement methods. This has made industry and the general populace aware of the need for advanced nations to tackle what seem to be almost innumerable problems, if people are to continue a safe and rewarding life on Earth and, further, to shield future generations from a deteriorating planet.

The triangle below (repeated from the entry on **Coal Conversion (Clean Coal) Processes)** illustrates the inevitable conflicts between three great factors — the economy, the energy, and the environment. These conflicting forces will remain until drastically new progress is made in our *energy supply* situation.



Economy. The economy of developed nations and of underdeveloped nations (in particular) depends on the availability of reasonably priced energy. Without affordable energy, the impact of energy costs on a national economy can be tremendous. The perfection of new, environmentally attractive energy sources can be achieved only at the expense of the economy. (There may be an exception in the case of nuclear energy, but this topic enters into the realm of public fears and apparently — with the exception of a few nations, such as France — is not politically viable in the absence of an effective educational program.) See also **Nuclear Power Technology**.

Environment. The triangle also shows the inevitable conflict between energy and the environment. See also **Acid Rain**; **Pollution (Air)**; and **Water Pollution**. The environment also conflicts with the economy because the effective partial or intermediate environmental solutions achieved thus far for traditional fossil fuels carry a great expense.

Environmental control equipment can account for 40% of the costs of a new power plant. This does not include operation and maintenance of the equipment, which amounts to perhaps 25–30% of operating costs. See Caruana reference listed.

Energy. The impact of energy costs on the economy has been demonstrated dramatically, notably in the early 1970s at the time of the Middle

East oil embargo. Although a large anti-coal sentiment has developed, particularly in the United States during recent years, the fact remains that coal represents a very significant portion of the nation's potential energy supply. Experience has demonstrated that technology also has its own problems (i.e., economic investment alone cannot hasten technical development beyond a certain pace). Technology has an inertial factor, not always appreciated by scientists and lay people alike. Breakthroughs cannot be legislated. Consequently, from a very practical standpoint, in the absence of a political and sociological solution to nuclear energy, it appears that, to remain a leading nation of the world, the United States cannot turn away from coal as a significant energy source. Logic thus dictates that using clean coal processes, including greatly improved combustion schemes, is of high priority for advanced technology. Thus, for those intermediate solutions previously mentioned, much funding and effort is being directed toward reducing and possibly ultimately eliminating serious damage to the environment.

Less frequently stressed is how the design of electricity-consuming equipment and conservation efforts on the part of consumers can reduce energy use and thus lessen the environmental impact. Although energy waste often is obvious, it is left uncontrolled. As one example, witness the overcooled buildings in summer; the overheated offices, apartments, and houses in winter!

Electric Power Technology Research Needs and Goals

Few major commercial and industrial enterprises interact with and depend upon so many segments of science and technology as the electric power industry does — in both the United States and other advanced industrial nations. Just analyzing and classifying the many research projects currently underway and to be continued and projecting research needs far into the future is a massive undertaking. A laudable effort along these lines began over a decade ago by a consortium of electric power suppliers across the country and in some cases in collaboration with electricity suppliers in other parts of the world.*

I. Extension of Electric Power Applications

1. Develop new appliances, tools, processes, manufacturing methods, and so on that can use electricity more efficiently or that substitute electric power for other energy sources that presently are polluting and inefficient.
2. Develop improved electric power delivery systems that are better tailored for specific end users.
3. Develop advanced refrigeration systems that do not require the use of polluting chlorofluorocarbons.
4. Develop new concepts in electric transportation systems that do not rely on polluting fuels. This includes research on electric cars, more efficient motors, batteries, and solar power.

II. Environmental, Health, Welfare, and Safety Issues

1. Electric and magnetic fields (EMF) assessment. Technologically, this remained a poorly understood subject as of the mid-1990s. However, the electric power industry must continue to evaluate all new findings and conduct research on possible health risks and, should the problem be assessed as a health risk, develop options and strategies to mitigate such proven risks.
2. Provide scientific and technical basis, as well as risk management tools for electric power industry response to the climatic change issue. (This concerns the still-controversial issue of the effects of carbon dioxide on global warming.) See also **Climate**.
3. Develop remedial measures, as may be required from future studies of the climate. Subprojects include development of an air quality study, air toxics management, and environmental risk management.
4. Improve technological approaches to ground/surface waters protection, solid waste (including radioactive), disposal, and numerous occupational health issues.

III. Sustaining the Future of Electric Power

1. Study the safety/economics of nuclear plants, innovative nuclear concepts, and advanced fossil fuel technology. Subprojects include improvement of combustion turbines, corrosion research to increase operating safety and reduce materials costs, coal gasification/fuel cells, and the concept of distributed smaller power plants versus the large central stations.
2. Study and develop renewable energy resources, including geothermal, solar, biomass, and so on.
3. Explore advanced transmission technology, leading to the development and demonstration of methodologies and strategies that are more flexible and less costly by new approaches, such as by the use of superconductors.
4. Research energy storage systems, including compressed air, battery, and superconducting energy storage systems.
5. Conduct exploratory research to assure a fundamental knowledge base to support the development of cost-effective and environmentally sound advanced supply, delivery, and end-use technologies.

IV. Electric Power Production Cost Control

The electric power industry currently faces increasing costs at a time when competitive pressures are increasing. Numerous programs are underway for determining the cost and productivity of fossil fuel, hydropower, and nuclear power plants. Among the specific projects are those directed toward better instrumentation and automatic control of plant operations, provision of suburban underground transmission and delivery systems, automated maintenance, and computerized load management systems.

* "Research & Development Plan" prepared by the Electric Power Research Institute, Palo Alto, California. This publication describes in detail several research projects already completed, underway, or scheduled for future attention, as of 1993.

ELECTRIC POWER RESEARCH INSTITUTE (EPRI). A nonprofit organization with its headquarters located in Palo Alto, California (94304) USA. The EPRI is committed to providing science and technology-based solutions of indispensable value to more than 1000 energy-related organizations in 40 countries. To carry out our mission, we manage a far-reaching program of scientific research, technology development, and product implementation to solve today's toughest energy and environmental problems.

The EPRI was born of crisis — a crisis of both confidence and capability. The great northeastern blackout of 1965 in the United States revealed for the first time, serious vulnerabilities in the nation's electricity supply system. War in the Mideast in 1967 foreshadowed the energy crises of the 1970s and the danger inherent in our growing dependence on foreign oil. And the National Environmental Policy Act of 1969 kicked off decades of environmental legislation that would challenge utilities' scientific and technical capabilities. The convergence of these and related issues called into serious question the ability of the existing energy infrastructure to effectively serve the needs of the nation.

The creation of organizations like the Electric Research Council (ERC) and the North American Electric Reliability Council was, of course, a key step in dealing with these pressing issues. But the real problem was that the utility business was substantially underinvested in the science and technology required to adapt to changing needs. Individual utilities had neither the resources nor the breadth of expertise to deal with all the technical difficulties that were coming to a head. And even as the ERC formulated its incisive and farseeing research plan for the industry, the lack of an effective, securely funded organization to carry out the work itself was obvious. Threatened by Senate proposal in 1971 to create a federal agency to conduct electricity-related R&D, America's public and private utilities banded together to develop an industry-organized alternative — the Electric Power Research Institute, now known simply as EPRI. Under the leadership of founding president Chauncey Starr, EPRI opened its doors in 1973, taking over R&D projects previously managed by the ERC and the Edison Electric Institute and quickly expanding its work to cover the industry's most urgent and difficult issues. Chauncey's extraordinary vision of how these problems could best be approached — through central management of collaboratively funded research activity — was both tremendously effective and far ahead of its time. Over the past quarter century, first under Chauncey and subsequently under the solid leadership of Floyd Culler and Dick Balzhiser, EPRI has grown to be the industry's most versatile and valuable technical resource. Its scientific and technical achievements, have returned benefits to utilities and their customers conservatively estimated at over $50 billion — nearly 10 times the collective utility investment in EPRI.

EPRI framework for R&D. The Electricity Technology Roadmap.

The EPRI initiated the Electricity Technology Roadmap in 1998 as an ongoing collaborative exploration of the threats and opportunities for electricity-based innovation over the next 25 years and beyond. Thus far, over 150 organizations have joined with EPRI and its members in shaping a comprehensive vision for increasing electricity's value to society through technical innovation, and creating a new framework for public/private R&D.

The Roadmap lays out an essential solution pathway for meeting the economic, environmental and societal challenges of the coming century. The Roadmap Initiative is designed to be an ongoing process, and the scope and geographic reach of participation will continue to expand. As the participation broadens, the vision will be sharpened, the priorities will be modified as new ideas and new knowledge are introduced.

Substantial progress was made in 1999 on the Electricity Technology Roadmap. The first phase of the process has been completed and a progress report published entitled, "1999 Roadmap Summary and Synthesis Report." The report centers five key destinations and calls for a substantial increase in collaborative R&D at a time when the trends are moving in the opposite direction.

The Five Roadmap Destinations:

1. Meeting the escalating power reliability challenge.
2. Seizing the growth opportunities for customer-managed service networks.
3. Enhancing electricity's role in economic growth.
4. Resolving the energy/carbon conflict.
5. Managing global sustainability issues — Electricity-based innovation.

See Fig. 1.

Near-Term Implications of the Roadmap

Infrastructure is one of the most distinguishing features of a modern society, and its importance will only grow as microprocessor-based technology transforms the global economy. The pace of technology innovation itself will come to depend upon the mega-infrastructure of electricity and communications needed to support the unique requirements of the information age. Further, since the key factors of production — labor capital and technology — are becoming mobile around the world, stationary infrastructure will increasingly become the differentiating factor in global competition. Innovation will flow toward geographic areas with the most robust infrastructure.

Longer-Term Implications of the Roadmap

The energy requirements of 10 billion people in 2050 will be prodigious, and today's technology is inadequate to meet this demand while also meeting the environmental requirements of the 21st century. The transition

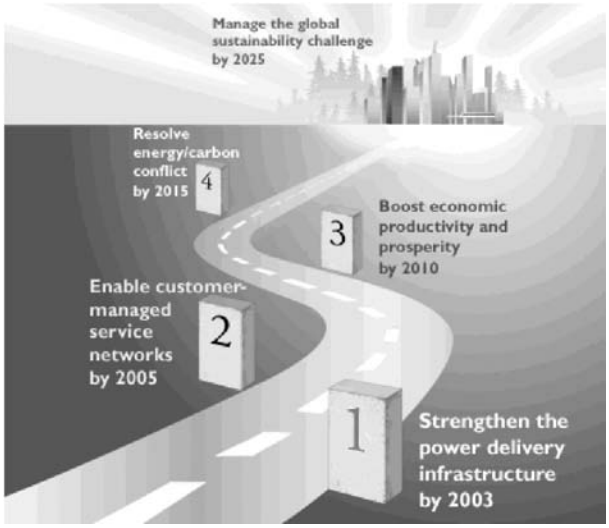

Fig. 1. The Technology Roadmap. *Electric Power Research Institute* (EPRI).

to lower-carbon fuels, underway for more than a century, must be accelerated to avoid high levels of greenhouse gas emissions. A robust, clean energy portfolio will require technical breakthroughs in solar, nuclear and fossil technologies, as well as methods of carbon sequestration in order to meet the goals by 2025.

The Institute maintains an on-line communications network (EPRINET).

ELECTRIC SHOCK. Experiments with human volunteers carried out by various researchers since 1933 have established that the mean threshold of perception (the first "tingle") experienced from an electric shock is 1.1 milliamperes (mA) for men and 0.7 mA for women. Slightly higher current (called reaction current) provides for the possibility of an unexpected involuntary reaction that might result, for example, in the dropping of a hot pan of grease or a fall from a ladder. In 1967, the American National Standards Institute (ANSI) and the Underwriters Laboratories (UL) were funded to determine reaction current levels. The result of these studies was an ANSI specification in 1970 that limited maximum current leakage levels to 0.5 mA for new, properly operating, 2-wire cord-connected appliances; and 0.75 mA for heavy, movable cord-connected appliances, such as freezers and air conditioners. While this specification predicts that new appliances should never give perceptible shocks, this may not be true after the hardware has aged for a number of years or has been misapplied or exposed to degrading environments. It should be emphasized that a poorly designed or poorly used 120-volt appliance is capable of delivering lethal shocks.

As the intensity of shock current increases, sensations of warmth, tingling, and muscular reaction increase and pain develops. Eventually, a current level is encountered at which a person cannot voluntarily "let go" because of muscular spasms and thus the victim is "frozen" to the circuit. This threshold is of great importance because under electrically induced muscular spasms, the musculature of breathing becomes paralyzed. Unless the circuit is interrupted, collapse, unconsciousness, and death may follow in a matter of minutes or fractions thereof. Research has shown that this threshold for men is 16 mA and 10.5 mA for women See Fig. 1. In the case of higher-current shocks, resumption of normal breathing may not occur for several minutes after the current is stopped. In these cases, artificial respiration is required to prevent physiological damage. At even higher current levels, heart action becomes seriously impaired or stopped, most frequently by the mechanism of ventricular fibrillation (VF).

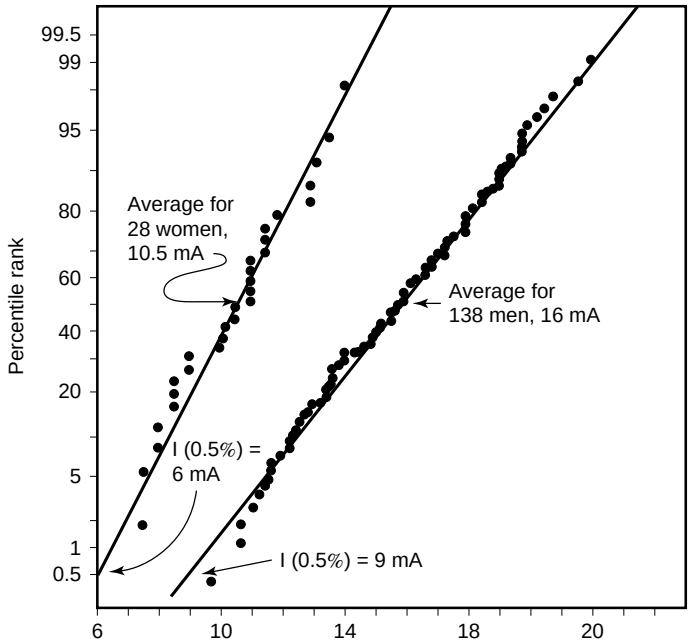

Fig. 1. "Let-go" currents for men follow a normal distribution, as do those for women, using a smaller test sample. Mean values (men and women) are in a ratio of two to three. (*After Dalziel*.)

Ventricular fibrillation, the most common cause of death from electric shock, is the result of desynchronizing the natural electrical impulses that govern the ordered muscular reactions that cause the heart to pump blood. In VF, the heart seems to "quiver" like a bag of jelly without effective pumping. Brain death normally occurs within 4 to 6 minutes when this condition sets in. After the onset of VF, normal heart action seldom resumes spontaneously and unless prompt defibrillation is effected by trained medical personnel, death is inevitable. Defibrillation is accomplished by applying a stronger, shorter duration shock of controlled amplitude and duration to electrodes on the chest. This stops the quivering for an instant and then allows the normal, synchronized heart action to resume. Cardiopulmonary resuscitation technique allows maintenance of circulation by rescuers for many minutes, even for hours with help, until defibrillation can be accomplished. See Fig. 2.

The complications that follow an electric shock vary considerably and depend mainly on the amplitude and duration of contact with electric current. In addition to heart complications, electrical burns and injuries caused by falling will require immediate attention. In addition to ventricular fibrillation previously mentioned, cardiopulmonary resuscitation may be required because of: (1) tetany of the breathing muscles, which is usually limited to the duration of exposure to the current; if the latter is prolonged, tetany may persist and cardiac arrest may occur because of anoxia; and (2) prolonged paralysis of breathing muscles, which may result from a massive convulsive phenomenon. This may persist for minutes after the shock current has terminated and may result in anoxic cardiac arrest. Cardiopulmonary resuscitation is only effective when performed on a victim who is in the horizontal position.

Of critical importance, the rescuers must make certain that they are in no danger of electric shock.

Considerable research has indicated that a normal, healthy 50-kilogram (110-pound) adult will not be likely to fibrillate if the current intensity is less than

$$I(\text{electrocution threshold}) = \frac{116}{\sqrt{T}}\text{mA}$$

where T is in seconds. The relationship to body weight appears to be direct; a 25-kilogram (55-pound) child's electrocution threshold is believed to be one-half the values given by the aforementioned formula. These values have been used in preparation of UL specification 943, which all UL labeled and listed ground fault circuit interrupters (GFCI) must meet. The National Electrical Code, which provides the basis for most building codes and inspections in the United States, requires the exclusive use of UL approved devices.

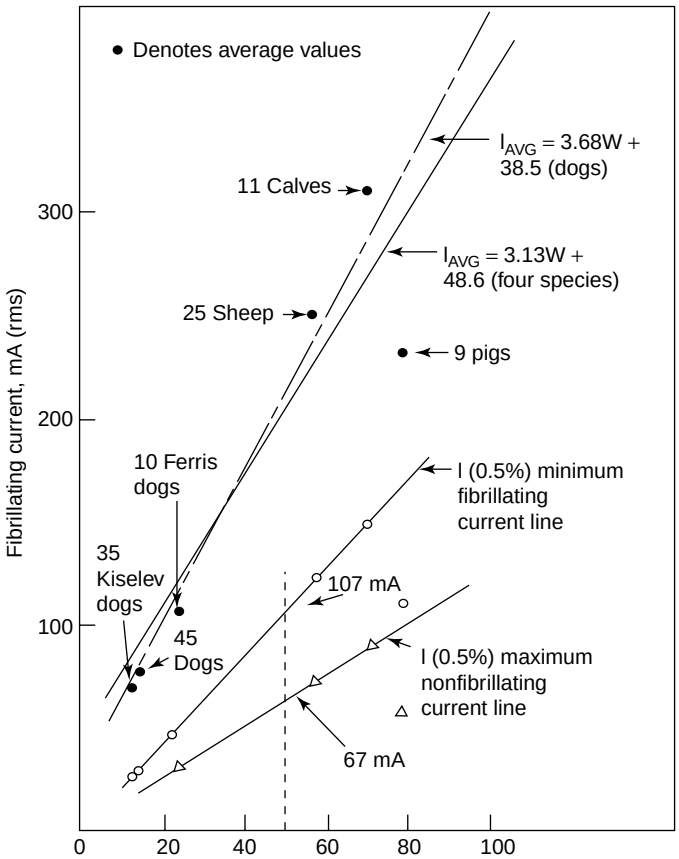

Fig. 2. Fibrillating current versus body weight for animals. These curves combine results of several experiments, including those on calves and pigs. (*GTE Laboratories*.)

The National Electrical Code (NEC) requires the use of GFCIs in all receptacle circuits of swimming pools, bathrooms, garages, and outdoor receptacles for new construction. In addition, all single-phase 120-volt receptacles used at construction sites or for other temporary use are required to have GFCI or specified other safety grounding measures.

ELECTRIDE. An experimental compound composed of an alkali-metal cation and an electron in which the electron functions as a chemical element (e.g., a halogen) in salt formation. Several such compounds have been made in the U.S. and abroad. The phenomenon is reported to be one that challenges accepted concepts of compound formation.

ELECTROACOUSTICS. See **Acoustics**.

ELECTROCAPILLARITY. The surface tension between two conducting liquids in contact, such as mercury and a dilute acid, is sensibly altered when an electric current passes across the interface. As a result, when the contact is in a capillary tube, the pressure difference on the opposite sides of the meniscus is affected by a current traversing the capillary column, to an extent dependent upon the direction of the current across the boundary.

ELECTROCARDIOGRAPHY. An electrocardiogram (ECG) is a graphical record of the electric potentials produced by activity of the heart. The normal beating of the heart is associated with the production of bioelectric currents in the organ. These currents are not strong, but they are carried to the surface of the body, where they may be measured by sensitive electrical instruments. The heartbeat normally is controlled by a rhythmically occurring electrical discharge that emanates from a spot in the right atrium known as the sino-atrial node (SA). This wave of electrical activity is spread through the heart muscle by a network of fibers known as Purkinje's network. As the wave spreads, the muscle of the heart rhythmically contracts and then gradually relaxes. The contraction, or squeezing of the muscle forces blood from the heart into the blood vessels, producing the needed pumping action.

As the wave of electrical activity spreads across the surface of the heart, the wave produces an electrical field, which spreads through the conducting medium of body tissues to the surface of the body. This field can be produced by an electric-dipole moment, which rotates and varies in amplitude in the course of the cardiac cycle. The pattern shown in Fig. 1 was produced by placing electrodes on the left and right arms. The characteristic features of this electrocardiogram are labeled as conventionally described by physicians.

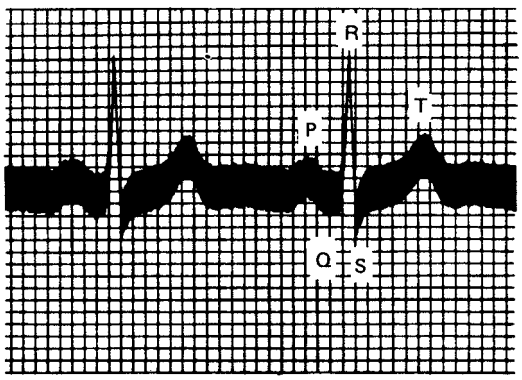

Fig. 1. Electrocardiogram of a normal subject.

The key wave is due to electrical activation of the atria of the heart; the QRS complex occurs at the time that the ventricles (or main pumps) of the heart contract; the T wave is caused by the repolarization or resetting of the electrical system following contraction. The contracting phase of the heart cycle is called *systole*, and the relaxed phase is known as *diastole*. Changes from the normal electrocardiographic pattern can be used to diagnose a heart attack and the progress and recovery from it. The pattern also can be used to diagnose and follow irregular heart rates (*arrhythmias*) and conditions of faulty conduction.

At the surface of the body, the voltage amplitude of a typical QRS complex will vary between 100 microvolts and 2 millivolts. Faithful reproduction of an electrocardiogram can be achieved with a frequency response flat between 0.25 and 100 Hz. There are some pathological situations that produce "splintering" of the QRS complex that can be easily detected only with a frequency response to approximately 1,000 Hz. This is not a common requirement and most recorders do not have a response above 100 Hz. To produce a faithful electrocardiogram, the voltage-amplifier input impedance should be above 0.1 million ohms and preferably above 1 million ohms.

In order to avoid motion artifacts in the record, care must be taken in the choice and application of the electrodes. Chemical action will cause a gradual change in the impedance of the skin-metal interface, which slowly will reduce the amplitude of the ECG and, more seriously, will produce an abrupt change in the DC level, as this resistance changes with relative motion between the skin and the electrode. If silver is used as the electrode, chloride ions from the sodium chloride in body perspiration gradually will deposit on the silver reducing the effective surface area and thus increasing electrode resistance. By coating the silver with a silver chloride surface and by further introducing a paste salt bridge between this surface and the skin, the process can be reduced by several orders of magnitude. The skin has a high resistance compared with the subdermal tissues. Thus, for good results, the skin usually is rubbed briskly before application of the electrode paste and the electrodes. Skin resistance typically can vary from 5,000 to 200,000 ohms under varying conditions of perspiration and surface condition — hence the need for a high-impedance input.

Since the body usually is in a 60-Hz electric field and the room in which an electrocardiogram is made is not shielded, the 60-Hz pickup between two points on the body frequently will be one or two orders of

magnitude greater than the desired ECG signal. To reduce this effect, ECG amplifiers employ several differential-input stages and a third electrode is attached to an arbitrary point on the body. This latter electrode is used as a "ground" or common-mode reference point. An ECG amplifier will have a common-mode rejection ratio of approximately 3,000:1.

Vector Cardiography. A variant on the conventional electrocardiographic presentation attempts to show the locus of the basic dipole moment that is producing the electrocardiogram. For this purpose, instead of using the usual pair of electrocardiographic electrodes, a minimum of two pairs of electrodes are placed on the patient's thorax, so that the vector sum of the instantaneous voltages appearing across each pair will show at any instant the direction and magnitude of the voltage emanating from the heart. The two output signals thus derived are passed through appropriate weighting networks and then displayed on an oscilloscope, presenting the locus of the tip of the potential vector as it rotates with time through the cardiac cycle as a closed loop.

Processing Electrocardiograms. Because of the importance of the electrocardiogram as a diagnostic tool and the skill required in interpreting it, means have been developed to increase the efficiency of interpretation. Telephone links can be used which permit taking an electrocardiogram by a general practitioner or at a small hospital and transmitting the information to a specialist in facsimile form for immediate analysis and telephonic diagnosis. A frequency-modulated audio tone generator connected to the transmitting ECG machine can be used. At the receiving telephone, the signal is demodulated and fed into a conventional ECG recorder. Monitors are available which permit the patient to wear a small, battery-operated electrocardiograph, which telemeters by FM radio over a relatively short distance. This permits examination of the patient's heart during exercise and other usual physical and psychologically stressful situations in the patient's life. Magnetic tape recording is also used which permits later analysis of ECGs at high speed, or for spot checking. Digital computer programs also are available for immediate ECG analysis. Because of cost and complexity, this approach involves remote transmission from numerous ECG sources.

Impedance Cardiography. An electrical measure of the mechanical activity of the heart may be made by passing 4 to 5 milliamperes of 100-kHz current vertically through the heart, using electrodes at the neck and wrist. The change in this current, as a function of the varying amount of blood in the heart through the cardiac cycle, is measured with a pair of electrodes placed along the left and right midaxillary lines at the level of the heart (along the sides of the trunk about 4 inches below the armpits of an adult). Since the blood has appreciably lower resistivity than the body tissues, the impedance between the electrodes, of approximately 25 ohms, will decrease during diastole by about 0.1 ohm as blood flows into the heart, and to increase sharply during systole as it is forced back out of the current path. Anomalies in the pumping cycle will show up if the blood moves out of the electrical field in an abnormal fashion.

Ballistocardiography. One important measure of heart activity is the force with which the heart ejects blood. If one stands quite still on a spring scale, one will note a small pulsation in the dial reading with each heartbeat. This ballistic recoil of the body as the blood is propelled from the heart can be measured more carefully if the subject lies on a specially constructed bed. Essentially, the bed becomes a platform that can be measured (motion) photoelectrically, or with a linear variable-differential transformer, or with a coil and magnet combination.

For analysis of cardiac output and mechanical heart function, the first- and second-derivative (velocity and acceleration) curves are generated as well as the curve of instantaneous position. These curves can be formed electronically by using high-pass filters, but such filters also increase the effect of noise in the system. To reduce this problem, some ballistocardiographs are made with a velocity pickup made by passing a magnet through a solenoid coil. The voltage appearing across such a coil will be proportional to the velocity with which the magnet is being moved through the coil. It then requires only one differentiation to obtain the acceleration curve and one integration to produce the motion curve, thus markedly improving the signal-to-noise ratio for the system.

Phonocardiography. Electronic stethoscopes have improved the efficiency of the strictly audio-type stethoscope. The latter instrument, of course, has been used for physicians for scores of years to detect heart sounds. An electronic system for heart-sound amplification should have a passband between 10 and 1,000 Hz. For the physician who has become accustomed to a conventional stethoscope, some retraining of the ear is required in switching to an electronic device.

Halter Monitoring. For a number of years, it has been possible to record the ECG of ambulatory patients on magnetic tape continuously over several hours for later playback and interpretation (halter monitoring). Only in recent years, however, has this method come into wide application. Such long period ECGs are helpful in: determining the etiology of dizzy spells or syncope of cardiac origin; studying the nature of palpitations and episodes of tachycardia; and assessing the effectiveness of anti-arrhythmic therapy; among other situations where a comparatively long time span of measurements is required to develop a complete picture.

See also **Heart and Circulatory System (Physiology)** and the list of entries included at the end of that entry.

ELECTROCHEMICAL MACHINING (ECM). In this method of metalworking, electrical and chemical energy become the cutting edges of the tool. Electrical energy causes a chemical reaction which, in turn, dissolves metal from a workpiece into an electrolytic solution. The ECM tool (cathode) is brought very close to the workpiece (anode). The distance will range from less than 0.001 to 0.010 inch (0.025 to 0.25 millimeter). A low-voltage, high-density direct current passes between them through the electrically conductive electrolyte solution. This solution is pumped through the gap at pressures ranging up to 300 psi (20.4 atmospheres). The solution normally is maintained at about 100–120 °F (38–49 °C). The current that is passed through the electrolyte solution ranges widely. Machines using up to 20,000 amperes have been used. As the current passes from the workpiece to the tool, metallic particles on the surface of the workpiece (ions) are caused to go into solution. These particles are then swept away by the rapidly flowing electrolyte. Some of the advantages claimed for ECM include: (1) there is virtually no tool wear; (2) no burrs are produced; (3) both hard and soft metals can be machined at same rate; (4) usually, additional finishing operations are not required; (5) no mechanical stresses are produced in workpiece surface; (6) no thermal effects are produced in the workpiece because of the relatively low temperature of the operation; (7) tough metals often can be removed faster by ECM than conventional methods; (8) good tolerances and repeatability are produced in complex as well as simple shapes; and (9) the process is easily automated. The basics of this process are also applied in deburring, grinding, and polishing operations.

ELECTROCHEMISTRY. That branch of science that deals with the interconversion of chemical and electrical energies, i.e., with chemical changes produced by electricity as in electrolysis or with the production of electricity by chemical action as in electric cells or batteries. The science of electrochemistry began about the turn of the eighteenth century.

Background. In 1796, Alessandro Volta observed that an electric current was produced if unlike metals separated by paper or hide moistened with water or a salt solution were brought into contact. Volta used the sensation of pain to detect the electric current. His observation was similar to that observed ten years earlier by Luigi Galvani who noted that a frog's leg

could be made to twitch if copper and iron, attached respectively to a nerve and a muscle, were brought into contact.

In his original design Volta stacked couples of unlike metals one upon another in order to increase the intensity of the current. This arrangement became known as the "voltaic pile." He studied many metallic combinations and was able to arrange the metals in an "electromotive series" in which each metal was positive when connected to the one below it in the series. Volta's pile was the precursor of modern batteries.

In 1800, William Nicholson and Anthony Carlisle decomposed water into hydrogen and oxygen by an electric current supplied by a voltaic pile. Whereas Volta had produced electricity from chemical action these experimenters reversed the process and utilized electricity to produce chemical changes. In 1807, Sir Humphry Davy discovered two new elements, potassium and sodium, by the electrolysis of the respective solid hydroxides, utilizing a voltaic pile as the source of electric power. These electrolytic processes were the forerunners of the many industrial electrolytic processes used today to obtain aluminum, chlorine, hydrogen, or oxygen, for example, or in the electroplating of metals such as silver or chromium.

Since in the interconversion of electrical and chemical energies, electrical energy flows to or from the system in which chemical changes take place, it is essential that the system be, in large part, conducting or consist of electrical conductors. These are of two general types — electronic and electrolytic — though some materials exhibit both types of conduction. Metals are the most common electronic conductors. Typical electrolytic conductors are molten salts and solutions of acids, bases, and salts.

A current of electricity in an electronic conductor is due to a stream of electrons, particles of subatomic size, and the current causes no net transfer of matter. The flow is, therefore, in a direction contrary to what is conventionally known as the "direction of the current." In electrolytic conductors, the carriers are charged particles of atomic or molecular size called *ions*, and under a potential gradient, a transfer of matter occurs.

An electrolytic solution contains an equivalent quantity of positively and negatively charged ions whereby electroneutrality prevails. Under a potential gradient, the positive and negative ions move in opposite directions with their own characteristic velocities; each, accordingly, carries a different fraction of the total current through any one solution. Each fraction is referred to as the ionic transference number. Furthermore, the velocity increases with temperature causing a corresponding increase in electrolytic conductivity. This characteristic is opposite to that observed for most electronic conductors which show less conductivity as their temperature is increased.

The concept that charged particles are responsible for the transport of electric charges through electrolytic solutions was accepted early in the history of electrochemistry. The existence of ions was first postulated by Michael Faraday in 1834; he called negative ions "anions" and positive ones "cations." In 1853, Hittorf showed that ions move with different velocities and exist as separate entities and not momentarily as believed by Faraday. In 1887, Svante Arrhenius postulated that solute molecules dissociated spontaneously into *free ions* having no influence on each other. However, it is known that ions are subject to coulombic forces, and only at infinite dilution do ions behave ideally, i.e., independently of other ions in the solution. Ionization is influenced by the nature of the solvent and solute, the ion size, and solute-solvent interaction. The dielectric constant and viscosity of the solvent play dominant roles in conductivity. The higher the dielectric constant, the less are the electrostatic forces between ions and the greater is the conductivity. The higher the viscosity of the solvent, the greater are the frictional forces between ions and solvent molecules and the lower is the electrolytic conductivity.

In 1923, Debye and Hückel presented a theory that took into account the effect of coulombic forces between ions. They introduced the concept of the ion atmosphere, in which at some radial distance r from a central ion, there is, on a time average, an ionic cloud of opposite charge which sets up a potential field whose magnitude depends on the magnitude of r. This interionic attraction leads to two effects on the electrolytic conductivity. Under a potential gradient, an ion moves in a certain direction. However, the ion cloud, being of opposite sign, will tend to move in the opposite direction, and because of its attraction for the central ion, will have a retarding effect, or *drag effect*, on the ion velocity, thereby leading to a lowering in the electrolytic conductivity. On the other hand, the central ion will tend to pull the ion cloud with it to a new location. The ion atmosphere will adjust to its new location in time, but not instantaneously, and the delay results in a dissymmetry in the potential field around the ion. This also causes a lowering in the conductance of the solution. These effects become more pronounced as the concentration of the solution is increased; for dilute solutions, below about 0.1 molal, the equivalent conductance decreases with the square root of the concentration. For more concentrated solutions, the relation between conductivity and concentration is much more complex and depends more specifically on individual solute properties.

Interionic attraction in dilute solutions also leads to an effective ionic concentration or activity that is less than the stoichiometric value. The *activity* of an ion species is its thermodynamic concentration, i.e., the ion concentration corrected for the deviation from ideal behavior. For dilute solutions the activity of ions is less than one, for concentrated solutions it may be greater than one. It is the ionic activity that is used in expressing the variation of electrode potentials, and other electrochemical phenomena, with composition.

When electricity passes through a circuit consisting of both types of electrical conductors, a chemical reaction always occurs at their interface. These reactions are electrochemical. When electrons flow from the electrolytic conductor, oxidation occurs at the interface while reduction occurs if electrons flow in the opposite direction. These electronic-electrolytic interfaces are referred to as *electrodes*; interfaces where oxidation occurs are known as *anodes*; and those at which reduction occurs, as *cathodes*. An anode is also defined as that electrode by which "conventional" current enters an electrolytic solution, a cathode as that electrode by which "conventional" current leaves. Positive ions, for example, ions of hydrogen and the metals, are called *cations* while negative ions, for example, acid radicals and ions of nonmetals, are called *anions*.

Laws of Electrolysis. In 1833, Faraday enunciated two laws of electrolysis which give the relation between chemical changes and the product of the current and time, i.e., the total charge (coulombs) passed through a solution. These laws are: (1) the amount of chemical change. e.g., chemical decomposition, dissolution, deposition, oxidation, or reduction, produced by an electric current is directly proportional to the quantity of electricity passed through the solution; (2) the amounts of different substances decomposed, dissolved, deposited, oxidized, or reduced are proportional to their chemical equivalent weights. A chemical equivalent weight of an element or a radical is given by the atomic or molecular weight of the element or radical divided by its valence; the valence used depends on the electrochemical reaction involved. The electric charge on an ion is equal to the electronic charge or some integral multiple of it. Accordingly, a univalent negative ion has a charge equal in magnitude and of the same sign as a single electron, and its chemical equivalent weight is equal to its atomic weight, if an element, or to its molecular weight, if a radical. A trivalent ion has $+3$ or -3 electronic charges, depending on whether it is a positive or a negative trivalent ion. For trivalent ions, then, the equivalent weight would be equal to its atomic weight, if an element, or to its molecular weight, if a radical, divided by three.

The quantity of electricity required to produce a gram-equivalent weight of chemical change is known as the *faraday*. A faraday corresponds, then, to an *Avogadro number of charges*. The most accurate determination of the faraday has been made by a silver-perchloric acid coulometer in which the amount of silver electrolytically dissolved in an aqueous solution of perchloric acid is measured. This method gives 96,487 coulombs (or ampere-seconds) per gram-equivalent for the faraday on the unified ^{12}C scale of atomic weights adopted in 1961 by the International Commission on Atomic Weights.

Electrochemical Equivalent. Preferably termed *coulomb equivalent* of an element or radical, this is the weight in grams which is equivalent to 1 coulomb of electricity and is given by the gram-equivalent weight divided by the faraday (96,487 coulombs per gram-equivalent); for example, the electrochemical equivalent of silver is given by 107.870/96,487 or 0.00111797 grams/coulomb, where 107.870 is the atomic weight of silver based on the unified ^{12}C scale adopted in 1961. The electrochemical equivalents of other elements may be calculated in like fashion.

In electrolysis and in any electric cell or battery, there is an electromotive force (emf) or voltage across the terminals. This emf is expressed in the practical unit, the volt, which is equal to the electromagnetic unit in the meter-kilogram-second system. In any one cell, the emf is the sum of the potentials of the two electrodes and of any liquid-junction potentials that may be present. Neither of the individual electrode potentials can be evaluated without reference to a chosen reference electrode of assigned

value. For this purpose, the hydrogen electrode has been universally adopted and is arbitrarily assigned a zero potential for all temperatures when the hydrogen ion is at unit activity and the hydrogen gas is at atmospheric pressure. A hydrogen electrode consists of a stream of hydrogen gas bubbling over platinized platinum or gold foil and immersed in a solution containing hydrogen ions; the electrochemical reaction is: $\frac{1}{2}H_2(\text{gas}) = H^+(\text{solution}) + \varepsilon$, where ε represents the electron. The potential of the hydrogen electrode, E_H, as a function of hydrogen ion concentration and hydrogen-gas pressure is given by

$$E_H = E_H^0 - (RT/nF)\ln(a_{H+}/p_{H2}^{1/2})$$
$$= E_H^0 - (RT/nF)\ln(c_{H+}f_{H+}/p_{H2}^{1/2})$$

where E_H^0 is the standard quantity assigned a value of zero, R is the gas constant, T the absolute temperature, n the number of equivalents, F the faraday, p_{H2} the pressure of hydrogen, and a_{H+}, c_{H+}, and f_{H+}, respectively, the activity, concentration, and activity coefficient of hydrogen ions. When a_{H+}, and $p_{H2}^{1/2}$, equal one, $E_H = E_H^0$. For very dilute solutions below 0.01 molal f_{H+} may be taken as unity without appreciable error.

The standard potentials, E^0, of other electrodes are obtained by direct or indirect comparison with the hydrogen electrode. Values are determined at 25 °C. The values for several metals and other elements are given in entry on **Activity Series**. The reducing power of the elements decreased on going down the column from those elements with negative standard electrode potentials to those with positive potentials. These values are for the ions at unit activity, and reversible or thermodynamic values as a function of metal or radical concentration are given by equations similar to the one above. For the general reaction: $M = M^{n+} + n\varepsilon$, the potential is given by $E_m = E_H^0 - (RT/nF)1na_{Mn+}$.

In electrolysis, at very low current densities, the potentials of the electrodes approximate in magnitude their reversible values and deviate somewhat from these values because of an *IR* drop in the solution and possible concentration polarization (the concentration at the electrode surface may differ from that in the bulk of the solution). Also for high current densities, especially for the generation of gases such as hydrogen, oxygen or chlorine, the voltage required exceeds the reversible voltage; the excess voltage is known as overvoltage, or overpotential for a single electrode, and arises from energy barriers at the electrode. Overpotential, in general, increases logarithmically with an increase in current density.

Scope of Electrochemistry. In addition to the foregoing, it is customary to include under electrochemistry: (1) processes for which the net reaction is physical transfer, e.g., concentration cells; (2) electrokinetic phenomena, e.g., electrophoresis, electroosmosis, and streaming potential; (3) properties of electrolytic solutions, if they are determined by electrochemical or other means, e.g., activity coefficients and hydrogen ion concentration; (4) processes in which electrical energy is first converted to heat, which in turn causes a chemical reaction that would not occur spontaneously at ordinary temperature. The first three are frequently considered a portion of physical chemistry, and the last one is a part of electrothermics or electrometallurgy.

The passage of electricity through gases is sometimes included under electrochemistry. However, in electrical discharges in gases, the principles are entirely different from what they are in the electrolysis of electrolytic solutions. Whereas in the latter, ionic dissociation occurs spontaneously as a result of forces between solvent and solute and without the application of an external field, for gases, relatively high voltages must be applied to accelerate the electrons from the electrode to a velocity at which they can ionize the gas molecules they strike. In this case, the resulting chemical reaction taking place between ions, free radicals, and molecules occurs in the gas phase and not at the electrodes as in the electrolysis of solutions. Studies of the electrical conduction of gases, accordingly, are generally considered under the physics of gases.

Electrochemistry finds wide application. In addition to industrial electrolytic processes, electroplating, and the manufacture and use of batteries already mentioned, the principles of electrochemistry are used: in chemical analysis, e.g., polarography, and electrometric or conductometric titrations; in chemical synthesis, e.g., dyestuffs, fertilizers, plastics, insecticides; in biology and medicine, e.g., electrophoretic separation of proteins, membrane potentials; in metallurgy, e.g., corrosion prevention, electrorefining; and in electricity, e.g., electrolytic rectifiers, electrolytic capacitors.

ELECTRODE. In an electric circuit, part of which is composed of other than the usual conductor of copper, or other metal, the terminal connecting the conventional conductor and the conducting substances is an electrode. Examples of electrodes are: the electric cell, where they dip in the electrolyte; the electric furnace, where the electrodes connect the external circuit with the heating arc; the metallic elements in thermionic tubes and gas-discharge devices; and in semiconductor devices, where electrodes perform one or more of the functions of emitting, collecting or controlling by an electric field the movements of electrons and ions. See also **Graphite**.

ELECTRODEPOSITION. The precipitation of a material at an electrode as the result of the passage of an electric current through a solution or suspension of the material, for example, alkaline-earth carbonates, rubber from latex, paint films on metal. A technique for electrodepositing refractory carbide coatings on metal has been reported. The electrode is in the shape of the desired article. An important advantage of electrodeposition is its ability to coat complex shapes having small and irregular cavities with exact thickness control.

ELECTRODIALYSIS. Electrodialysis (ED) is a process for moving ions across a membrane from one solution to another under the influence of a direct electric current. In 1940, a multicompartment ED was invented by K. Meyer and W. Strauss in Zürich. Such process and apparatus is what is now meant by ED. In such an apparatus, many membranes *A* selective to anions alternate with membranes *C* selective to cations between a single pair of electrodes. When a d-c potential is applied, cations M^+ move toward the negatively charged cathode and are able to permeate the cation-selective membranes, but not the anion-selective membranes, if the latter are perfectly selective. Similarly, anions X^- move toward the positively charged anode and are able to permeate the anion-selective membranes, but not the cation-selective ones. As a result, odd-numbered compartments become depleted in the electrolyte, the even-numbered compartments enriched. The choice of which electrode is positive and which negative is arbitrary. If the left hand electrode is negative and the right hand one positive, then the odd numbered compartments become enriched in electrolyte, the even-numbered ones are depleted. This is the basis of reversing type ED (EDR) invented by W. McRae in 1956, in which the polarities of the electrodes are reversed regularly at intervals of 15 minutes to 1 week depending on the details of the application.

The depletion compartments (and in some applications, the enrichment compartments as well) may be filled with ion-exchange beads, fibers, or fabric (see **Ion-Exchange Resins**), leaving interstices through which fluid may flow. This type of filled cell ED was invented by W. Walters, D. Weiser, and L. Marek in 1955. They filled both depletion and enrichment compartments with a mixture of anion exchange (AX) and cation exchange (CX) beads. This process is called electrodeionization (EDI).

Ion-Exchange Membranes

In 1948, ion-selective membranes having high selectivity, low electrical resistance, good mechanical strength, and good chemical stability were invented by W. McRae. They were essentially insoluble, synthetic, polymeric, organic ion-exchange resins in sheet form. Typical chemical structures for modern membranes of this type are shown schematically in Figure 1. The cation-selective membranes (Fig. 1**a**) consist of cation-exchange (CX) resin composed of polystyrene having negatively charged sulfonate groups chemically bonded to most of its phenyl groups. The charges of the sulfonate groups are electrically balanced by positively charged cations (counterions). Sulfonated polystyrene swells greatly in water. The amount of swelling is typically controlled by including cross-linking agents in the polymer, e.g., divinyl benzene; by incorporating electrically neutral polymers; or by having extensive regions (blocks) in the polymer which lead to substantial microcrystallinity. The positively charged counter-ions, e.g., Na^+, Ca^2+, or Mg^2+, are appreciably dissociated from the chemically bound negatively charged groups once the membrane is exposed to water. Thus the counter-ions are mobile and may be exchanged for other cations from an ambient solution, maintaining the electrical neutrality of the membrane. This high (typically >1 meq/cm^3 of membrane) concentration of counter-ions in ion-exchange resins is responsible for the low electrical resistance of the membrane. The high concentration of bound negatively charged groups tends to exclude mobile, negatively charged ions (co-ions) from an ambient solution and is responsible for the high ion selectivity of the membranes.

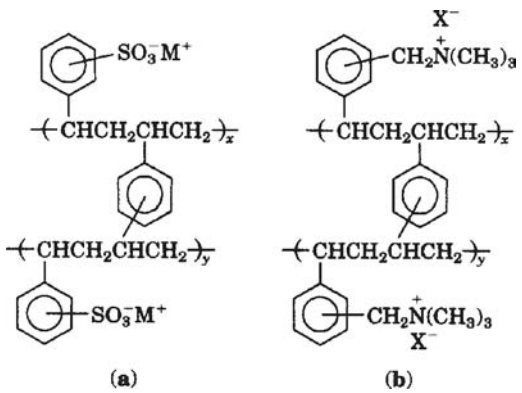

Fig. 1. Schematic representation of (**a**) cation-exchange resin, and (**b**), anion-exchange resin.

The anion-selective (AX) membranes (Fig. 1**b**) may also consist of cross-linked polystyrene, but have positively charged quaternary ammonium groups chemically bonded to most of the phenyl groups in the polystyrene instead of the negatively charged sulfonates. In this case, the counter-ions are negatively charged, e.g., Cl^-, HCO_3^-, NO_3^- or SO_4^{2-}.

The membranes described above called homogeneous ion-exchange membranes, represent about half the world production of ion-exchange membranes are made by bonding about 75 parts of AX or CX powder with 25 parts of, e.g., polyethylene and are called heterogeneous. Whether homogeneous or heterogeneous, the ion-exchange membranes tend to transfer divalent ions (such as Ca^{2+}, Mg^{2+}, SO_4^{2-}, relatively more rapidly than univalent ions. Skinned homogeneous membranes tend to transfer univalent ions much more rapidly than divalent. CX membranes based on perfluorinated polymers and having carboxylate CX groups on one surface and sulfonate groups on the other are used in membrane chloralkali cells.

A large quantity of homogeneous ion-exchange membranes are made annually for separators in alkaline batteries. See also **Batteries**.

Commercial membranes are usually reinforced with woven, synthetic fabrics to improve the mechanical properties. Several hundred thousand square meters of ion-exchange membranes are now produced annually. The mechanical and electrochemical properties are varied by the manufacturers to suit the proposed applications. The electrochemical properties of most importance for ED are (1) the electrical resistance per unit area of membrane; (2) the ion transport number, related to current efficiency; (3) the electrical water transport, related to process efficiency; and (4) the back-diffusion, also related to process efficiency.

Apparatus

The apparatus for ED is fundamentally an array of alternating AX and CX membranes terminated by electrodes. The membranes are separated from each other by gaskets which form the fluid compartments between the membranes. The enrichment and depletion compartments also alternate through the array. Holes in the gaskets and membranes register with each other to provide two pairs of internal hydraulic manifolds to carry fluid into and out of the compartments. One pair communicates with the depletion compartments and the other with the enrichment compartments. Much effort has been expended on the design of the entrance and exit channels from the manifolds to the compartments to prevent unwanted cross-leak of fluid intended for one class of compartment into the other class. This effort is made increasingly difficult by the continuing trend to thinner membranes and gaskets, the latter determining membrane spacing and the thickness of the fluid compartments; such trends are intended to reduce energy consumption. A contiguous group of two membranes and the associated two fluid compartments is called a cell pair. A group of cell pairs and the associated end electrodes is called a stack or pack. Generally 100–600 cell pairs are arranged in a single stack, the choice being made on the basis of ED capacity desired, the uniformity of flow distribution achieved among the several compartments of the same class in a stack, and the maximum total direct current potential desired. One or more stacks may be arranged in a press, designed to compress the membranes and gaskets against the force of fluid flowing through the compartments thereby preventing fluid leaks to the outside and internal cross-leaks between compartments. For small presses such compression is usually provided by tie-rods; for larger presses, hydraulic rams are frequently used.

Commercial membranes have typical thicknesses of ca 0.15–0.5 mm; the compartments between the membranes have typical thicknesses of ca 0.3–2 mm. The thickness of a cell pair is therefore in the 1.3–5.0 mm range, commonly about 3.0 mm. One hundred cell pairs have a combined thickness of about 300 mm. The effective area of a cell pair for current conduction is generally on the order of 0.2–2 m^2.

In concentrated electrolytes the electric current applied to a stack is limited by economic conditions, the higher the current I the greater the power consumption W in accordance with the equation $W = I^2R_s$ where R_s is the electrical resistance of the stack. In relatively dilute electrolytes, the electric current which can be applied is limited by the ability of ions to diffuse to the membranes across a convection free, laminar flow, diffusion layer contiguous with the depletion faces of the membranes. The need for such diffusion is due to the fact that almost all the current passing through a membrane is carried by its counter-ions, whereas, in the ambient solution roughly only half the current is carried by such counter-ions, the remainder by the co-ions. Therefore, there is a deficit of counter-ions at the membrane-solution interface. When the concentration c of electrolyte at the interface between an AX membrane and the solution in the depletion compartment is negligible compared to the concentration c_b in the bulk solution (i.e., outside the laminar flow layer), then the rate at which ions can diffuse to the interface is a maximum and the AX membrane and the apparatus are said to be concentration polarized or simply polarized. The applied current density corresponding to such maximum rate of diffusion is the limiting current density $i_{\lim}$. As the applied current density approaches $i_{\lim}$, the electrical resistance of the ED stack increases substantially even though the bulk solution in the depletion compartments may still contain an appreciable concentration of electrolyte. This is a sign of polarization; $i_{\lim}$ is not a wall. At applied current densities above $i_{\lim}$ much of the increase in current through the AX membrane is carried by hydroxide ions (OH^-) resulting from dissociation of water at the interface. As a result, the enrichment compartments become somewhat alkaline and the depletion compartments somewhat acidic. This is also a sign of polarization.

The rate at which ions can diffuse to the interface, and therefore, $i_{\lim}$, is inversely proportional to δ (the thickness of the convection free, laminar flow, diffusion layer). The latter is typically reduced by including turbulence promoting structures (such as screens) in the depletion

compartments, and generally also in the enrichment compartments. In such case, i_{lim} in A/cm^2 is, in order of magnitude, equal numerically to the concentration c_b in gram-equivalents/L. i_{lim}, measured in terms of the AX membrane area, can also be increased (by a factor of 10 or more) by including ion-exchange beads, fibers, or fabrics in the depletion compartments as in EDI.

Applications

ED is used principally in the production of high purity water, in demineralization of brackish water (about 1/10th the concentration of seawater), in concentration of seawater (to 18–20%), and in deashing cheese whey. For the production of high purity water it is typical to use EDI. When EDI is operated at currents well above i_{lim} for the filled cells, then substantial water dissociation occurs and EDI behaves in many ways as a continuously electrically regenerated mixed-bed ion exchanger producing ultrapure water equivalent to that produced by chemically regenerated mixed beds. EDI is rapidly replacing chemically regenerated ion-exchange for the production of high purity water.

EDR is typically used for demineralization of brackish water, which often contains poorly soluble minerals such as calcium bicarbonate and calcium sulfate, as well as colloids such as humic and fulvic acids and iron hydroxides. The periodic reversal of the direction of the electric current avoids scaling and fouling of the membranes by such substances.

Univalent ion selective membranes are used in nonreversing ED for seawater concentration. Both EDR and nonreversing ED are used for whey deashing.

Bipolar ion-exchange membranes have one surface consisting of CX resin and the opposite surface of AX resin. The interface between the CX and AX resins may be regarded as a zero gap ED compartment. When a direct current is passed through such a membrane in a direction to pull anions out of such interface and through the AX resin, the interface rapidly becomes depleted of all ions other than those resulting from the dissociation of water. Dilute alkali can therefore be produced at the outer surface of the AX region and dilute acid at the outer surface of the CX layer.

The bipolar membranes are used in a more or less conventional ED stack together with conventional unipolar membranes. Such a stack has many acid–alkali producing membranes between a single pair of end electrodes. The advantages of the process compared to direct electrolysis seem to be that because only end electrodes are required, the cost of the electrodes used in direct electrolysis is avoided, and the energy consumption at such electrodes is also avoided.

The disadvantages appear to be that the bipolar membranes are comparatively expensive, and the economic life is limited to about one year. Such short lifetime appears to result from the very high ($\sim 10^6$ V/cm) potential gradients at the interface between the AX and CX regions. Additionally, practical current densities are limited to about 1000 A/m^2 available area. See also **Desalination**; **Ocean Resources (Energy)**.

ELECTRODYNAMICS. The science dealing with the forces and energy transformations of electric currents, and the magnetic fields associated with them.

ELECTROENCEPHALOGRAM. A graphic tracing of the electric impulses of the brain, sometimes abbreviated EEG. The instrument that makes the record is known as an electroencephalograph. The electrical activity of the brain is manifested at the surface of the scalp by small potential changes on the order of 5 to 200 microvolts in a frequency band from 1 to 50 Hz. A sample of so-called brain waves or electroencephalogram is shown by the Fig. 1. When viewed casually, the usual EEG would appear to be simply random noise, but spectral analysis and some direct electroencephalograms show pronounced components at several frequencies. The lowest (1 to 3 Hz) is termed the *delta rhythm*. Next highest are the *theta waves* (4 to 7 Hz). The *alpha rhythm* is the most pronounced and occurs between 8 and 13 Hz. A third pronounced rhythm appears between 13 and 30 Hz and is termed the *beta rhythm*. As shown in Fig. 1, the alpha rhythm is most pronounced during light sleep, while the delta rhythm appears during deep sleep. One of the uses of the EEG is determination of stages of sleep in sleep research and associated investigations.

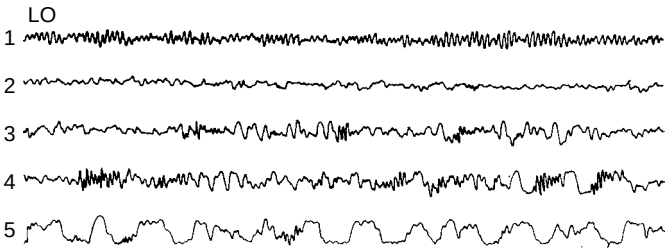

Fig. 1. EEG tracings of normal subject during sleep. Numbers shown at left indicate increasing depth of sleep.

In several diseases of the brain, especially epilepsy and cerebral tumors, very slow delta waves of higher-than-average voltage may be seen. Occasionally, as in epileptic seizures, similar waves of very high frequency may occur. In tumors, the appearance of such waves is confined to the area immediately surrounding the tumor; hence electroencephalography has some ancillary value in the localization of cerebral tumors. See also **Seizure (Neurological)**.

Electroencephalographic techniques also have been used rather extensively in research on sleep and sleep apnea associated with insomnia.

A conventional electroencephalogram is taken by placing a series of 6 to 10 electrodes symmetrically on each side of the head from the front to the back, with a reference electrode on the mastoid bone or some other similar spot. Sometimes the electrodes consist of small pins that puncture the skin to make better contact, but usually the scalp electrode is a small sponge soaked with saline solution and held down with tape. Usually, it is not necessary to shave the hair from the scalp. The usual EEG machine uses a multichannel, direct-writing recorder with 6 to 10 channels and speeds ranging from 2 to 50 millimeters per second, the width per channel typically being about 25 millimeters. Because the EEG amplitude is an order of magnitude smaller than the electrocardiograph amplitude, the criteria for the design of an EEG amplifier apply much more strenuously. See also **Electrocardiography**. Common-mode rejection should be at least 10,000:1, and the recording should be done in a shielded room. In contrast, low-frequency response need not be as good for the EEG as for the ECG; thus polarization of the electrodes is not so critical. When making an EEG recording, it is necessary that the shielded room be relatively free of external stimuli, such as changes in ambient light, sound, or vibration because sudden changes may produce startle-response artifacts.

A technique known as the evoked-cortical-potential makes it possible to see the effect on the EEG of a sensory stimulus. At the same time as the stimulus is initiated (such as a flash of light or burst of sound), an EEG recording is made and stored in a computer memory, usually on a digital basis. Each time a fresh stimulus is applied, the storage is updated, so that after 50 or 100 trials, the digital memory contains an average EEG synchronized with the stimulus. A typical computer memory for this application may contain 2,500 bits; 50 elements in one direction could represent fifty 10-millisecond periods, starting with the onset of the stimulus, while the 50 elements in the orthogonal direction would represent the average amplitude of the EEG for each time period. This technique is useful for research work on sight, sound, touch, and other sensory stimuli and, under some circumstances, in the location of disorders causing blindness or deafness.

Work on the brain and on individual fibers frequently requires the use of microelectrodes to stimulate and detect the responses from very tiny spots. Microelectrodes, consisting of very fine wires surrounded by thin glass insulation, are made down to an active diameter of approximately one micrometer. The impedance of such an electrode can be 10 to 100 million ohms, and the frequency of the signal can have components up to 10 kHz. At the same time, the signal-to-noise ratio can be very low. Thus, the requirements of very high common-mode impedance, very high input impedance, and virtually no input capacitance dictates a special class of amplifier in which the input capacitance is neutralized by feedback.

Apparatus is available that allows the simultaneous use of an electrode for producing a stimulus and recording the response. The input and output circuits to the electrode must be carefully isolated to make this possible.

ELECTROLUMINESCENCE. See **Luminescence**.

ELECTROLUMINESCENT DISPLAYS. The phenomenon of electroluminescence (EL) was discovered by George Destriau in 1936. As the name implies, it is the direct conversion of electrical energy into luminous energy. Another way to describe it is the production of light by electrical activation of a solid material. In EL displays, the electrons associated with the chemical elements in the solid material acquire a high energy level from the electric field. Light is produced when the electrons return to their normal, or *ground-state*, condition. The *term high field electroluminescence* is sometimes used to describe the behavior.

The first devices to exploit EL technology were not displays, but lamps. GTE Sylvania developed electroluminescent luminaries it called *Panelescent Lighting*. These panels were to replace overhead lighting in offices and homes by covering ceilings and walls with light-emitting panels. Imagine the effect of being in a room with no shadows and uniform lighting from all directions. Despite the decade-long effort applied to make the panels more efficient and more reliable, the company could not find a process and gave up in the early 1960s. GTE obtained a basic patent for a matrix-addressed EL display as a result of this effort, however.

The first working model of an EL display was made in 1963, followed two years The next commercial activity was the announcement of a matrix-addressed thin-film electroluminescent (TFEL) panel in 1983. That same year, a 320×240 pixel display was put into one of the first portable computers, the Grid Compass.

AC Thin-Film Electroluminescent Displays

Thin-film electroluminescent (TFEL) displays are composed of stacked layers of metal electrodes, an insulator, an electroluminescent layer (usually doped zinc sulfide or ZnS), an insulator, and a conductor, all deposited by thin-film techniques on a glass substrate. See Fig. 1

The phosphor material consists of a host material and an activator, which is the center of light emission. A host material must have a band gap that is large enough ($>$2.5 eV) to emit light without absorbing it. This limits the choice of materials to the large band gap semiconductors. Also, the host material must be able to provide transport for high-energy electrons. The oxide phosphors used in cathode ray tubes (CRTs) do not provide this transport ability. The II-VI semiconductor materials appear to be the most suitable host compounds. These include zinc sulfide (Zns, strontium sulfide (SrS), and calcium sulfide (CaS).

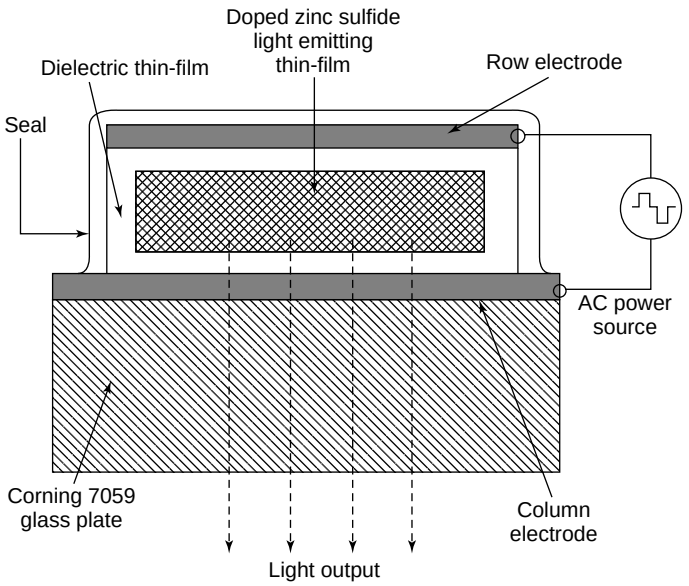

Fig. 1. Basic structure of AC thin-film panel.

The application of a field above the threshold voltage causes visible light (usually orange-yellow) to emit from the central layer. The phenomenon is believed to operate by the following mechanism. A high-strength field ($>15 \times 10^6$ volts/cm) is applied to the zinc sulfide (ZnS) layer. As the stack of insulators and the thin-film phosphor become charged and exceed the threshold voltage, current flows within the EL layer. The impact excitation of the light-emitting centers [manganese (Mn) atoms in a ZnS phosphor] is the source of the light, with a wavelength of 585 nm. The field on the ZnS layer is then reduced, and conduction stops until the field is reversed (AC).

Multiplexing is required to drive a dot matrix TFEL panel. Every row and column of the display must be directly connected to a channel of a high-voltage driver circuit. The phenomenon normally requires the switching of about 190 volts by the row drivers and 60 volts for the column drivers. These high-voltage drivers make up the largest portion of the manufacturing costs of a TFEL panel. The drive scheme of an AC–TFEL display dictates that after a single pulse is applied to a pixel, another pulse of opposite polarity must be applied before light can be generated again. Light is emitted at each pulse, positive or negative, so the light output is dependent on the frequency of refreshing. The display emits light during the period of the voltage rise, which lasts five microseconds, followed by a dwell period, and then a fall. Light output decreases during the dwell time, so if the dwell time is too long, the display will begin to flicker. Larger displays require faster refresh rates and consume more power. The higher the rate, the more light output. Refresh rates of 60, 70, 90, and 400 Hz are typical.

Achieving gray scale is a challenge, because the brightness–voltage curve for EL displays is very steep. Controlling the voltage accurately enough to reproduce the intensity consistently is difficult. Units operating at video rates with 16 gray shades are now available. The luminous efficiency of the light-emitting phenomenon in a TFEL display is one of the highest of any type of light emission: up to 9 lumens/watt has been reported, and 5 to 6 lumens/watt is normal for monochrome displays. Inefficiencies occur because of capacitive coupling and losses in the drivers and conductors.

In a 640×480 pixel, 10-inch (diagonal) TFEL display, the amount of power used to generate light is slightly more than 1 watt. In operation, power losses are generated by both row and column circuits. The high-voltage signal applied to the rows accounts for only about 2.6 watts in the display under discussion. The column drivers operate at a much lower voltage level, but under certain conditions they can dissipate over 12 watts. The maximum amount of power is dissipated when 50% of the pixels are in the *on* state. Regardless of whether only 10% or 90% of the pixels are on, the row portion of the power consumption of a standard display is

about 5 watts. The column drivers are charging capacitors made up of all the rows, not just the row that is being written.

There are several ways to reduce power consumption. One method of increasing the efficiency is to recapture the capacitively stored charge at each pixel. By using inductive elements, the power consumption of a TFEL panel can be reduced to 6 watts. Another way to reduce power is to use multistep charging (that is, using two frames to apply the full writing voltage). This approach is limited to smaller-format displays. If a reduction in brightness can be tolerated, the power can be reduced by a factor of 4 for every factor of 2 reduction in brightness. This approach can be used in instances in which 50% of the pixels are on.

Production yields of AC–TFEL panels have reached levels of 85% and more. The largest hurdle faced in TFEL production has been the defect-free processing of large areas of thin-film materials. The active matrix EL layer of zinc sulfide, as well as the insulating layers, must be deposited uniformly over a large-area substrate at a thickness of 0.5 micron with virtually no pinholes.

All TFEL panels are "burned-in" or "aged" by the manufacturer for about a day in order to stabilize the emission output. The burn-in process is important for the life and the stability of the panel. The luminance of the panel continues to decrease logarithmically with time at voltage, but panels are now rated at a minimum of 10,000 hours with proper drivers. Materials used as EL layers are sensitive to moisture; they must be protected from the atmosphere by a barrier, or the display will be subject to catastrophic failure. Some time ago it was discovered that the driving technique for TFEL displays must be symmetrical. For example, the row drivers must switch + and −150 volts, and the columns must switch + and −40 volts. When AC–TFEL displays are driven in only one direction, the threshold voltage eventually is reduced, and a latent image can be burned into the screen. This is a problem known as differential aging. The solution requires doubling the switching voltage or doubling the number of driver circuits required.

Several major and minor suppliers of AC–TFEL displays, as well as independent laboratories are engaged in EL research.

A proprietary thin-film deposition process based on chemical vapor deposition display has been manufactured. The major using atomic layer epitaxy (ALE), effort to research and develop EL displays in Finland began in 1977. The ALE process allows the luminescent layer to be uniformly deposited, resulting in a highly stable and long-lasting display. The layers are believed to be deposited atomic layer by atomic layer, with precise control over the stoichiometry. The ALE process is reported to have the drawback of being quite low in throughput.

One of the biggest problems of the EL display has been the contrast reduction in a high-brightness environment. The reduction in contrast results from the reflection of ambient light from the electrodes. This reflecting light remains whether the pixels are on or off, reducing the contrast ratio and generally degrading performance. One solution is to place a contrast-enhancing filter over the display. Ambient light is then reduced on its way into the display and again on its way out, while emitted light is reduced only one time, as it leaves the display.

Planar Systems (http://www.planar.com/Website/main.nsf?Open) has developed a proprietary technology called ICE (integral contrast enhancement). In this process, the back-row electrode layer absorbs incident light and boosts the contrast ratio. The refresh rate has been increased to 120 Hz, thereby increasing the light output. In total, the brightness/contrast performance has been improved by a factor of four. Eliminating the need for polarizing filters reduces manufacturing costs.

Luxell Technologies of Ontario, Canada, (http://www.luxell.com/pages/products.html) has developed and manufactures a high-performance TFEL display. The uniqueness of this display is its ability to be viewable in all light conditions, ranging from total darkness to full sunshine. This sunlight-legibility feature of Luxell's displays is due to an optical interference thin-film structure referred to as the *black layer*, which is patented. This was developed by the National Research Council of Canada (NRC) in collaboration with Luxell. The first model being offered by the company is the Model S-11 -ETL3, an amber-over-black, low-profile display. It is designed for such applications as avionics, test equipment, medical instrumentation, and special vehicles, in which legibility is a must.

Color TFEL displays are still in the development stage. There are three basic approaches to full-color generation: patterned phosphor, patterned filter, and stacked substrates. The first involves laying down the red, blue, and green phosphors side by side in much the same way as a shadow mask or Trinitron CRT is made. A modification involves placing patterned red and green phosphors on one substrate and stacking a separate blue display on top. Because the layers of the blue substrate are transparent to some degree, the red and green colors can be emitted and mixed through the layers. This approach is now in favor.

The other approach uses a white phosphor in conjunction with color filters made in much the same way as those used for LCDs. A white phosphor is one that emits wavelengths in the red, green, and blue regions. A successful color display requires efficient red, green, and blue phosphor materials. Unfortunately, the most efficient phosphors now are the yellow orange, Mn-doped zinc sulfide.

Green phosphors using ZnS doped with terbium (Tb) or terbium fluoride (TbF_3) are the most widely studied types. Emissions are broad, with peaks at 490, 550, 590, and 625 nm. Progress has been good; the work on green phosphors in 1979 reported a pixel luminance of 20 cd/m^2. The latest figure exceeds 92 cd/m^2.

Much red phosphor work has centered on Mn: TbF_3 doped ZnS. Recent reports have the red pixel luminance up to 37 cd/m^2. The problem with this system is that the color is not very saturated, that is, peaks start at 520 nm and go to 700 nm. The ZnS:Sm (zinc sulfide:samarium) provides a better red. Others report that SrS:Eu (strontium:sulfide:europium) can be used to produce an acceptably bright red.

An efficient blue phosphor is the key to full-color TFEL displays. The current prospective materials are cerium (Ce) doped compounds, such as strontium thiogallate:cerium ($SrGa_2S_4$:Ce) and calcium thiogallate:cerium ($CaGa_2S_4$:Ce). These materials are fully miscible and have peak wavelengths at 459 and 445 nm. Copper (Cu) doped strontium sulfide (SrS:Cu) materials, emitting from 390 to 620 nm with a peak at 470 nm, have also been identified.

A white phosphor is needed for one approach to making color EL displays. White is particularly difficult to make with semiconductor materials because it emits light at specific wavelengths, rather than over a broad spectrum. Scientists at Tottori University, Tottori, Japan, (http://www.tottori-u.ac.jp/tottori e.html) developed white electroluminescent devices with new phosphor thin films based on strontium sulfide (SrS) doped with praseodymium (Pr), potassium (K), cerium, and/or europium (Eu). Three types of phosphors (SrS:Pr,K, SrS:CeK,Eu, and SrS:Ce,K/SrS:Eu) show higher luminance levels of 1,500 cd/m^2 (438 ft-lamberts) at 5 KHz and 500 cd/m^2 (146 ft-lamberts) at 1 KHz, with the color coordinates close to the values of standard white-light sources.

However, these devices show a luminance of only 30–50 cd/m^2 (9–15 ft-lamberts) at 60 Hz, which is about half that required for practical EL panel applications. This study, therefore, has led to an interest in the prospects for white-light EL displays, which are thought to have superior ergonomics. Another approach was to use multilayered SrS:Ce and ZnS:Mn thin films as phosphors. The emission is not a pure white light, but rather a yellowish white light. The university scientists found that the structure of the stack of films affected the luminous output, and they could achieve 250 cd/m^2 at approximately 225 applied volts at 1 kHz.

SrS:Ce, Eu as a white phosphor has been investigated (http://itri.loyola.edu/opto/ad nkerl.htm). This material emits in the red, green, and blue wavelengths. Strontium sulfide is very sensitive to moisture, and it has a very low breakdown voltage. The luminous output for the white prototype made in 1992 was 20 cd/m^2.

Active Matrix Thin-Film Electroluminescent Displays

Active matrix thin-film electroluminescent (AM-TFEL) displays are miniature AC-TFEL structures constructed on an integrated circuit backplane. By using active matrix addressing, higher information content devices are possible; devices with pixel formats as large as $1,280 \times 1,024$ have been demonstrated, using a 0.7-inch diagonal substrate and a resolution of 2,000 lines per inch. The high voltages (80 volts A.C.) used in such devices require the use of silicon-on-insulator substrates that isolate the high voltage signals from nonselected pixels and logic. Color AMEL devices have been produced using filtered white phosphor and field-sequential liquid crystal shutters.

The first AM-TFEL head-mounted display was designed for such applications as hands-free maintenance computers, military targeting and communications systems, portable personal communications and computing, medical imaging and virtual reality for commercial applications, and consumer entertainment. This display is a miniature flat panel computer display, which measures approximately 1 square inch, is 3 mm thick, and

weights 4 grams. The image is comparable to that of a 25-inch television screen at a distance of three feet. This unique head-mounted technology was developed in part through a U.S. Government Advanced Research Projects Administration (ARPA) (http://www.arpa.mil/) Technology Reinvestment Program (TRP) grant.

Hybrid Electroluminescent Displays

A new type of EL display technology, a SSD (Solid State Display) has been developed (http.www.westain.com). It is based on the use of a proprietary combination of screen-printed thick films, sol-gel processing, and vacuum-deposited thin films. Instead of glass, the substrate is a ceramic similar to that used in the printed circuit industry. Although temperature processing to be used. A screen-printed high dielectric constant insulator is used to generate a high brightness effect in a ZnS:Mn phosphor utilizing fairly low voltages. Materials such as lead niobate ($PbNb_2O_6$) and barium titanate ($BaTiO_3$) have been used as the dielectric. A schematic of the device is shown in Figure 2.

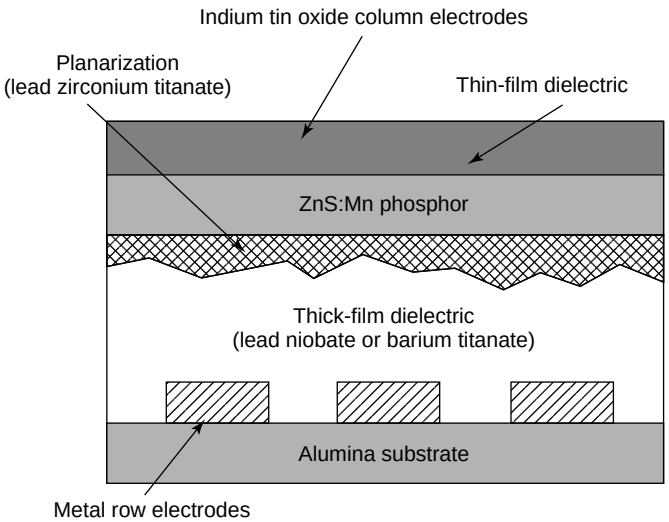

Fig. 2. Structure of thick dielectric EL panel.

The first step in fabricating the SSD is to screen-print a metal-resin paste onto a ceramic substrate, thereby forming a pattern of row electrodes. When the material is fired at a high temperature, the organic resin is completely burned off, leaving pure metal electrodes formed into a pattern of rows. A glass substrate would not survive this high-temperature firing process, so a ceramic substrate is required.

The thick-film dielectric material, combined with a resin to form a paste, is then screen-printed over the patterned metal electrodes and fired at a high temperature to leave a layer of pure dielectric material. At this point the surface is too rough for thin-film deposition, so a leveling, or planarization, layer is applied to provide a smooth surface. This is accomplished using a sol–gel process, whereby a metal–organic solution is applied in the liquid phase then fired to create a layer of lead zirconium titanate ($PbZrTiO_3$). This material fills the voids between the relatively large particles of the dielectric thick film, thus providing a smooth surface for the thin-film processing to follow.

The manganese-doped zinc sulfide (Mn:ZnS) phosphor is then deposited using a vacuum thin-film deposition process. A similar process is used to deposit a thin film of indium tin oxide (ITO) over the phosphor. The ITO is then formed into the column electrodes using laser scribing. Sealing a piece of ordinary glass over the ITO finishes the cell assembly. In multicolor displays, the glass plate has a pattern of color filters printed on its inside surface.

SSD devices can produce luminance. A 600 cd/m^2 peak luminance was observed at 180 volts (only 40 volts modulated) and a 30 Hz refresh rate. The high dielectric constant of the thick-film dielectric maximizes the portion of the voltage that is applied to the phosphor, producing a steep luminance-voltage curve. The firm claims that its monochrome SSD device can exhibit a luminous efficiency of more than 7 lumens/watt in a single pixel. In a fully addressed panel, the total power conversion efficiency is said to be 1 to 2 lumens/watt.

There are some drawbacks to this technology. For example, the thick dielectric stack does not lend itself well to applications with a very high resolution. Small geometries approaching the stack thickness lead to significant field distortion at electrode edges, resulting in partial lighting of adjacent pixels (crosstalk). Thus, SSD panels are limited to subpixel pitches of about 0.1 mm, which is not close enough for head-up display or viewfinder applications, but is certainly adequate for large-screen displays. Another drawback is the high current demand on the panel IC drivers, which is caused by the high capacitance of the thick dielectric film. Initially this drawback impeded commercialization, because it required the development of specialized drivers. However, the SSD panel can be driven at lower voltages than AC-TFEL devices, so the overall power dissipation in the chips should not increase dramatically, according to iFire.

Remarkable progress has been made in the further development of the SSD in a relatively short period of time. The first laboratory demonstration of a 3-color, 2-inch panel with a luminance of 10 cd/m^2 occurred in mid-1995. In 1998 iFire advanced the technology of the point at which it could fabricate a 27-color, 8.5-inch panel with a luminance of 50 cd/m^2. In 1999 the company demonstrated an 8.5-inch, video-rate panel with 16.7 million colors and a luminance of 100 cd/m^2. A 17-inch panel with 27 colors and a luminance of 20 cd/m^2 was also shown. Plate to improve the performance of its 17-inch display to 250 cd/m^2 and 16.7 million colors by 2001, as well as build 34-inch and 42-inch panels for television applications by 2003 have been made.

DC Powder Electroluminescent Displays

An older EL technology is the DC powder technique, which employs a thick film of zinc sulfide as the active matrix element and differs from the AC-TFEL panel in a number of significant respects. The DC panel is resistive, and the brightness is limited by pulse repetition rate. The DC EL panel uses a current to drive the display, and the brightness is a linear function of the current and the pulse repetition frequency. The dynamic resistance of the DC electroluminescent phosphor is quite low, approximately 100 ohms. To prevent excessive currents, which damage the phosphor, it is necessary to develop an adjustable constant current drive circuit for the column drivers. However, no commercial development is underway at this time.

Transparent Electroluminescent Displays

Researchers, including S. Kanda, M. Katayama, Y. Hattori, and N. Ito, at Denso Corporation recently reported the development of a transparent thin-film EL display for automobile applications. Self-illumination type EL displays can provide higher visibility compared to LCDs both in sunlight and at low operating temperatures; this has enabled development of what Denso calls a Dual Vision Optitron Meter®, which is a device combining an array of conventional analog needle point gauges with a digital meter having a transparent EL panel. The new meter consists of a transparent EL panel placed over an analog meter, enabling reading of the information from the digital meter without the need to move the line of sight. In addition, the features of the digital meter have been optimized to make it possible to display not only a single item of information, but also to switch between items of information. The device now appears in a luxury sedan sold in Japan. See also **Luminescence**, and the family of articles catalogued under **Flat Panel Display Technology**.

ELECTROLYSIS. Decomposition of water and other inorganic compounds in aqueous solution by means of and electric current, the extent being proportional to the quantity of electricity passing through the solution. The positive and negative ions formed are carried by the current to the oppositely charged electrodes, where they are collected (if wanted) or released (if unwanted). Metallic ions deposited on the electrode form a coating. A simple electrolysis is the separation of water into oxygen and hydrogen. Somewhat more complicated is electrolysis of brine to chlorine and sodium hydroxide; this is carried out in electrolytic cells of the diaphragm or mercury type, with water taking part in the reaction. In electroplating, metal salts dissociate into their constituent ions, the positively

charge metal ions coating the cathode. There are a number of variations of this process (electrodeposition, electrocoating, electroforming).

See also **Electrochemistry**; **Electrolytic Cell**; and **Ionization**.

ELECTROLYSIS-TYPE CHEMICAL ANALYZER. Sometimes referred to as electroplating analyzers, these devices can be used for determining metals and other materials that will plate out on an electrode which is part of an electrolytic cell. Alloys, such as stainless steel, brass, and bronze that contain chromium, copper, lead, iron, nickel, and tin-bearing metals containing bismuth, can be analyzed in this fashion. The sample must be relatively easy to dissolve so that an electrolyte can be formed and it must be sufficiently large to permit plating out a quantity of material that can be accurately weighted. The potential required to effect plating of a specific material should be known in advance. Complex materials usually are identified on a cumulative basis by making stepwise increases in plating potential, with intermittent weighing of the plated electrode.

ELECTROLYTE. A substance that will provide ionic conductivity when dissolved in water or when in contact with it; such compounds may be either solid or liquid. Familiar types are sulfuric acid and sodium chloride, which ionize in solution. One solid electrolyte, used originally in fuel cells, is a polymer of perfluorinated sulfonic acid used as the core of a water electrolysis cell for production of hydrogen and oxygen. When saturated with water, it has high conductivity. Another solid type is a ceramic mixture of sodium, aluminum, lithium, and magnesium used as a separating medium in the liquid-sodium–sulfur (β) battery under continuing development. The most common application of electrolytes is in electroplating of metals in which dissolved (ionized) metal salts are the electrolytes.

See also **Electrolysis**; and **Electroplating**.

ELECTROLYTIC CELL. An electrochemical device in which electrolysis occurs when an electric current is passed through it. Ionizable compounds dissociate in the aqueous solution with which the electrodes are in contact. Such cells are of two types: (1) the diaphragm cell, which has two compartments separated by a porous membrane; and (2) the mercury cell, in which mercury is the cathode. The anodes of both types have long been made of graphite. Because this decomposes rapidly as electrolysis progresses, they are being replaced with dimensionally stable types consisting of titanium coated with oxides of ruthenium and other rare metals, which are also much more efficient. In electrolysis of sodium chloride, the current causes the chloride ion to the anode, where it is collected as chlorine gas; sodium hydroxide and hydrogen are also formed, the hydrogen being discharged. The overall cell reaction is: $2HaCl + 2H_2O \rightarrow H_2 + Cl_2 + 2NaOH$. This principle is applied in the electroplating of metals, electrodeposition of colloids, and similar processes.

See also **Diaphragm Cell**; and **Electroplating**.

ELECTROLYTIC CONDUCTIVITY AND RESISTIVITY MEASUREMENTS. Industrial interest in the measurement of electrolytic conductivity (of which electrolytic resistivity is the reciprocal) arises chiefly from its usefulness as a measure of ion concentrations in water solutions. Also, by comparison with other analytical methods, this is relatively simple and inexpensive.

Pure water is a very poor conductor. Water, such as may be produced by passage through a mixed-bed ion exchanger, has a conductivity approaching very closely the theoretical minimum of approximately 0.05 μS/cm (18 MΩ · cm) at 25 °C, which is due to the dissociation products of water itself (S/cm = siemens/centimeter). The conductivity of a water solution, as encountered in industrial practice, is almost exclusively due to a dissolved electrolyte rather than to the solvent (water) ions, and thus a criterion for electrolyte concentration can be established. Solutions of strong electrolytes follow a rather uniform pattern of change in conductivity with concentration, which is almost linear at low concentrations, rising more gradually to a maximum (usually about 20–30% wt) and then falling as the concentration rises further. A series of such conductivity-concentration curves is given in Fig. 1.

Practical applications of these measurements include: (1) Gauging the quality of pure water, such as distilled or demineralized water and condensed boiler steam; (2) measuring the extent of reactions, such as neutralization, precipitation, and washing of soluble electrolytes from insoluble materials; (3) detecting contamination, such as leaks in heat exchangers and resultant contamination of heating or cooling media as in acid coolers, condenser coils, and steam coils; (4) checking possible saltwater intrusions in streams and wells; (5) checking on process interface levels where, for example, oil-in-water and water-in-oil emulsions may be distinguished by the fact that the former are conductive and the latter are essentially nonconductive; and (6) the enhancement of the conductivity of certain ions of interest. For example, very conductive hydroxyl ions may be removed from boiler water by the addition of a weakly ionized organic acid to reveal a conductivity which is more nearly proportional to that of the remaining dissolved salts. Or, conductive ammonium hydroxide may be removed from steam condensate by passage through a hydrogen cation exchanger to reveal the conductivity of the remaining dissolved salts, which are converted to their corresponding mineral acids. Similarly, samples may be boiled or sparged to remove conductive dissolved gases.

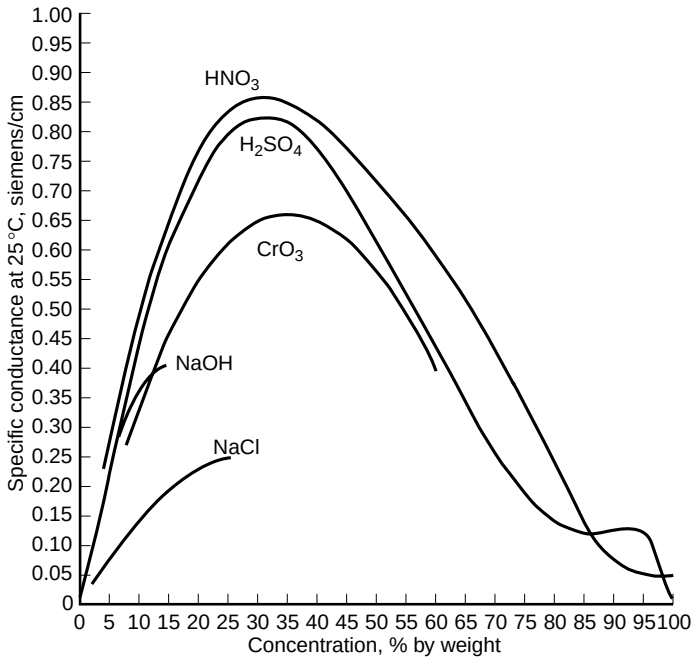

Fig. 1. Conductivity-concentration curves for certain electrolytes.

Measurement Fundamentals

The flow of electricity through matter is accomplished by movement of electric charges, which, in metallic conductors, are electrons, and in electrolytic conductors are positive and negative ions. Conducting solutions in general are electrolytic conductors. In electrolytic conductors, current is usually introduced and leaves the system through metallic electrodes on the surface of which chemical reactions occur. It is possible when using alternating current to cause current to flow by inductive coupling as well as by direct contact between electrode and electrolyte. Positive ions or cations move toward the cathode, where reduction takes place, and negative ions or anions move toward the anode, where oxidation takes place. The conductivity of a solution depends upon the concentration and mobility of all ions present. The ion mobility, in turn, depends upon ion size and charge, as well as the dielectric constant of the solvent and the solution temperature and viscosity.

The determination of electrolytic conductivity presently consists of measuring the A.C. electrical conductance of a column of solution. Although A.C. measurement methods greatly reduce errors associated with electrolysis, when electrodes are used, they introduce other errors associated with series and shunting capacitance which must be compensated for in the design of the measuring instrument. A precision of 0.01% can be obtained in laboratory measurements by following the bridge techniques first discussed by Grinnell Jones and his coworkers. Industrial conductivity meters are capable of providing accuracies of 1% of the actual conductivity under ideal conditions.

Electrolytic conductivity is most often measured by placing electrodes in contact with the electrolytic solution which is contained in such a way that

the measured electrical conductance between the electrodes can be related to the conductivity of the solution. The conductivity cell most commonly comprises an enclosure made of electrically insulating material, such as glass or plastic, which serves to hold or isolate a portion of the electrolytic solution and to accommodate the two electrodes. The cell constant of such a device is then used to relate the measured electrical conductance between the electrodes to the actual electrolytic conductivity.

Two electrodes, 1 centimeter square, located on opposite interior faces of a hollow cube, 1 centimeter on an edge, would have a cell constant of 1/cm; a measured conductance of 100 microsiemens at 25 °C would indicate a conductivity of 100 microsiemens/cm (10 millisiemens/m) at 25 °C.

Definitions and Units. Electrolytic conductivity is often defined as the electrical conductance of a unit cube of solution as measured between opposite faces. It is expressed in the same units as electrical conductivity, i.e., reciprocal ohms per unit length. Most commonly we find Mho/centimeter (Ω^{-1} cm^{-1}), siemens/centimeter (S cm^{-1}), and siemens/meter (S cm^{-1}):

$$1\ \Omega^{-1}cm^{-1} = S\ cm^{-1} = 100\ S\ m^{-1}$$

Few solutions exhibit conductivities as great as 1 siemens/cm. The most commonly used decimal submultiples are microohm/centimeter ($\mu\Omega^{-1}cm^{-1}$), microsiemens/centimeter ($\mu S\ cm^{-1}$), and millisiemens/meter ($mS\ m^{-1}$):

$$1\ \mu\Omega^{-1}cm^{-1} = 1\ \mu S\ cm^{-1} = 0.1\ mS\ m^{-1}$$

Electrolytic resistivity (the reciprocal of conductivity) is similarly defined as the electrical resistance of a unit cube of solution. It is expressed in the same units as electrical resistivity, i.e., ohms times a unit of length. Most commonly we find: ohm-cm (Ω-cm) and ohm-meter (Ω-m):

$$100\ \Omega\text{-cm} = 1\ \Omega\text{-m}$$

Again, decimal multiples commonly encountered are megohm-centimeter and megohm-meter:

$$100\ M\Omega\text{-cm} = 1\ M\Omega\text{-m}$$

Resistivity units are used almost exclusively to describe ultrapure water in the 10 megohm-cm to 18 megohm-cm (0.1 microsiemens/cm to 0.055 microsiemens/cm) range generated by mixed bed ion exchange and used as boiler feed water and in certain critical washing applications.

The cell constant of a conductivity cell is defined as a factor that relates the measured conductance between the cell terminals to the conductivity of the electrolyte being measured. It is generally expressed in reciprocal units of length (although occasionally in units of length for certain European manufacturers). Most commonly we find 1/centimeters (cm^{-1}) and 1/meters (m^{-1}):

$$1\ cm^{-1} = 100\ m^{-1}$$

The conductance measured between the cell terminals is multiplied by the cell constant given in reciprocal units of length to calculate the conductivity. To calculate the resistivity, the measured resistance between the cell terminals is divided by the cell constant. Although the cell constant (in reciprocal units of length) can be calculated from the dimensions of the conductivity cell by dividing the length of the electrical path through the solution by the cross-sectional area of the path, in practice, these measurements are difficult to make and are only used to approximate the cell constant, which is determined by use of standard solutions of known conductivity or by comparison with other conductivity cells which have been so standardized.

Measuring Circuits

Although there are several circuits used for measuring electrolytic conductivity, the ac Wheatstone bridge is widely applied and is potentially the most stable and accurate.

AC Wheatstone Bridge. A typical system is shown in Fig. 2 and comprises the bridge, including the voltage source, the null indicator, and the conductivity cell. In Fig. 2, *D* represents an ac voltage-sensitive device called the *detector*. The ac source may be the low-voltage tap on a line-frequency operated transformer or battery or line-powered electronic oscillator for higher frequencies. The magnitude of the bridge voltage

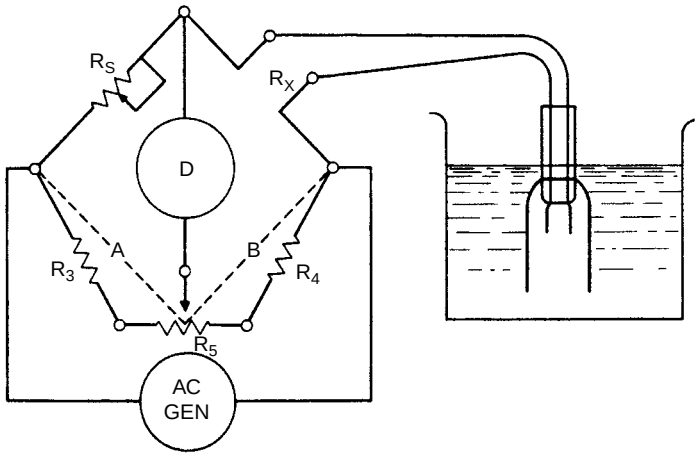

Fig. 2. Alternating current Wheatstone bridge used in electrolytic conductivity measurements.

necessarily is related to the sensitivity of the detector and also to the general characteristics of the electrolytes to be tested.

The usual industrial measuring and control equipment is supplied with bridge voltages of 1–10 V. The frequency of this ac source in commercial units is commonly 60 Hz and more rarely 1000 Hz. Where measurements are to be made on high-resistance electrolytes, such as distilled water or steam condensate, the lower bridge source frequency is preferable. For measurements in high-conductivity solutions, the higher bridge frequencies are of advantage.

R_S is the so-called *standard arm* of the bridge; it is generally made variable, as a device either to change the range of the instrument by selecting one of a number of resistors differing in resistance by powers of 10, or to correct for the temperature coefficient of resistance of the electrolyte. R_3 and R_4 are end resistors whose function is to establish the limits of the bridge calibration. R_5 is the calibrated slidewire potentiometer. With R_3 and R_4 short-circuited, the range of the bridge would be zero to infinity in resistance or conductance. Increasing values of R_3 and R_4 compared with the value of R_5 will reduce the range covered. It should be noted that the slidewire contact resistance is in series with the detector, and thus variable values of this resistance cause no error in bridge readings. R_X is effectively the resistance of the electrolyte measured between the two electrodes of the conductivity cell immersed in the liquid under test. The condition for balance of the Wheatstone bridge is that $A/B = R_S/R_X$, and this condition is indicated by no current flow through the detector *D*.

While most laboratory conductivity bridges are manually balanced, the Wheatstone bridge circuit also finds use in a variety of conductivity monitors, controllers, and recorders where it is mechanically rebalanced by a servomechanism operated by the detector. Generally in these devices, advantage is taken of the phase shift, which occurs in the detected signal as the bridge is driven through balance by the servo motor.

Conductivity Meter. A second system utilizes a simple ohmmeter circuit, shown in Fig. 3. A meter, transformer secondary winding, and conductivity cell are connected in series so that the current is a function of the cell conductance. The meter may be calibrated in resistivity or conductivity units.

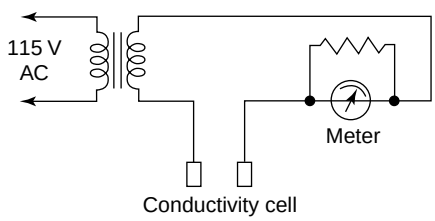

Fig. 3. Conductivity measurement system utilizing a simple ohmmeter circuit.

While early circuits of this type suffered from inaccuracies due to line voltage variations, the addition of a regulated power supply to drive the

transformer has brought this relatively simple and inexpensive circuit into wide use. Complete isolation may be achieved by interposing a second transformer between the cell and meter. Generally, a stage of amplification is added to increase sensitivity and to reduce nonlinearity caused by meter resistance. This, combined with gated detection, reduces those polarization errors associated with series capacitance at the electrodes. Driven shields are employed to reduce the errors associated with the shunt capacitance of long cell leads. The addition of automatic temperature compensation, alarm contacts, and electrical outputs make the conductivity meter the most widely used instrument for industrial measurement and control applications.

Electrodeless Circuit. An electric current may be caused to flow in an electrolyte by means of induction without the use of contacting electrodes. In such electrodeless systems, the electrolyte is contained in an electrically insulating tube which passes through the cores of two transformers (Fig. 4) in such a way that the electrolyte forms a closed loop linking the flux in both cores. In the first transformer, this loop of electrolyte serves as a single-turn secondary winding in which an alternating voltage is induced. In the second transformer, the loop forms a single-turn primary winding, providing a means for measuring the resulting current which is directly proportional to the specific conductance of the electrolyte comprising the loop. Alternatively, both transformers may be located about an insulated tube immersed in the electrolytic solution.

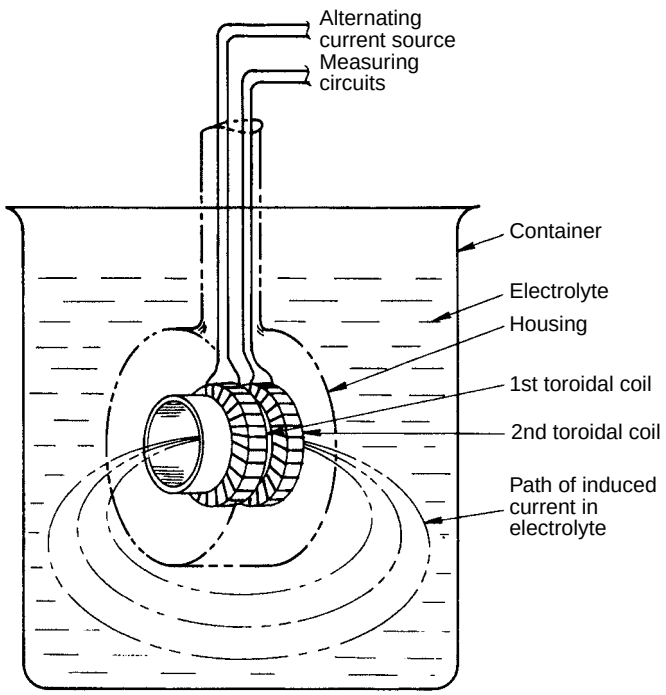

Fig. 4. Inductive electrolytic conductivity measuring circuit.

Variations of these systems employing glass tubes were in use before 1907. However, more recently, the introduction of chemically resistant, high-temperature electrical insulators, such as the fluorocarbons, has simplified the design of the insulated tube comprising the electrodeless conductivity cells. Since no contacting electrodes are used, all the problems associated with electrodes, such as polarization and electrode surface maintenance, simply disappear. Wide application of these systems is found in highly conductive electrolytes, such as the strong mineral acids and bases — often in conjunction with abrasive slurries or materials containing entangling fibers.

Four-Electrode Circuit. This method avoids errors caused by polarization and fouling by using a set of measuring electrodes located between a set of current-producing electrodes. See Fig. 5. The measuring electrodes are used to determine the voltage drop in the electrolyte caused by the current. The conductivity of the electrolyte between the measuring electrodes is proportional to the current divided by the potential. Laboratory measurements may be made with either AC or DC. However, process instrumentation almost always utilizes AC. In practice, the alternating

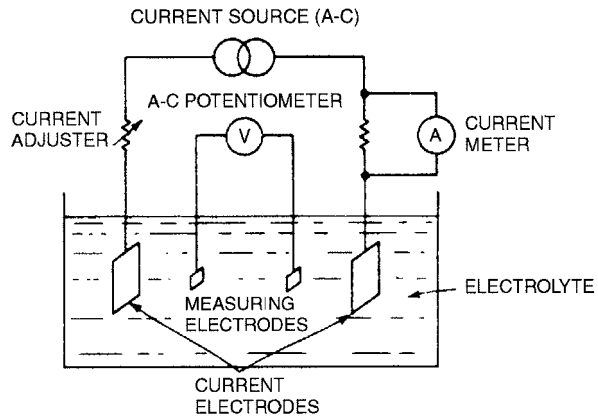

Fig. 5. Four-electrode conductivity circuit.

current through the entire cell is varied to maintain a constant potential between the measuring electrodes. When this is done, the conductivity of the electrolyte between the measuring electrodes is proportional to the cell current. Changes external to the measuring electrodes, such as may be caused by current electrode polarization or fouling, will not cause a change in the cell current, which will be maintained at such a value that the potential between the measuring electrodes is constant. Systems have been designed that can accommodate a tenfold increase in impedance at the current electrodes due to polarization and fouling. Fouling and polarization errors do not occur at the measuring electrodes since the measurement there is essentially potentiometric with no current flowing through the measuring circuit. Size and orientation of the measuring electrodes are also chosen to avoid such errors.

Conductivity Cells

These are simple in basic structure, consisting typically of two metal plates or electrodes spaced within an insulating chamber. Examples are shown in Figs. 6 and 7. This arrangement permits isolation and measurement of a portion of the solution and serves to make the measured resistance independent of sample volume and proximity to conductive and nonconductive surfaces. In laboratory cells, platinum electrodes mounted in a glass are commonly employed for their excellent chemical resistance.

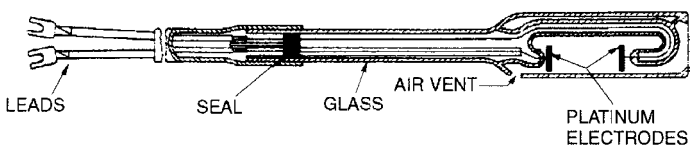

Fig. 6. Dip-type conductivity cell.

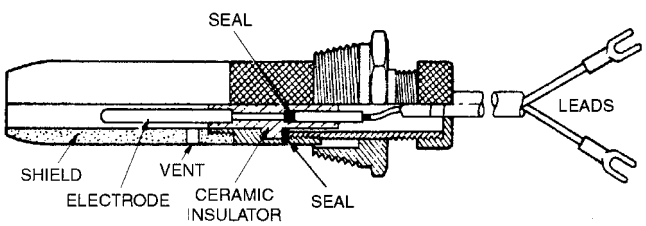

Fig. 7. Screw-in conductivity cell for high-pressure service.

Dip Cell. This is designed for dipping or immersing into open vessels. See Fig. 6.

Screw-in Cell. This is designed for permanent installation in pipelines and tanks and is equipped with threaded fittings. See Fig. 7.

Insertion Cell with Removal Device. This is configured to permit removal of the element without closing down or depressurizing the line in which it is installed.

Flow Cell. This type of cell is built in sections of plastic or glass tubing with bores from several millimeters to one inch (25.4 mm) and more. The

cell has internal electrodes, usually metallic or carbon rings, mounted flush with the wall to offer little resistance to flow.

ELMER SPERRY and JOHN NAGY, Beckman Industrial Corporation, Cedar Grove, NJ

ELECTROLYTIC TRANSDUCER. A device whose electrolytic resistance is caused to change when exposed to the variable being measured. A simple configuration comprises two electrodes that are separated by a small distance, with the volume between the electrodes occupied by an electrolyte. To be used as a transducer, as in the case of displacement measurement, the distance between the electrodes or the effective cross-sectional area of the electrolyte can be varied. Very little force is required to produce a displacement and the device can be made quite small. The devices are very temperature sensitive, a disadvantage for practical, industrial applications. Also, like other electrolytic cells, the devices are subject to polarization. Because of these limitations, electrolytic transducers are not commonly used.

ELECTROMAGNET. A magnet whose field is produced by an electric current, and which is largely demagnetized upon cessation of the current, is an electromagnet. In order to obtain the strongest field possible, highly permeable soft iron or steel is employed for the core of electromagnets. In an electromagnet the current flows through a solenoid, which is a conductor wound in the form of a helix, and which produces a strong magnetic field coaxial with the helix. The core is placed inside the helix in order to give a magnetic path of the least reluctance. Electromagnets are found in a number of different forms, such as the plain solenoid with cylindrical core, or the horseshoe electromagnet, much used in electric bells, telegraph instruments, and telephones. See Fig. 1. Very powerful electromagnets are often used to move masses of iron, such as scrap iron, and have the advantage that the loading or unloading of the crane to which the magnet is attached is simply a matter of applying or disconnecting the electric current.

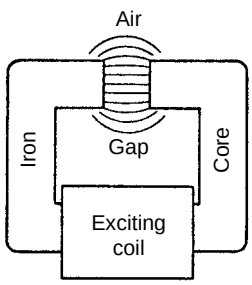

Fig. 1. Electromagnet having two poles, one of a large variety of available designs.

The use of superconductors can significantly increase the effectiveness of an electromagnet.

ELECTROMAGNETIC LIGHT WAVES. Electromagnetic light waves are the "visible light" that our eyes can see. Visible light, which is optical radiation, is part of the electromagnetic spectrum, a range of electrical and magnetic fields (hence the name)—radio waves, microwaves, infrared, optical, ultraviolet, x-rays, and gamma rays—traveling through space. Of these, visible light is the only radiation we can see with our eyes. We need to use sensitive instruments to see the other types. All these types of radiation travel in waves and every electromagnetic wave has a unique frequency, and a wavelength associated with that frequency.

Visible light waves carry energy and momentum that can be detected by the human eye and other instruments. They carry information about the structure of the matter that generated them, what the matter is made of or its temperature, for example.

- Different frequencies of light waves are detected as different colors by thehuman eye because the eye has sensor cells that detect different wavelengths. Light wavescan be broken down into a continuum of colors, and then we see a rainbow.
- This can be demonstrated by looking at a prism. White light goes in, all the colors of the rainbow come out. A prism separates the visible "white" light into its different wavelengths. In the visible range of the electromagnetic spectrum red has the longest wavelength, while violet has the shortest.
- Light is a form of energy that has been used by astronomers since ancient times to study the Universe. In Einstein's theory, energy (radiation) can also be carried by the vibrations of space and time, which are predicted to travel at the speed of light, 299,792,458 meters per second (186,282 miles per second). These vibrations are gravitational waves.

See also **Electromagnetic Spectrum**; and **Electromagnetic Radiation**.

ELECTROMAGNETIC PHENOMENA. The term *electromagnetic* is used to describe the combined electric and magnetic fields that are associated with movements of electrons through conductors and to describe the combined electrical and magnetic effects exhibited by and used by equipment, apparatus, and instruments. In terms of radiation, the term is used to describe the radiation that is associated with a periodically varying electric and magnetic field traveling at the speed of light, such as light waves, radio waves, x-rays, gamma radiation, and so on.

Electromagnetism. The pioneer discovery of the magnetic effect of the electric current was made by Oersted at Copenhagen in 1820. In experimenting with battery currents, he happened to bring a compass needle near a wire in which there was an electric current, and noted that the needle was deflected. Such a wire is surrounded by a magnetic field so that, to one looking along the wire in the direction from the positive to the negative battery terminal (the so-called "direction of the current"), the direction of the field, as indicated by the north pole of the compass needle, is clockwise (Ampère's rule).

If the wire carrying the current is placed in a magnetic field perpendicular to its direction, this field reacts with that due to the current in such a way as to give the wire a lateral thrust, perpendicular to both the wire and the field in which it is placed. For a wire of length l carrying current I and placed across a field of intensity B, this lateral force is given by the equation $f = BlI$, which follows from the definition of the ampere. An electric motor is driven by forces thus produced.

If the wire is bent into a circular loop of radius r, still carrying current I, there is produced at its center, perpendicular to the plane of the loop, a magnetic field of intensity $H = I/2r$. This, and the statement in the preceding paragraph, may be shown to be interdependent. If more loops are added, forming a coil of n equal turns close together, the resulting field is n times as great. By winding the n turns along a cylinder, forming a "helix" of radius r and axial length a, one obtains something greatly resembling a bar magnet, the ends of the helix corresponding to the poles. The field intensity at the center of the axis of this helix is

$$H_0 = \frac{nI}{\sqrt{4r^2 + a^2}}$$

The above expressions are all appropriate in the rationalized mksa system.

If we now insert an iron core, we have an electromagnet, and the helix supplies the magnetomotive force nI ampere-turns for a magnetic circuit composed partly of iron and partly of air.

More general calculations of electromagnetic effects are based upon Ampère's law, the Biot-Savart law, and Maxwell's equations.

Electromagnetic Induction. Probably the most noteworthy of the many scientific contributions of the renowned Michael Faraday was his discovery in 1831 of electromagnetic (or, more logically, magnetoelectric) induction. As exhibited in the usual experimental arrangements, this phenomenon is the setting up, in a circuit, of an electromotive force due to the variation of the magnetic flux linked with the circuit. The magnitude of that electromotive force is, as Faraday found, proportional to the rate at which the flux through the circuit, or the "linkage," varies. If the flux linkage with the circuit, in weber-turns, is expressed by $N\phi$ (the actual flux, ϕ, times the number of turns, N), the electromotive force generated by its variation, in volts, is

$$E = N\frac{d\phi}{dt}$$

The electromotive force is positive (counterclockwise) when $d\phi/dt$ is positive, that is, when the flux is increasing, negative when it is decreasing; as viewed by one looking in the direction of the magnetic induction.

Another aspect of the matter is that, if a conductor moves through a magnetic field, or if a magnetic field sweeps over a conductor, in such a way that the conductor cuts across the lines of force, the electricity in the

conductor experiences forces at right angles to the field and to the (relative) motion. More general still is the Maxwell concept that when magnetic lines of force move sidewise, their movement results in an electric field at right angles to the magnetic lines and to their motion.

Faraday's discovery was almost accidental. Happening to thrust a bar magnet into a coil connected with a galvanometer, he noted a momentary deflection of the needle. If the north pole is thrust downward into the coil, so as to increase the flux linked with the coil, the current will be counterclockwise as viewed from above, and reverses on drawing the magnet out again. See Fig. 1.

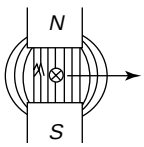

Fig. 1. Wire (W) moving to the left across an upward magnetic field has induced in it an emf away from the observer.

The far-reaching consequences of this simple observation can hardly be overestimated. It was the forerunner of the invention of electric generators and alternators, of the original Bell telephone, of the induction coil, of the transformer, of the induction motor, of magnetic damping devices, and of many other electric appliances. It is the basis of Lenz's law and of the Wilson experiment, and the explanation of eddy currents. The volt and the henry are definable in terms of it. The phenomenon is called mutual induction when the variation of current in one circuit causes a variation of magnetic flux through, and hence an electromotive force in, another coupled circuit. It is a curious fact that in a vacuum, the linkage through one circuit A due to unit steady current in a neighboring circuit B is equal to the linkage through B due to unit current in A; hence, the mutual inductance of two circuits is the same no matter which is the primary circuit. If the circuits are closely coupled and have high self-inductance, and if an alternating electromotive force E be applied to A, the resulting ac induces an electromotive force in B approximately equal to $(N_B/N_A)E$; in which N_A and N_B represent the numbers of turns in the respective circuits. The principle is utilized in induction coils and in potential transformers.

Electromagnetic Field. Traditionally and in a simplistic way, it may be stated that a wire carrying an electric current is surrounded by a magnetic field whose lines of force are circles with the wire as their axis. This statement implies that the magnetic field is directly traceable to the moving electricity in the wire. This is an oversimplified explanation, however, because each electric "particle" projects into space a radiating field of electric force; and as the particles move along the wire, the lines of force move with them.

Theory of Maxwell. As will be developed later, the Maxwellian theory of the electromagnetic field has been supplanted and refined. Prior to the more detailed description of modern concepts, it may be in order to develop the earlier Maxwell concept. According to the theory of Maxwell, it is the motion of these lines of electric force that sets up the magnetic field transverse to them. More generally, a variable electric field is always accompanied by a magnetic field; and, conversely, a variable magnetic field is accompanied by an electric field. The joint interplay of electric and magnetic forces here described is what is called an electromagnetic field, and is considered as having its own objective existence in space apart from any electric charges or magnets with which it may be associated. An essential feature of the theory is that this process, whatever it is, represents a flow of energy at right angles to both electric and magnetic components. The flux density of this energy (corresponding to the intensity of radiation) is represented by what is known as the Poynting vector. Electromagnetic radiation is, on this theory, the propagation of these electric and magnetic stresses through space with the speed of light, somewhat as the much slower waves of elastic stress are propagated through steel. The conditions in an electromagnetic field are expressed mathematically by Maxwell's equations.

When an electric charge is set into motion, it builds about itself an electromagnetic field, and this implies a distribution of energy throughout space. The density of this energy at any point of the field is proportional to the product of the electric and magnetic vector components and the sine of the angle between them (vector product). The total field energy can be obtained by suitable integration, and is greater than that of the purely electric field of a stationary charge. Maxwell's theory treats this excess as kinetic energy, thus endowing the moving charge with an "electromagnetic mass" and an "electromagnetic momentum" inherent in its electrical character.

The Maxwell equations comprise a set of four classic formulae of the electromagnetic theory. They deal with certain vector quantities pertaining to any point of a region under varying electric and magnetic influence. If the point is in empty space, the equations are somewhat simplified; in general, provision must be made for the presence of dielectrics, conductors, or magnetizable bodies. In these equations, $\mathbf{H}$ is magnetizing force, $\mathbf{B}$ is magnetic induction, $\mathbf{E}$ is electric intensity, $\mathbf{D}$ is electric induction, ρ is electric charge density, $\mathbf{J}$ is conduction current density, t is time. The "curl" and the "divergence" of a function are well-known operators of vector analysis. The equations, in rationalized mks units are

$$\text{Curl } \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J} \tag{I}$$

$$\text{Curl } \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{II}$$

The additional relations

$$\text{Div } \mathbf{B} = 0 \tag{III}$$

$$\text{Div } \mathbf{D} = \rho \tag{IV}$$

are frequently included as part of Maxwell's system, although they are not independent relations if one assumes the conservation of charge. The last two are also known as the Gauss law. For linear homogeneous isotropic media, $\mathbf{B} = \mu\mathbf{H}; \mathbf{D} = \varepsilon\mathbf{E}$. The values of μ and ε for a vacuum satisfy

$$\mu_v \varepsilon_v = 1/c^2$$

where c is the speed of light, μ is permeability and ε is permittivity.

Electromagnetic Radiation

The electromagnetic spectrum is the total range of wavelengths or frequencies of electromagnetic radiation. As shown in Table 1, this range extends from the longest radio waves to the short cosmic rays.

Prior to Maxwell's studies of the electromagnetic field in an effort to substitute electric and magnetic forces for elastic forces in the theory of light propagation, light was believed to be a transverse wave motion in an *ether* that behaved like an elastic solid. According to Maxwell's views, it was postulated that light is the result of vibrating electric charges. These set up alternating electric and magnetic fields at right angles to each other and to the direction of propagation, which pass on the energy from one portion of the ether to the next as an electromagnetic wave. (Poynting's theorem states that the rate of this energy transfer is proportional to the product of the electric and magnetic intensities.) The theory was successful in explaining many of the electrical and magnetic properties of light, such as the Faraday effect and the Kerr effect.

Maxwell suggested that it should be possible to produce waves of much longer wavelength than light by causing electricity to oscillate in a conductor. This was a forecast of the radio waves, upon which radio transmission depends, and which exhibit many of the characteristics of light, such as reflection, refraction, diffraction, interference, polarization, etc., but on a gross scale. Other researches showed that the infrared and the ultraviolet radiation have these same properties. It was therefore natural to classify them together as the same phenomenon in different frequency ranges. X-rays for a time could not be identified with this group, but their diffraction by crystals finally demonstrated their wave character and they now take their place next to the ultraviolet. Meanwhile the quantum theory put a new aspect on the whole matter, and the gamma rays were added to the radiation family.

Present Concepts of Electromagnetic Theory. The task of electromagnetic theory is to account for the effects of electrical charges in various states of motion. Although historically electromagnetic theory was developed from Coulomb's celebrated law, it is at present more economic to develop it differently. The macroscopic effects are described with remarkable accuracy by the following set of equations (rationalized mks system of units):

$$\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B} \tag{1}$$

TABLE 1. ELECTROMAGNETIC SPECTRUM SHOWING PRINCIPAL RADIATION CATEGORIES

Frequency (Hz)	Type of Radiation	Wavelength (cm)

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0 \tag{2}$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J} \tag{3}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{4}$$

$$\mathbf{D} = f_1(\mathbf{E}) \tag{5}$$

$$\mathbf{B} = f_2(\mathbf{H}) \tag{6}$$

$$\mathbf{J} = f_3(\mathbf{E}, \mathbf{H}) \tag{7}$$

provided the functional relationships indicated in Equations (5), (6), and (7) are known explicitly. With these equations and the laws of mechanics, classical electromagnetic theory becomes essentially a branch of applied mathematics.

Equation (1), sometimes known as the Lorentz force equation, defines the field quantities, **E**, the electric field intensity, and **B**, the magnetic induction, in terms of an observable, the force **F** on a charge q. In Equation (1), **v** is the velocity of the charge relative to the observer. Equation (2) is a statement of the law of conservation of electric charge in terms of the charge density ρ and the total current density **J**. Equation (3) is the differential form of Ampère's law,

$$\oint_{\text{cofs}} \mathbf{H} \cdot \mathbf{dl} = \iint_{s} \mathbf{J} \cdot \mathbf{dS} = I$$

which relates the magnetic field intensity **H** to the current, including in addition the displacement current density term $\partial \mathbf{D}/\partial t$, which was added by Maxwell to make the law applicable to time-varying fields. The term **J** represents the total current density. Equation (4) is the differential form of Faraday's law of electromagnetic induction. Equations (5), (6), and (7) are functional relationships, for the most part determined experimentally, by means of which the effects of different materials are accounted for. Mathematically, these equations are employed to reduce Equations (3) and (4) to a pair of equations in only two unknowns. In free space, Equations (5), (6) and (7) take their simplest form, respectively, $\mathbf{D} = \varepsilon_0 \mathbf{E}$, $\mathbf{B} = \mu_0 \mathbf{H}$, $\mathbf{J} = 0$ (or $J = J_s$, a source current independent of **E** and **H**), where ε_0 and μ_0 are constants whose value depends on the system of units (in the mks system $\varepsilon_0 = 8.854 \times 10^{-12}$, $\mu_0 = 4\pi \times 10^{-7}$). Since matter itself is a relatively dilute collection of charged particles, it is always theoretically possible to define terms so that the theory is a description of the effects and interactions of charges in free space, with consequently no essential distinction between **D** and **E** or between **B** and **H**, as indicated above. In practice, however, effects of materials are usually best handled in another way. Dielectric polarization effects are accounted for by making the **D** vector include the electric dipole moment density **P**, $\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}$, and then introducing a material constant, the permittivity ε, such that $\mathbf{D} = \varepsilon \mathbf{E}$. The relative permittivity of a dielectric material is then equal to one plus the electric susceptibility. Magnetic polarization effects are handled similarly by defining the field vector **B** so that it includes the magnetic dipole moment density **M**, $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$. The material permeability is then introduced so that it depends upon the magnetic susceptibility analogously, and $\mathbf{B} = \mu \mathbf{H}$. Effects of conductors are represented by a material conductivity σ, such that $\mathbf{J}_c = \sigma \mathbf{E}$. With these simple forms for Equations (5), (6) and (7), Equations (3) and (4) take on the useful form

$$\nabla \times \mathbf{H} = \varepsilon \frac{\partial \mathbf{E}}{\partial t} + \sigma \mathbf{E} + \mathbf{J}_1 \tag{8}$$

$$\nabla + \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \tag{9}$$

provided μ and ε are constant in time. The term $\mathbf{J}_1$ here includes currents arising from charges in free space plus any (source) currents that are independent of **E** and **H**. If there are no free charges in the region, $\mathbf{J}_1$ includes only the source currents; these latter are known, so Equations (8) and (9) may be solved for **E** and **H**. Since the equations are partial differential equations, boundary conditions over closed surfaces are required for unique solutions. Boundary conditions on the field quantities, which must hold at any boundary between two regions, may be derived from these equations. The conditions are: across a boundary (a) tangential **E** must be continuous, (b) tangential **H** must be continuous, (c) normal **D** and normal **B** must be continuous. Idealizations of material properties are sometimes helpful. For example, a perfect conductor has no nonstatic fields inside it, and, at its surface, tangential **E** and normal **B** are zero, tangential **H** is equal and perpendicular to any surface current density, and normal **D** is equal to any surface charge density.

Two additional equations, especially useful in static problems, may be deduced from Equations (2), (3) and (4):

$$\nabla \cdot \mathbf{D} = \rho \tag{10}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{11}$$

Solutions to the field equations are most readily obtained by imposing a restriction on the time dependence. If the fields are assumed to be independent of time (static), then Equations (3) and (4) or (8) and (9) decouple. One of the equations becomes $\nabla \times \mathbf{E} = 0$. This means that **E** is irrotational and may be represented by a scalar potential function, ϕ, $\mathbf{E} = -\nabla\phi$. Combining this with Equation (10) gives the fundamental equation of electrostatics,

$$\nabla^2 \phi = -\rho/\varepsilon \tag{12}$$

Poisson's equation. This equation for the electrostatic potential is solved by the standard methods of partial differential equations. The boundary conditions on the potential may be found from the boundary condition on the fields. In practice, it is frequently necessary to solve for the potential and electric field in a restricted region in which the charge density is zero, but the potential at the boundary is held at some particular value(s). The problem then is to solve Laplace's equation, $\nabla^2 \phi = 0$, subject to the stated boundary conditions. The standard techniques for solving boundary value problems are employed. However, if the region of interest is partially open, known analytical techniques are sometimes inadequate to solve the

problem. In two-dimensional problems of such a difficult type, the method of conformal transformations (conjugate functions) is often helpful.

The main applications of electrostatic theory are in: (a) the theory of material properties; (b) the calculation of charged particle trajectories in electron guns, deflection systems, and accelerators (here in conjunction with magnetostatic theory); (c) the calculation of circuit component values, such as capacitance; and (d) the determination of voltage gradients in connection with voltage breakdown problems.

Magnetostatic theory is developed from Equations (11) and (8). Since **B** is divergenceless, it can be represented by the curl of a vector **A**, which is known as the magnetic vector potential. Equation (8) can usually be written in terms of this potential as follows:

$$\nabla^2 \mathbf{A} = -\mu \mathbf{J} \tag{13}$$

Taken one rectangular component at a time, this equation is of the same form as Poisson's equation [Equation (12)] and may be solved in the same way. The boundary conditions on **A** may be found from those on **B** and **H**. In regions with no current, Equation (8) becomes $\nabla \times \mathbf{H} = 0$ so that **H** may be represented by a scalar potential function $\mathbf{H} = -\nabla \phi_{\mathrm{m}}$. In such regions then, in view of Equation (11), the magnetic scalar potential, ϕ_{m}, must satisfy Laplace's equation

$$\nabla^2 \phi_{\mathrm{m}} = 0 \tag{14}$$

provided $\nabla \mu = 0$ in the region. The techniques and solutions of electrostatics are applicable to many magnetostatic problems. Unfortunately, however, in practice many of the systems designed to establish a given magnetic field incorporate ferromagnetic materials. For such materials, the magnetic susceptibility (and hence the permeability) is not independent of the field intensity and the field equations become nonlinear. Present mathematical techniques for handling nonlinear problems are severely limited. Practical magnetostatic problems are, therefore, frequently solved by some approximation. One of the simplest and most useful approximations is a representation by a magnetic circuit. Series and parallel branches of the magnetic circuit may be recognized, and the techniques of linear and nonlinear circuit analysis can be applied to obtain a solution.

Magnetostatic theory is applicable to myriad magnetic devices including deflection systems, motors, generators, relays, magnetic pickup devices, permanent magnets, memories, transducers and coils. To date, the need for particular solutions has frequently arisen before sound analytical methods have been available, so many devices are developed empirically.

Energy is required to establish electric and magnetic fields, and such energy is associated with the fields. The field energy in a given volume may be computed in most cases from a volume integral of one or both of the following energy density expressions: $W_e = \frac{1}{2}\varepsilon E^2$, $W_m = \frac{1}{2}\mu H^2$, respectively the electrostatic and magnetostatic values.

When the fields are time varying, Equations (8) and (9) are coupled and must be solved simultaneously. Almost invariably, a potential function such as a vector potential or a Hertz potential is introduced. For example, Equation (11) implies that **B** may be replaced by a vector potential such that $\mathbf{B} = \nabla \times \mathbf{A}$. Equation (9) implies the following equation for **E**,

$$\mathbf{E} = -\nabla \phi - \frac{\partial \mathbf{A}}{\partial t} \tag{15}$$

so that **H** and **E** may be replaced in Equation (8), and with the condition on **A**, $\nabla \cdot \mathbf{A} = \mu\varepsilon \partial\phi/\partial t$, the following equations may be obtained for **A** and ϕ (σ assumed zero here):

$$\nabla^2 \mathbf{A} - \mu\varepsilon \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu \mathbf{J} \tag{16}$$

$$\nabla^2 \phi - \mu\varepsilon \frac{\partial^2 \phi}{\partial t^2} = -\rho/\varepsilon \tag{17}$$

That is, both the vector potential **A** and the scalar potential ϕ satisfy a differential equation known as the inhomogeneous wave equation.

Because of their simplicity and practical importance, solutions for those sources and fields that simply oscillate at a single frequency have been studied extensively. In this case, the time is eliminated as an independent variable, as if by a transform operation. (In fact, transform methods are often the best means of obtaining transient field solutions.) In the equations, the time derivatives are replaced by frequency multipliers so that the resulting equations are functions of the space variables only. The vector potential may then be found by standard techniques of partial differential equations and boundary value problems. Having **A**, the field quantity **B** is found from $\mathbf{B} = \nabla \times \mathbf{A}$ and **E** is found from Equation (8). In practice, a theorem that can be derived from the field equations, called the reciprocity theorem, is often helpful. The theorem relates the fields $\mathbf{E}_{\mathrm{a}}$ and $\mathbf{E}_{\mathrm{b}}$ produced respectively by a pair of current distributions $\mathbf{J}_{\mathrm{a}}$ and $\mathbf{J}_{\mathrm{b}}$. The theorem is

$$\iiint \mathbf{E}_a \cdot \mathbf{J}_{\mathrm{b}}\, dv = \iiint \mathbf{E}_b \cdot \mathbf{J}_a\, dv \tag{18}$$

For example, if $\mathbf{J}_{\mathrm{b}}$ is selected to be a point current at point P, directed along x(represented mathematically by a Dirac delta function), then Equation (18), $E_{\mathrm{ax}}(P) = \iiint \mathbf{E}_{\mathrm{b}} \cdot \mathbf{J}_{\mathrm{a}}\, dv$, gives a formula for the computation of the field due to $\mathbf{J}_{\mathrm{a}}$ which is equivalent to a superposition integral involving a Greens function.

Perhaps the most fundamental problem of electromagnetic theory is the determination of the fields of a point charge, at rest, in oscillation, or in some general state of motion. For a point charge q, at rest in free space, the solution may be obtained by solving Equation (12) in spherical coordinates. With the point charge at the origin, symmetry conditions may be employed to eliminate the angular variation, and the remaining differential equation in r can be solved subject to Equation (10) to give $\phi_G = (q/4\pi\varepsilon_0 r)$ for the potential associated with the point charge. A superposition integral

$$\phi = \iiint \frac{\rho\, dv}{4\pi\varepsilon_0 r} \tag{19}$$

may then be employed to find the potentials associated with more complicated distributions. The field of an oscillating dipole, which is equivalent to a point alternating current, is also of great interest. This solution may be obtained from Equation (16) (single frequency version). If the point current is directed along z, the z-component of the vector potential may be found by a procedure similar to that employed for a point charge. The final result is

$$A_{ZG} = \frac{I\,\Delta Z}{4\pi\mu_0 r} \cos\omega(t - \sqrt{\mu_0\varepsilon_0 r}) \tag{20}$$

where $\mathbf{I}\Delta z$, the current moment, is equal to $q\,\Delta z$, the maximum dipole moment of the oscillating dipole. The factor $(t - \sqrt{\mu_0\varepsilon_0 r})$ exhibits the time delay required for the effects of the oscillating charges to propagate to distant points. The electric and magnetic fields may be computed from Equation (20) as indicated above. The magnetic field strength produced by an oscillating dipole (point current) is, for example, in the spherical coordinate system (r, θ, φ)

$$H_\varphi = \frac{I\,\Delta Z}{4\pi} \sin\theta \left[\frac{\cos\omega(t - \sqrt{\mu_0\varepsilon_0} r)}{r_2} - \frac{\omega\sqrt{\mu_0\varepsilon_0}}{r} \sin\omega(t - \sqrt{\mu\varepsilon_0} r) \right]$$

This form, like Equation (20), shows that the crests and valleys of the field oscillations are propagated in spherical waves at the speed of light $v = (\mu_0\varepsilon_0)^{-1/2}$. The solution for a point current may be employed in an integral similar to Equation (19) to find the vector potential of a more complicated distribution of current. Such solutions may also be employed to find the radiation patterns and input impedances of antennas.

The potentials and fields produced by a charge moving in an arbitrary way may also be obtained.

In regions free of source currents and charges, the fields and potential satisfy the homogeneous wave equation [for example Equation (16) with $\mathbf{J} = 0$]. Then one of the simpler solutions that can be obtained is that of the plane electromagnetic wave. With appropriate orientation of the rectangular coordinate system, the solutions show that plane waves may progress along z, with components as follows:

$$E_x = E_0 \cos\omega(t - \sqrt{\mu_0\varepsilon_0} z)$$

$$H_y = E_0 \sqrt{\frac{\varepsilon_0}{\mu_0}} \cos\omega(t - \sqrt{\mu_0\varepsilon_0} z)$$

where E_0 is an arbitrary constant amplitude. Note that **E**, **H** and the direction of propagation are all perpendicular to one another. The Poynting vector, $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, points in the direction of the propagation. Moreover, the power carried through a closed surface by an electromagnetic field may be computed from a surface integral of the Poynting vector.

With single frequency fields in source free regions, both **H** and **E** can be represented by vector potentials, $\mathbf{H}_1 = \nabla \times \mathbf{A}_1$, $\mathbf{E}_2 = \nabla \times \mathbf{A}_2$, and moreover the coordinate systems may be oriented so that $\mathbf{A}_1$ and $\mathbf{A}_2$ each have a single component. In cylindrical systems, this single component is commonly along z. $\mathbf{H}_1$ is then transverse to z (TM) the set of fields, $\mathbf{E}_1$,

$\mathbf{H}_1$, derivable from $\mathbf{A}'_1$, are called TM fields. $\mathbf{E}_2$ is likewise transverse to z and the set of fields, $\mathbf{E}_2$, $\mathbf{H}_2$, derivable from $\mathbf{A}_2$, are called TE fields. This procedure is particularly helpful in problems involving transmission lines and waveguides.

Some of the most interesting and fundamental problems of electromagnetic theory are concerned with the scattering and diffraction of electromagnetic waves. For example, exact solutions are available for the scattering by cylinders and spheres, as well as an infinitely long slit. Approximate solutions are available for many other shapes. The methods are those outlined above, supplemented by generalizations of the principles of Huygens and Babinet.

Another topic of wide interest is the nature of fields in ionized gases or plasmas. The applications range from ionospheric propagation to microwave devices to nuclear apparatus to magnetohydrodynamics to satellite reentry problems. The simplest theory for these effects is developed from Equations (3) and (4) (single frequency version) by separating the ion current term $\mathbf{J}_e = \rho\mathbf{v}$ from $\mathbf{J}$, and employing Newton's law to eliminate $\mathbf{v}$ in favor of $\mathbf{E}$, $\mathbf{H}$ and whatever mechanical constraints are applicable.

Effects peculiar to charges moving with very high velocities have not been included in this discussion. Numerous entries throughout this encyclopedia are concerned with electromagnetic phenomena. See also **Magnetism**.

ELECTROMAGNETIC PROPULSION. Sporadic attempts have been made for more than 150 years to use electrical energy to launch projectiles at high velocities. Throughout the world during the last 20 years, most of the funding invested in electromagnetic (EM) launcher development has been for military applications. In most cases, the perceived advantage has been attaining higher velocities than can be achieved with propellant guns, leading to enhanced lethality. The elimination of gun propellants would also reduce vulnerability as well as allowing an increased number of stored rounds and enabling extended missions. The EM rail gun has been the preferred choice for this application because it has already repeatedly demonstrated muzzle velocities well above those of conventional guns — typically 2500 m/s versus 1750 m/s. The military challenge is to fit the electric pulsed power equipment into a battleworthy vehicle, especially if it needs to be compact. The main potential applications are direct fire tank guns, long-range artillery, and air and missile defense.

Several electrical or electromagnetic (EM) concepts have been suggested, as described later, but their potential for space applications is, as yet, limited. However, the technological bases are now being created on which future EM launch systems for space exploration could be based in the twenty-first century. Such systems could include launch to space from the surface of Earth, the Moon or asteroids, Maglev launch assist for large rocket systems and, possibly, EM thrusters for space transportation. Electrical ion engines have been used in space, and the Hall plasma thruster is under development for NASA.

The interest in electric launchers for military applications has led to improved understanding and advances in many technical areas. Most military applications for EM launchers require gigawatt power levels for pulse lengths of a few milliseconds to accelerate a useful projectile in a launcher of acceptable length. Coupled with the need for compact and robust equipment, this is a challenging goal for the pulsed power system. The desire to achieve muzzle velocities significantly greater than those of conventional guns — from 2–3 km/s — also requires developing the launcher and projectile. Recent progress in these areas could be the basis for future space applications.

History

The first known scientific account of an EM launcher was provided by Prof. Page of the Colombian College, Washington, DC, in 1845, only 10 years after Faraday's pioneering studies on electricity. Page's description of the electric launcher stated,

Another curious instrument is the galvanic or magnetic gun. Four or more (helical coils) arranged successively, constitute the barrel of the gun, which is mounted with a stock and breech. The (iron) bar slides freely through the (coils) and, by means of a wire attached to the end towards the breech of the gun, it makes and breaks the connection with several coils in succession and acquires such a velocity as to be projected to the distance of forty or fifty feet.

The well-known Norwegian inventor, Birkeland, developed an EM launcher using multiple coils. He obtained the first patent for an electric gun, formed a company to exploit the technology, and successfully tested two 4-m long induction launchers in 1902. However, his widely advertised public demonstration in 1903 spectacularly failed to live up to the claims that the projectile would be launched without flash or noise, and within weeks, he moved on, in this case successfully, to a different technical career.

Seeking a different approach, Fauchon-Villeplee started studies on EM rail launchers in France during World War I. In 1917, he successfully constructed a small working model powered by batteries. The principles of his direct current (dc) electric rail gun were different from those of the coil, or solenoid, launchers. A cross section of the basic configuration taken from one of his patents is shown in Fig. 1. The structure of the gun was iron, and it had two pole pieces to concentrate the magnetic flux into the region where the projectile was located. The magnetic field was energized by copper windings that extended along the length of the barrel and used the same current as fed into the fins of the projectile through sliding contacts. The lightweight projectile was a plastic tube that had a wooden tail in which copper fins transferred current via a sliding contact with the rails. Fauchon-Villaplee proposed that an EM cannon could be built to launch a mass of 100 kg at 1600 m/s. This formidable gun, shown mounted on a railway bogie in Fig. 2, was supposed to have a muzzle energy of 128 MJ — an energy level that has still not been achieved. When World War I ended, these projects were abandoned, but the work did not go unnoticed. A 1923 report by Korol'kov of Russia critiqued the physics and engineering calculations of Fauchon-Villeplee and commented positively and negatively on the claimed advantages of electric guns:

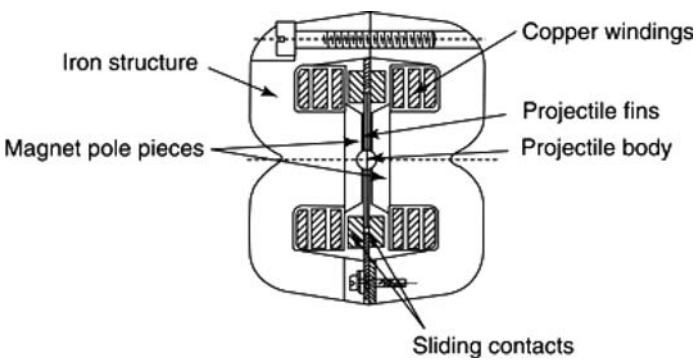

Fig. 1. Cross section of Fauchon-Villaplee's iron-cored rail gun barrel (ca 1918).

- Electric guns fire without smoke and with virtually no noise.
- Electric gun efficiencies are considerably higher than those of conventional guns.
- Electrical guns use fuels whose energy is greater than explosives and are less expensive.
- The force propelling the projectile is applied along the entire projectile, not just its base.
- The velocity and range of the projectile can be changed by varying the voltage without changing the angle of elevation of the barrel.
- There is no (powder) charge in electric guns, and there cannot be a premature explosion in the gun barrel.
- The power of electric guns . . . depends only on the instantaneous energy of the electrical source.

MacLaren's U.S. patent of 1921 described a traveling magnetic wave induction launcher powered by a high-frequency, three-phase generator. In this, the traveling magnetic wave induced currents in the projectile and provided the EM force that accelerated the projectile through the barrel. In the 1930s, Professor Northrop undertook experiments at Princeton University with similar launchers powered by motor-generators and capacitors. The work was described in a novel written by Northrop[1] in which the theme was a journey to the Moon using an EM coil launcher in place of the conventional cannon proposed by Jules Verne. Northrop provided considerable detail on the engineering calculations, as well as several photographs illustrating the equipment needed — some of which were retouched to appear more impressive.

During World War II, a group led by Hansler in Germany was involved in developing EM launchers. The experiments started with induction

[1] Using the pen name "Pseudoman."

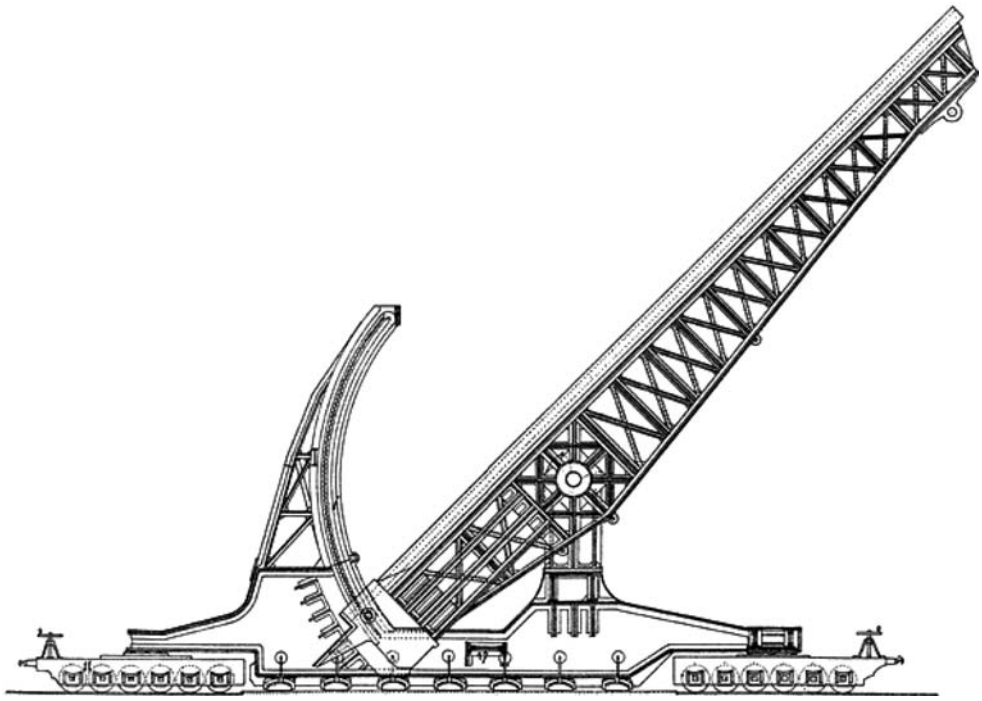

Fig. 2. Fauchon-Villaplee's long-range gun concept (ca. 1918)

launchers but because little success was achieved, refocused on rail guns. Hansler's first rail launcher tests in September 1944 used an iron barrel similar to Fauchon-Villaplee's that was energized by windings to create a transverse magnetic field to give the $J \times B$ forces needed for accelerating a projectile (Fig. 3. A velocity of 1080 m/s was achieved using a spring-loaded arrangement to ensure good electrical contact between the projectile fins and the rails. To meet the wartime needs of defending against high-altitude bombing raids, the development of a 40-mm EM gun with a high velocity (2000 m/s) and rate of fire of 72 rounds/min. was proposed. The initial design had a 10-meter iron barrel with a 3-tesla magnetic field. However, Hänsler soon realized that the performance required could be achieved only with an air-cored barrel that had a much higher magnetic field, as shown in Fig. 4. This was designed, but not built, when the war ended. Modern EM rail-gun launchers are of this type, and operating currents are so high that pulsed magnetic fields >20 T are generated, making the presence of iron irrelevant. Starting in May 1946, the Armour Research Foundation in the United States evaluated Hansler's work. A comprehensive document was created based on reports, blueprints, and equipment from Germany. After evaluating the material and performing calculations, the report concluded that the anti-aircraft EM rail gun was technically feasible.

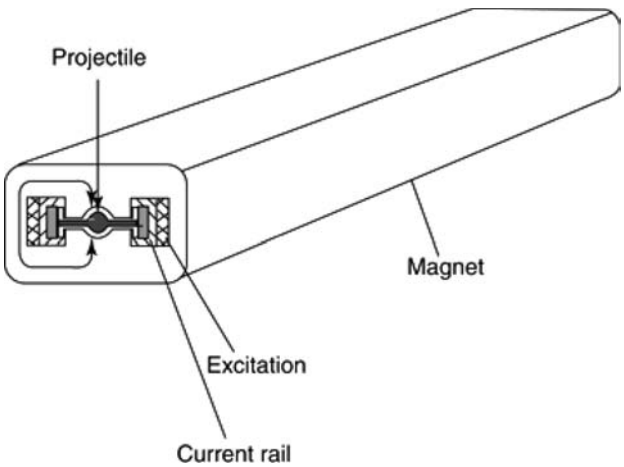

Fig. 3. Sketch of Hansler's iron-cored rail-gun (ca. 1944).

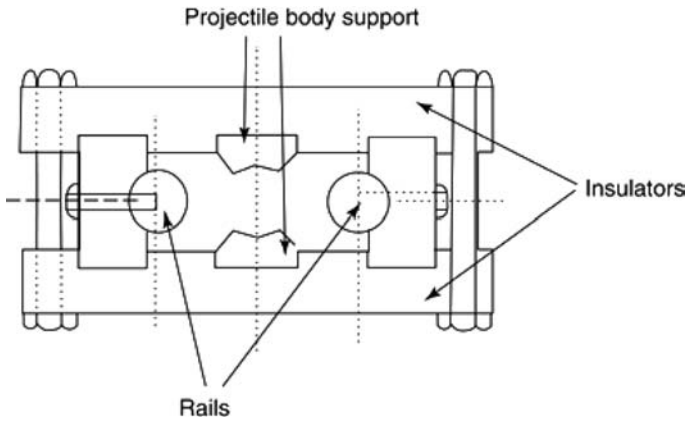

Fig. 4. Hansler's air-cored rail-gun cross section.

Relatively few efforts were undertaken in the aftermath of World War II, with one or two exceptions, until rail-gun experiments were undertaken at the Australian National University in the early 1970s based on the concept of macroparticle acceleration to high velocities for meteorite impact studies. These experiments led to a growth of interest in the United States and also caused non-U.S. efforts to accelerate. Most of these efforts were for defense applications, but launch-to-space was studied by MIT and NASA.

The early pioneers of electric gun research would be impressed to see what has been accomplished in the last decade. Pulsed power supplies using capacitors and rotating generators have provided currents in excess of 3 MA to EM rail launchers. Velocities of more than 6 km/s have been achieved in rail guns using projectiles of a few grams, and muzzle energies of 5–8 MJ have been achieved for larger masses at velocities up to ~4 km/s. Induction launcher technology has been demonstrated for low velocities (some 100's m/s), but the highest confirmed velocity is 1 km/s.

Electric Launcher Configurations

Rail launchers and coil launchers rely solely on electromagnetic (EM) forces to accelerate projectiles to high velocities. Most single-stage laboratory EM rail launchers operate at efficiencies of 30% or less, so that substantial energy is needed at the breech of the launcher for each shot. Modifications to improve launcher efficiency are described later.

Some of these are more appropriate for launch-to-space than for ordnance applications.

Most experimental and theoretical studies of EM rail launchers during the last 20 years have used the simple air-cored rail-gun arrangement proposed by Hansler. In this, a short pulse of high-current electrical power is fed to the breech of a two-rail configuration in which the projectile is accelerated by the Lorentz ($J \times B$) force (Fig. 5). This configuration has operated successfully across a wide range of conditions.

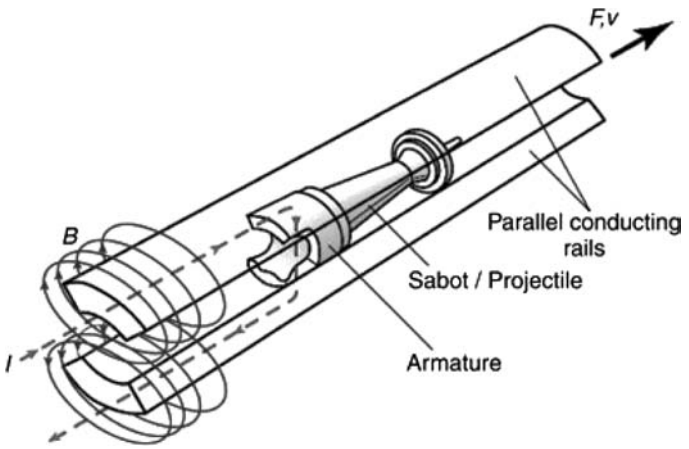

Fig. 5. The two-rail,breech-fed rail-gun arrangement.

Because the induced magnetic field in the air-cored launcher bore is created by the current I passing through the rails, the $J \times B$ accelerating force (F_{EM}) can be expressed as

$$F_{\mathrm{EM}} = 0.5L'I^2 \tag{1}$$

where L' is the inductance gradient ($= dL/dx$) of the rails in the vicinity of the projectile. L' is a relatively invariant quantity that depends on rail-gun bore geometry, more accurately, the relative fraction of the bore cross section occupied by the rails: a typical value is ~0.5 μH/m. L' is small, so a large current is required to accelerate a a significant mass m to a high velocity because

$$F_{\mathrm{EM}} = 0.5L'I^2 = ma \tag{2}$$

Currents of several megamperes have been successfully used in 90-mm bore rail guns in laboratory experiments.

Because the accelerating force depends on I^2, it is independent of current direction and, in principle, an alternating current (ac) could be used. Some early systems were of this type, but shorter barrels and a better acceleration profile can be achieved by using a unipolar (dc) current pulse. Modern rail launchers use a current pulse that has a fast rise to a constant current for the majority of the acceleration, followed by a decrease in current near the muzzle exit to minimize muzzle flash. This "flattopped" pulse shape can be achieved using several short pulses in sequence from each section of a subdivided energy store or generator. Using this approach, the subpulses must be correctly timed and overlapped to achieve the desired total pulse shape.

One major source of inefficiency in the simple rail launcher is the magnetic energy remaining in the barrel at the instant of projectile launch. For an idealized constant current pulse, the inductive energy left in the barrel at launch equals the projectile muzzle energy so that the launcher efficiency[2]even without other losses, cannot exceed 50%. Reducing the current at the muzzle exit decreases the magnetic energy stored in the barrel but increases the barrel length. The need for compact power supplies has led to the invention of alternative launcher configurations that may have higher efficiency, as described later. None of these has yet been widely studied, and further research is required to determine whether the advantages of these concepts outweigh their disadvantages.

Numerical models are used for the detailed design of EM rail launchers, but simple expressions can illustrate the fundamental principles and provide approximate engineering parameters, as shown here.

[2] The efficiency is the kinetic energy of the projectile at the muzzle exit divided by the electrical energy supplied to the breech of the launcher.

When the fundamental definitions of acceleration a and velocity v are integrated for the condition of constant acceleration a, they yield the well-known result that: "*work done (or energy) equals force times distance*." For an EM launcher this can be written as

$$E_{\mathrm{muz}} = 0.5mv_{\mathrm{muz}}^2 = \overline{F}_{\mathrm{EM}}^{s} \tag{3}$$

in which s is the launcher barrel length and F is the average EM force. Assuming that the force is constant across the cross-sectional area A of the barrel, the accelerating force is also

$$F_{\mathrm{EM}} = pA \tag{4}$$

In EM launchers, as in propellant guns, the accelerating pressure p does not remain constant during the launch process, unless special design approaches are taken. The measure of how close the acceleration is to the ideal is the piezometric efficiency, η_{P}

$$\eta_{\mathrm{P}} = p_{\max}/p_{\mathrm{ave}} \tag{5}$$

For a propellant gun, $\eta^P > 2$, but simple rail launchers have operated with $\eta_P \sim 1.5$, and operation to 1.3 or lower may be possible. Even lower values may be feasible with the "distributed" EM launchers described later.

From Equations 3,4 and 5,

$$E_{\mathrm{muz}} = p_{\max}A_s/\eta_{\mathrm{P}} \tag{6}$$

showing that, for a given barrel length and area, the muzzle energy is determined only by the average pressure p, or by the maximum pressure, $p_{\max}$ and the piezometric ratio.

Using $I^* = I/h$ as a measure of the linear current density on the inner surface of the rails that carry current (where h is the height of the rail at the inner bore from one insulator to the other), Equation 2 can be written as

$$F_{\mathrm{EM}} = 0.5L'I^{*2}h^2 \tag{7}$$

Combining Equations 4, and 7 and using $A = h^2$ for a square barrel yields

$$p_{\mathrm{sq}} = 0.5L'I^{*2} \tag{8}$$

Typical values in this expression are $L' = 0.5$ μH/m and, for a copper rail, $I* \sim 40$ kA/mm, to give $(p_{\mathrm{sq}})_{\max} = 400$ MPa. This is the highest pressure that a simple EM rail launcher can achieve. Substituting $(p_{\mathrm{sq}})_{\max}$ in Equation 6 allows rail launcher parameters to be estimated.

For simplicity, the above analysis assumed a square rail launcher bore. Other geometries (e.g., rectangular or circular) have been investigated experimentally and analytically. Calculating L' is complicated in complex barrel crosssections and requires knowledge of the variation of current density and temperature around the periphery of the rail.

The maximum acceleration pressure achievable in a simple rail launcher is lower than the peak values achieved in powder guns, but useful performance levels can be still achieved with a rail launcher, even within these pressure constraints, as shown in Table 1

TABLE 1. MAXIMUM LAUNCH ENERGY (MJ) ACHIEVABLE IN A SIMPLE SQUARE BORE RAIL LAUNCHER

	Bore height, mm			
Barrel length, mm	80	100	120	140
4	7.9	12.3	17.7	24.1
5	9.8	15.4	22.2	30.2
6	11.8	18.5	26.6	36.2
8	15.8	24.6	35.4	48.2
10	19.7	30.8	44.3	60.3

Some techniques for increasing the achievable pressure have been sought, as described later, but they are still limited by Equation 8. Increasing I^* requires different rail materials, but the potential benefits of

TABLE 2. LIMITING RAIL CURRENTS FOR SEVERAL MATERIALS

Rail material	$I_{max}*$, MA/m
Copper	40.9
Aluminum	25.3
Silver	32.8
Tungsten	56.2
Graphite	35.0
Stainless steel	32.7
Molybdenum	45.5
Elkonite (67% W, 33% Cu)	65.5

using high-temperature materials is largely offset by their poorer electrical and thermal properties, as can be seen from Table 2.

For example, although tungsten, has a melting point three times higher than copper, it will reach surface melting when $I^* = 56$ kA/mm, which is only a 37% improvement over copper. In the absence of fundamental material improvements, it may be necessary to use other rail launcher configurations that have higher L' values, as described later.

Augmented Rail Launcher. In early concepts, external magnets — either superconducting or permanent — were proposed to provide a steady magnetic field that would permeate the entire launcher bore volume to add to the induced magnetic field produced by the applied current. However, such fields are generally small compared with the pulsed field resulting from the main current in large bore launchers, and this technique has now been replaced by additional rails close to the main launcher rails to enhance the magnetic field in the launcher bore. The augmenting rails may be energized either by (*1*) using all of the current that goes through the main rails, (*2*) using a separate supply, or (*3*) taking part of the main current and diverting it through the augmenting rails. The first option has generally been used experimentally because it is simple and only one power supply is needed.

The advantage of augmentation is that the current in the main rails and armature is reduced for a given accelerating force, thereby decreasing bore erosion and easing the task of the armature designer. In addition, the power supply can operate at lower current.[3] For single augmentation (one augmenting turn in addition to the rails in the barrel bore), $L' \sim 1$ μH/m; double augmentation yields $L' \sim 1.2$ to 1.3 μH/m. Singly and doubly augmented barrels have been successfully demonstrated with small-bore rail guns. Augmentation has not been widely considered for military applications because the launcher is larger and heavier than a simple barrel, complicated breech and muzzle current connections are needed, and additional magnetic energy is stored inductively in the barrel at the muzzle exit. However, this may not be a concern for a fixed launcher, as for a launch into space.

DES Rail Launcher. A second alternative to the simple rail gun is the distributed energy store (DES) launcher. In this, multiple power-feed points are located along the rails so that energy can be fed from several independent energy sources. This allows the maximum current to the projectile armature to be provided at just the right time in the acceleration process to maximize the EM force on the launch package.

To supply this launcher, the energy source[4] needs to be segmented into separate sections that are energized sequentially as the projectile passes. The magnetic energy is switched into each stage of the launcher exactly when the projectile reaches that stage and is switched off after the projectile leaves. Therefore, the amount of inductive energy left in the barrel when the projectile leaves the muzzle is only that from the last one or two sections. If there are n sections, only $\sim 1/n^{th}$ of the usual amount of inductive energy remains in the barrel, so that the overall launch efficiency is much improved. This concept may be especially advantageous for a long static system, such as for launch to space. For a military system in which it is necessary to slew the barrel rapidly, the need for multiple power leads to transfer current to each stage from many independent power supplies is a significant disadvantage.

Mutirail Launcher. The third alternative version of the simple rail gun is the multiple rail arrangement. In this concept, the rails of the simple rail gun are subdivided, so that one-n^{th} of the normal current passes through each rail. The rails are electrically insulated from each other and are electrically in series so that a low-current, high-voltage source can be used. The current required from the power supply is divided by the number of rails, but there is a corresponding increase in the applied voltage. Electrical shorting prevents this technique from being applied with plasma armatures, but it can be used with solid armatures if arcing contact between adjacent rails can be prevented. The concept has been demonstrated experimentally but has received relatively little attention because of the concern about the ability to *always* prevent arcing. If arcing occurs between the rails or within the armature, the power supply could be electrically shorted out with disastrous consequences, unless precautions were taken.

Staged Transiently-Augmented Rail (STAR) Launcher. The STAR concept combines the features of an augmenting magnetic field and the DES power feed. The augmenting field is provided by a series of independent coils that are energized only when the projectile is nearby. Figure 6 illustrates a three-section version of such a launcher; many such sections would be arranged in series for an Earth-to-space launcher. The energy used in these coils (less losses) is then transferred from coil-to-coil as the projectile accelerates along the barrel. The energy required for augmentation is therefore much less than in the usual augmentation concept. This arrangement allows the main rail current to be reduced, which is beneficial for the power supply and the barrel. The total launcher efficiency will also be better than that of the simple rail launcher because the augmentation is transferred forward with the projectile, rather than permeating the entire barrel structure. Although STAR is merely a concept at present, high-field pulsed magnets have been tested at magnetic fields up to 68 tesla — a level that is significantly higher than that used in present EM launchers. The STAR concept is most appropriate for a long static system and is a possible candidate for launch to space.

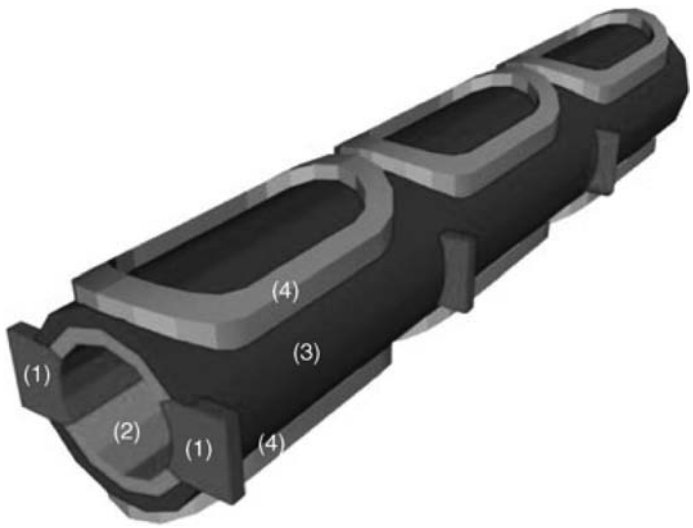

Fig. 6. STAR-staged transiently augmented rail gun — module, showing the rails(1), insulator(2),containment(3),and pulsed augmetning magnet coils(4).

EM Induction Launchers. In principle, having no direct sliding contacts and operating with relatively low currents, EM induction launchers promise high efficiencies and contactless launch. Operating velocities of a few 100 m/s have been achieved by several groups, but there have only been two reports of velocities near or above 1000 m/s. As a consequence, there has been little funding for research on high-velocity launch applications, and this technology lags that of rail launchers. However, the approach may be useful for lower velocities and could replace the first stage of a rocket system.

Several induction launcher approaches have been studied. The barrel-type launcher consists of two parts — a stationary array of drive coils and a moving conductive projectile. The stationary coils generate a rapidly varying magnetic field that induces currents in the projectile. The interaction between the applied magnetic field and the induced magnetic field creates an axial propelling force and, in some configurations, a radial centering force that eliminates the need for a contacting guide rail system. The geometry can be coaxial or flat channel, and the induction can be

[3] Although at the expense of an increased voltage.

[4] And, in some configurations, the barrel rails.

pulsed or traveling-wave. The flat arrangement could be applied to the wings of a projectile in a toroidal configuration.

The single-stage pulsed induction launcher consists of a coaxial, single, fixed, drive coil and movable conduction ring. When the drive coil is pulsed with current i_1, an induced current i_2 is created in the conduction ring that generates a magnetic field in the direction opposite to that in the drive coil. The mutual repulsion between these two coils causes acceleration of the ring. The EM accelerating force is

$$F = i_1 i_2 \frac{dM}{dx} \tag{9}$$

where M is the mutual inductance and x the distance between the coils. High velocities and extremely high accelerations were reported with close-coupled, single-stage repulsion launchers of this type. A modified arrangement uses a smaller movable ring that can be nested inside the drive coil. This can be further modified by adding additional drive coils to create the barrel of a launcher that can be operated either synchronously or asynchronously. In the synchronous mode, only one drive coil is energized at a time and is synchronized by a feedback switching control system to match the movement of the accelerated coil or cylinder. The pulsed magnetic field from the driving coils induces an azimuthal magnetic field in the rear of the inner coil or cylinder in a direction that opposes the applied field, so that the inner coil is accelerated along the launcher. To maintain a unidirectional azimuthally induced current in the projectile, the current in all of the drive coils must be in the same direction. In strictly synchronous operation, the dc component of the current induced in the projectile decays with time, so that the direction of induced current flow has to be reversed.

Another system is the traveling wave induction launcher in which alternating currents are separately fed to a number of the drive coils across a region that is longer than the projectile being accelerated. This creates a traveling magnetic field that travels with a velocity v:

$$v = 2\tau f \tag{10}$$

where 2τ is the wavelength of the magnetic wave and f is the frequency of the current in the drive coils. The traveling wave induces azimuthal currents in the projectile and an associated magnetic field pattern that is similar to that generated by the drive coils. However, the induced magnetic field pattern is displaced relative to the driving field pattern, and the projectile is "dragged" along the barrel at a velocity close to that given by Equation 10. The advantages of this arrangement are that the propelling force acts more uniformly across the entire body of the projectile, a radial centering force acts to keep the projectile centered in the barrel, and the need for exact synchronization between the projectile and the drive coils is eliminated. Disadvantages include the need to divide the barrel into several sections that are fed with different frequencies so that the slip velocity and thermal losses can be minimized.

Energy Storage and Pulsed Power

Energy Requirements and Options. From the earliest days of electric launcher research, it has been understood that supplying the required high-power pulses of electricity is a critical issue. Conventional guns and rockets have reached high level of capability after hundreds of years of development in which very energetic propellants have been created. Energy densities in propellants are impressively high — several MJ/kg. Achieving similar energy densities in a system that stores and transfers electrical energy is not yet possible, as can be seen from Table 3. Some of the other benefits of electrical systems such as higher velocities and improved safety due to the absence of propellants offset this disadvantage. In many situations, the capability to easily control the electric launcher to provide the required muzzle energy offers a benefit that is not available from conventional propellants.

The energy needed for an EM launcher is determined by the mission requirements. A notional set of input energy requirements for several launcher technologies for a muzzle energy of 20 MJ is given in Table 4. Other applications, such as an EM catapult for aircraft launch or launch to space, may require much more energy.

It is necessary to provide *average* power to the electrical system at a rate that matches the launch rate. The prime mover[5] is typically coupled to a generator and operates through a transformer/rectifier to provide electrical power to the energy storage system. The availability of stored energy in a flywheel or battery pack can permit a few launches to occur quickly without energizing the main prime mover power system for certain applications. The design of this subsystem depends on the type of launcher and the firing rates required. For high firing rates or continuous operation, it is necessary to cool the components.

Capacitor Banks. Most early electric launcher experiments used capacitor banks because they are inexpensive in small sizes and the components are widely available. Early experiments used banks with an oscillating output current whose characteristic time period was matched to the transit time of the projectile through the rail gun. Because this results in substantial current variation and very nonuniform acceleration, it is generally not preferred. In some cases, a high-frequency, rapidly ringing bank was used, and the averaged fluctuating current was accepted as an inexpensive way to undertake experiments. A better arrangement is to "crowbar" the circuit after the current has reached its peak value, which extends the high-current portion of the output pulse. To achieve this, a closing switch connects the current to the gun, and a diode is used in the crowbar leg with another closing switch.

[5] Usually this is a gas turbine or internal combustion engine.

TABLE 3. ELECTRICAL ENERGY STORAGE OPTIONS

Device	Storage mechanism	Defining equation	Assumption	Limiting values	Energy density MJ/m^3
Capacitor	Electrostatic	$E = \frac{cv^2}{2}$	High-energy-density plastic film	$E_{op} = 400$ V/μ m $\varepsilon_r = 10$	7
Rotor	Inertial	$E = \frac{i_m \omega^2}{2}$	High-speed composite/conductor rotor	$\rho = 1500$ kg/m^3 $v_{periph.} = 600$ m/s	135
Inductor	Magnetic	$E = \frac{B^2}{2\mu_r \mu_0}$	High-field air-cored inductor	$\mu_r = 1$ $B = 40$ T	640
Battery	Electro-chemical		Li ion	3.5 volts	4000
Propellant or explosive	Chemical		High-energy-density materials	Few eV per bond	5000–10,000
Diesel fuel	Chemical		"Free" oxygen from atmosphere	More exothermic bonds	40,000

TABLE 4. INPUT ENERGIES NEEDED FOR 20-MJ MUZZLE ENERGY

Electric launcher type	Energy input per shot, MJ	Peak current, kA	Peak voltage, kV	Pulse length, ms	Minimum average instantaneous power, GW
EM railgun	40	4000	10	6	7
ETC gun	4	150	16	4	1
ETC igniter	0.4	50	10	1	0.4

Even when a single capacitor bank is "crowbarred," current droop can cause inefficient energy transfer for a launch time that is longer than the characteristic decay time of the bank. The solution is to subdivide the capacitor bank into separate modules that can be independently triggered but are connected together at the current feed point into the launcher breech.[6] A practical benefit of the modular approach is that repair and maintenance can be carried out on some modules while the remaining units continue to operate. The design of individual modules and the way in which they are connected depends on the type of gun and the duty required. A flat-topped current pulse can be created for a rail gun by triggering several modules sequentially to match the transit time of the projectile through the barrel. To get the desired high initial acceleration, a high-energy module is fired initially, followed by subsequent discharge of smaller modules. Because the projectile is traveling at higher velocity further down the barrel, later modules have smaller inductors in series with the capacitor modules to achieve faster rise times.

To ensure high efficiency, the output switches that connect the modules to a single load connection (the launcher breech) must prevent current from later modules from being routed back into modules that discharged earlier. If this is not done, considerable stored energy may be lost resistively, as it transfers from one module to another without ever reaching the launcher. Capacitor voltages are generally in the range of 10–15 kV, but values of 22, 44 kV, and higher have been used for some experiments. Such values necessitate close attention to insulation integrity and component locations to prevent electrical breakdown.

The capacitors in which energy is stored are the single largest contributor to the size and mass of the total system. The energy stored in a dielectric is proportional to the dielectric constant ε_r and to the square of the operating electric field strength $E_{\mathrm{op}}{}^2$, which is chosen as near as possible to the breakdown strength of the dielectric material while ensuring a low probability of spurious breakdown. Capacitors that use paper dielectric with foil electrodes were standard for many years. Plastic films such as polyethylene (PE), polypropylene (PP), and polyvinylidene fluoride (PVDF) provide better performance (see Table 5).

The performance of PE and PP capacitors is well characterized, and capacitors made from these materials are widely available. Units made from PVDF have been developed in the last decade. Although offering high energy density, this nonlinear material is more difficult to characterize, less efficient in operation, and more difficult to integrate into a complete system. As a result of these disadvantages, there is much to be gained if new dielectric materials could either be discovered or created. Recent small-scale experiments have been performed using siloxane-based materials with promising results. However, substantial investments are needed to bring a new capacitor material to reliable large-scale manufacture, and few sponsors have yet been found.

It is important to consider the entire capacitor system when component development is planned. If extremely high-energy-density dielectric materials were to become available, the volume of the system would then be dominated by other components, such as switches or inductors. Therefore, these components also need to be developed to reduce their size and weight. Integrated systems, in which component functions are combined, rather than by being individually optimized, may have significant benefits.

Rotating Machines — Homopolar Generators. Laboratory studies of electric launchers were undertaken in the 1970s and 1980s using homopolar generators (HPGs) which operated as electrified flywheels to deliver a low-voltage but high-current output. The HPG voltage, typically 100–200 V for an iron-cored machine, is much less than that required to drive an electric gun directly. Therefore, it is necessary to add a pulse compression stage in which energy is transferred into an inductor where it is temporarily stored as magnetic energy before delivery to the launcher at a higher voltage. Getting the energy into the inductor is relatively simple, but getting the energy out of the inductor to the gun can be difficult. An opening switch is needed that can carry a current of megamperes during inductor charging, but which can open quickly when transfer of the current into the gun is required. Such switches are not readily available, although laboratory versions have been developed. The need for the opening switch and storage inductor has caused the HPG to go out of fashion during the last few years in favor of other rotating machines.

Pulsed Alternators. Synchronous ac generators of very large sizes (>1400 MW) operate successfully for many years for electric utilities delivering voltages greater than required for most electric launchers. A short-circuit fault near the terminals of such a generator could cause a substantial overcurrent to flow and would damage the machine. To prevent this, utility generators are deliberately designed so that the resistance seen by such a fault (the "subtransient reactance") is high enough to limit the current to a value that does not cause serious damage. However, such machines can be modified to deliver a limited number of higher than normal current pulses. For example, in 1963, a 3-GVA machine was used for testing circuit breakers with asymmetrical currents of 300 kA at 16.5 kV.

A pulsed alternator deliberately designed with a low subtransient reactance to deliver safely a high current is an alternative to the HPG for an electric launcher. Instantaneous power of several GW is typically needed for electric launchers, usually for subsecond pulse durations. Such a machine has to operate under conditions so extreme that they would be acceptable only once or twice in the lifetime of a utility machine.

Pulsed iron-cored machines are too heavy for many electric launcher applications. Therefore, during the last few years, the United States has invested in the development of pulsed alternators that have disk and drum topologies. These machines can be driven up to full speed in seconds to minutes and then discharged into the electric launcher. Multipolar geometries are used to ensure compactness so that the ac output current has to be rectified for launchers that require dc. The rectifier and switching assembly can be a significant part of the total system mass, volume, and cost. High rotational speeds enable small machine sizes to be achieved but necessitate the use of lightweight, high-strength rotor materials in which the conductors necessary to carry current are embedded. Carbon fiber composites are the modern structural choice. At high rotational speeds, aerodynamic losses become important, and it may be necessary to partially evacuate the machine interior to minimize heating.

One feature shared by all rotating machines is their capability to store more energy inertially in the rotor than required for each shot. The voltage, power, and energy storage requirements need to be evaluated for each particular launcher type and mission to give the optimum design. In some cases, the machine size and geometry may be determined by the electrical design (required output voltage or power), but in other cases the stored energy is the dominant feature. Decoupling the design for electrical power production from the energy storage design may be possible by using flywheels that are separate from the power generator.

Linear Magnetic Flux Compressors. Linear flux compressors have been suggested as an alternative to rotating machines and capacitors for driving electric launchers. By using large quantities of high explosives to drive conductors together to compress a magnetic field, current pulses greater than 250 MA have been achieved in musecond pulses at low efficiencies (>1 to 10%). Neither of these conditions is ideal for an electric launcher that might require pulses of a few milliseconds, especially because the use of explosives implies single-shot operation. Replacing

[6] For a single point breech-fed simple rail gun.

TABLE 5. PLASTIC FILM DIELECTRICS

Material	Dielectric constant	Breakdown voltage, V/μm	Stored energy Density, MJ/cum
Polypropylene	2.1	200	0.37
Polyethylene	3.25	300	1.3
Polyvinylidene fluoride	10	400	7
Siloxane	9.3	~400	~2.5[a]

[a] Measured with composite materials that had siloxane on akraft paper backing for strength.

explosives with a fuel/air combustion system has been suggested for multishot systems but has not been tested. Flux compressor efficiencies are likely to fall to low levels as pulse lengths are extended, as a result of diffusion of the magnetic field into the conductors and correspondingly increased resistive losses.

Magnetohydrodynamic Generators. In a magnetohydrodynamic (MHD) generator, the flow of an electrically conducting gas (a "plasma") through a magnetic field generates a voltage which, when extracted through electrodes in a generator channel, can transfer current to an external load without the intervention of any rotating element, such as a turbine or generator. A practical device consists of a plasma source and a channel, though which the plasma flows following acceleration in a supersonic nozzle, together with a magnet and electrodes embedded in the channel. The plasma is produced by reacting fuel and oxidant, together with "seeding" by a material of low ionization potential, such as a potassium or cesium compound. Early electric utility concepts also considered high-temperature, gas-cooled nuclear reactors cooled with cesium-seeded helium as the heat source. It is possible that a future space system could employ a similar Brayton or Rankine-cycle arrangement.

Considerable research was undertaken in the 1960s and 1970s on MHD devices for long-duration, low-current, utility power generation, but relatively little research has been done for pulse lengths of a few milliseconds. Repetitive, low-current (kA) pulses at a frequency of ~2 Hz and rise/fall times of tens of milliseconds were generated for pulses of a few seconds during operation of a liquid oxidizer/solid fuel rocket-driven generator. Currents as low as this would need to be transformed up for most electric launcher applications. Explosively driven, highly ionized argon systems have produced extremely high power (>GW) and high current (>MA) for tens of museconds.

The claimed advantage of MHD generators is the relative simplicity of their "direct conversion" of thermal to electrical energy. However, the relatively low conductivity of most partially ionized plasmas limits the current that can be obtained from MHD generators to 10's kA, rather than MA desired for large electric launchers. One experiment to power a low-current rail gun with a MHD generator via energy storage in an inductive current transformer has been reported.

Inductors. Pulsed inductors have been used for intermediate energy storage and as a pulse compression component in HPG-powered rail-gun systems. Any low-voltage source including batteries, can be used to provide current for the inductor. The inductor can be regarded as a pressure vessel for mechanical design purposes; the stored magnetic energy is given by

$$E = B^2/2\mu_0 \tag{11}$$

where B is the magnetic field strength (teslas) and $\mu_0 = 4\pi \times 10^{-7}$ H/m. A toroidal inductor is ideal for minimizing EM interference with external circuits caused by fringing magnetic fields. Shielded solenoids are a less expensive alternative that can also have low fringing fields.

For large EM launchers, the need to store and deliver tens of MJ at a few MA necessitates inductances L of a few μH. Using high currents, it is difficult to achieve system resistances R less than tens of μΩ with room temperature conductors, so that characteristic current decay times ($\tau = L/R$) are typically <0.1 s. This requires discharging the inductor very quickly after charging, otherwise substantial current decay and losses occur. It is helpful to cool the inductor to cryogenic or even superconducting temperatures, so that R is reduced and τ increased. Cooling copper to liquid nitrogen temperatures (77 K) is beneficial in reducing resistance. Liquid hydrogen (20 K) with high purity (99.999% purity) aluminum is even better but requires careful handling. At liquid helium temperatures (4 K), many materials become truly superconducting, and large inductors have been made with NbTi and $NbSn_3$ conductors for nuclear fusion experiments. Liquid helium is unlikely to be acceptable on cost or logistic grounds for military applications but could be attractive for static ground-based systems that operate for long times with low losses.

The last decade has seen spectacular progress in high temperature superconductors based on copper oxide compounds: superconductivity has been demonstrated at temperatures well into the liquid N_2 range (over 130 K). So far, critical current densities are low, and present conductors are not yet candidates for high-field inductors. Nevertheless, there are promising developments in the development of high current density (>1 MA/cm^2), YBaCuO films on flexible substrates that could be used for inductors, and further improvements seem likely.

Batteries and Flywheels. The two options usually considered for energy storage are chemical batteries and flywheels. Batteries store large amounts of energy very compactly (a standard lead-acid automobile battery may contain 50 MJ) but cannot deliver high-power pulses. The recent international interest in developing electric vehicles for the consumer market is likely to lead to battery improvements. Unfortunately, electric vehicle requirements do not match the energy or pulse length needs of electric launchers. Modified batteries for high-power delivery generally use bipolar geometry, but even these are not well matched to most electric launcher requirements unless coupled with a multistage inductor. Lithium-ion battery technology has recently progressed rapidly, but other candidates are also possible. In all cases, batteries (and a similar system, the ultracapacitor) are based on electrochemical reactions that have characteristic voltages of 2–4 volts, so that multicell units are necessary to get voltages of 100–500 V. The voltages needed for electric launchers require multiple series/parallel strings or, more likely, electronic inverters to transform the battery dc output to high voltage dc.

Flywheel energy storage is another alternative. Very high energy storage densities can be achieved, especially at high peripheral rotor speeds. Oak Ridge National Laboratory has achieved peripheral speeds >1400 m/s using carbon fiber composites. Less highly stressed versions of such flywheels are now in service commercially on a limited scale for passenger buses in Europe. There are significant differences between long-term energy storage and discharge for commercial applications versus the short pulses needed for electric launchers. The flywheel requires support subsystems for bearings, lubrication, and vacuum housing and needs to be coupled to a generator with a transformer/rectifier to produce high-voltage dc for launchers.

Auxiliaries. All of the power delivery and energy storage devices described here require auxiliary components. For example, switches are required to connect the pulsed power source to the electric launcher. These need to transfer high currents and to hold off high voltages. Options include solid-state devices, spark-gap switches, vacuum switches, and plasma-filled devices. Other auxiliaries depend on the specific power technology. For example, high-speed rotating generators require brushes and slip rings, vacuum enclosures, and cabling to connect the components together and to the gun breech. Operation of the entire launcher system requires a control system that includes the diagnostics necessary to monitor the total system health. This control system must integrate inputs from the prime power, pulsed energy and power system, launcher control system, and an overall mission control system.

Space Applications

First Stage/Orbiter Launch. A natural progression from the early work of Birkeland and Northrop was for low-velocity applications of launcher technology to merge with the development of linear induction motors. Linear motors are usually considered for continuous applications such as "people movers" in transit systems or for intercity trains where magnetic levitation can be employed in "maglev" systems. These motors operate continuously. A class of applications that has arisen recently is linear motors in amusement park rides in which short-term "launches" of a few seconds provide passengers the "thrill" of a high (or low)-g ride. An extension of this is to the launch of aircraft or other military equipment.

During World War II, a full-scale EM catapult called the "Electropult" was developed and built by the Westinghouse Corporation for the assisted launch of U.S. bombers from short runways on small mid-ocean atolls in the Pacific. Although successful, the project was finished too late to enter the war and was not pursued further. Similar efforts have been restarted in the last few years by the U.S. Navy to develop an EM Aircraft Launcher System (EMALS) to replace the steam catapult on an aircraft carrier. Depending on the results during the next few years, it is possible that future aircraft catapults could be of this type. The masses launched in these systems are 5–50 tons, and the required velocity is usually 25–100 m/s, so that launch energies of 50–100 MJ are typical. The challenge in this case is to accomplish the launch in the limited distance onboard the aircraft carrier, which is about 100 meters. The aircraft is therefore subjected to an acceleration of about 3 gs. The most important system concern is reliability; failure rates need to be less than 1 in 10 million to be acceptable for naval aviation.

The NASA Space Flight Center in Huntsville is currently testing a small-scale system of this type that could form the basis for a future replacement of the first stage for an Earth-to-space orbiter launch system.

This could eliminate the first stage of a multistage missile system by boosting the orbiter to the speed at which the later stages can be ignited for further propulsion. A system of this type, known as *Maglifter*, was proposed in 1994. A similar proposal, made recently by the Russians, suggested the use of MHD generators to power the launcher. Based on the technical success of experimental maglev trains in Japan and Germany, the successful development of such a system seems quite feasible.

Direct Launch to Space. It is remarkable that one application that was apparently considered by the early developers of EM technology was that of launching manned or unmanned objects directly into space.[7] The interest was based on the idea that, in principle, EM forces can act at very high speeds, so that there should not be any *fundamental* physical barriers to their operation. Though this is largely true, some physical effects have been encountered at speeds in excess of 3 km/s that are not yet fully understood, and the velocities required for a direct Earth-to-space launch have not yet been reached except with gram-sized projectiles.[8]

Two concepts have been studied — the coil-based inductive system and the rail-gun system. The earliest versions of coil launchers, referred to as "mass drivers," were studied at Princeton University by O'Neill and his colleagues and at MIT in the late 1970s and early 1980s. Only relatively low velocities of ($<$100 m/s) were achieved, but because O'Neill's suggestion was to use the mass drivers for escape from the Moon or to move objects from one orbit to another, very high velocities were not necessary. What was important was the use of renewable energy — so that solar panels were proposed. Scientists at the Sandia National Laboratories, where velocities up to 1 km/s have been achieved with a coil system, have suggested launch-to-space using a coil gun, but the required muzzle velocity of 6 km/s has not been achieved. Rail guns have been much more successful in demonstrating high velocities (up to 4.3 km/s with 0.6 kg and $\sim$7 km/s with gram-sized projectiles) and high energies (up to 9 MJ), and this has led to a number of detailed studies of possible space launch.

Very high energies and power levels are required to accelerate large masses into space. Launching a 1000-kg aeroshell of the type illustrated in Fig. 7 requires an armature and sabot system that may make the total mass 1250 kg (see Fig. 8). At a launch velocity of 7.5 km/s, this represents a muzzle energy of 35 GJ. One suggested approach would use a staged transiently augmented rail-gun (STAR) launcher of the type illustrated in Fig. 6.

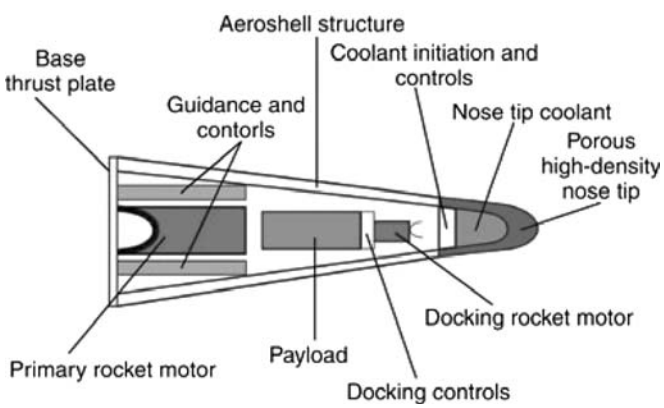

Fig. 7. A flight body concept

This concept offers very high efficiency because the energy needed for the launch is transferred from section to section along the launcher during acceleration. With a launcher efficiency of 80%, the energy input for the launch of this package would be 44 GJ. The cost of the electricity for such a launch would be negligible — less than $1000. A substantial capital investment would be required to build, install, and operate such a facility,

[7] There is a report that the Russian, Rynin, stated in 1929 that "the Austrian, Heft, in 1895 proposed a solenoid gun for launching interplanetary spaceships at speeds exceeding the 11.8 km/s needed to reach interplanetary space."

[8] Launch from the Moon or from an asteroid would require a much lower velocity and may be within the reach of present laboratory velocities. However, there is no requirement now for a system with such capabilities.

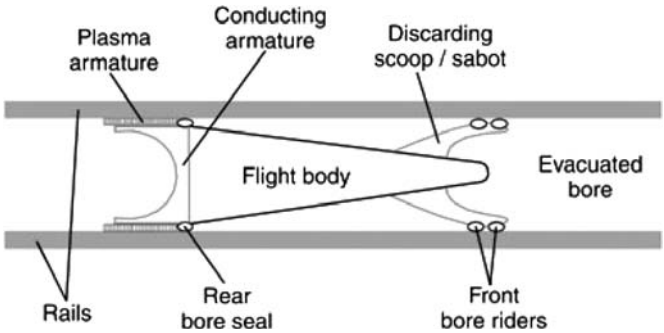

Fig. 8. The launch package concept

including a dedicated power supply or link to the utility network. For a moderate peak acceleration (by gun standards) of 30,000 g's, the launcher would be some 230 meters long while for 2000 g's, it would be about 1 mile long.[9] One recent estimate of the cost of such a system is about $1.4B (see Table 6). A proposal for an induction launcher system also estimated a capital cost of $1–$2B. These costs are competitive with conventional launch methods and are similar to the cost of a single Shuttle-Orbiter vehicle.

TABLE 6. CAPITAL COST ESTIMATE FOR AN EARTH TO SPACE EM LAUNCHER

Component	Cost per unit	No. units	Total component cost
Ac generators	$3 M	100	$300 M
Switching	$3 M	100	$300 M
Barrel	$0.3 M/m	1600 M	$480 M
Busbars and structure			$100 M
Civil engineering			$250 M
Total			$1450 M

System needs have not yet been fully evaluated. One of the most important issues (for an Earth-based system) is the "inverse reentry" problem of getting a gun-launched projectile up through the atmosphere without substantial ablation. Techniques for dealing with this, such as sacrificial ablative coatings or gas/vapor nose-tip cooling, appear feasible at first analysis. A mitigating factor is that the projectile should transit the atmosphere in only a few seconds. Launching from an equatorial site at high altitudes, as shown conceptually in Fig. 9, would be doubly beneficial because the atmospheric density would be lower and there is about a 400 m/s velocity contribution from Earth's rotation.

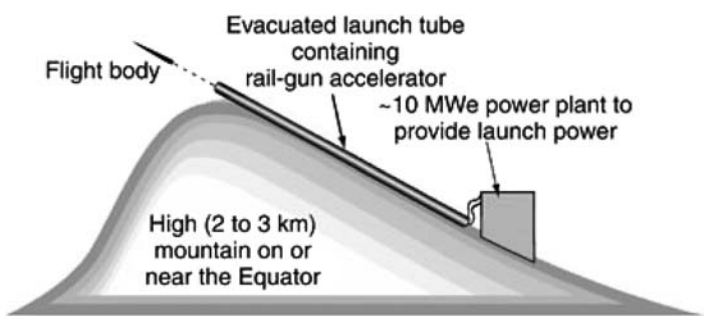

Fig. 9. The preferred launch site layout

EM Spacecraft Propulsion. To reduce the mass of fuel that has to be carried by a rocket, it is beneficial to increase the exhaust velocity of the propellant. Chemical rockets generally operate with a specific impulse (I_{SP}) in the range from about 250 to 400 seconds. To increase this, other techniques need to be developed. These include ion thrusters which have

[9] Of course, only rugged materials such as fuel, water, food, or engineering supplies could be launched at such accelerations.

an $I_{SP} \sim 2000$ to 3000 s, plasma thrusters, and even EM launchers. All of these are applicable only for use in space, not for launch into space from the surface of a planet.

Two studies of EM launchers for spacecraft propulsion were published in the early 1980s. Snow, et al. evaluated an induction launcher (known as the "mass driver") as a reaction engine for LEO to GEO orbit transfers. The goal was an I_{SP} of 500–1000 s, which requires an exhaust velocity of 5 to 10 km/s. As discussed earlier, induction launcher performance is far from this at present. Bauer et al. proposed to use a rail gun that launched pellets of an unspecified material at velocities of 5 to 20 km/s, corresponding to an I_{SP} of 500–2000 s. Apart from the failure of induction or rail launchers to reach the required velocities, a major concern with these concepts is the hazard created for other spacecraft, such as commercial satellites in near-Earth orbits, from ejecting high-velocity projectiles. In principle, these techniques could be considered for other missions, but there are competing technologies that are likely to be more attractive.

U.S. and International Programs

The best resources to consult for a review of EM launcher developments are the *Proceedings of the EM Launcher Symposia* that have been held every 2 or 3 years since 1982. These conferences have been published in archival form in special editions of the *IEEE Transactions on Magnetics*. Some papers can also be found in the nonarchival, but widely circulated, *Proceedings of the Pulsed Power Conference*, which is also now sponsored by the IEEE. Proceedings of specialized journal issues or conference in different countries are also availa ble occasionally. Because of the defense-related nature of much of this work, as well as the desire of industrial companies to protect their proprietary concepts, it seems likely that much R&D has occurred that has not been openly published. This overview is based on information from open sources.

United States. Although one or two isolated studies were undertaken in the late 1950s and 1960s, it was not until the mid-1970s that significant efforts began to develop in the United States. Following the approach pioneered at the Australian National University, several of these programs used homopolar generators as the energy and power source. These include facilities at Picatinny Arsenal (30 MJ), the University of Texas (60 MJ), and Eglin Air Force base (13 MJ). Large facilities were built with capacitors at Picatinny Arsenal (52 MJ) and Westinghouse (32 MJ). One facility installed by the USAF at Eglin used thousands of automotive batteries to charge an inductor that powered a rail gun. A larger number of small facilities were also used for R&D, based mostly on capacitors in independent modular arrangements. The largest rail guns used were 90-mm bore diameter and up to 8 meters long. Muzzle energies achieved with these rail guns were close to 9 MJ. In the last few years, financial strictures have forced rationalization of these facilities, and most have been dismantled or "mothballed." Coil-gun research has been more sporadic; the last remaining organization that has interest in this area is Sandia National Laboratories, although this effort is now not active.

Europe. Efforts on EM launchers and related technology developments are being, or have been, undertaken in recent years in Britain, Germany, France, Italy, Sweden, Israel, the Netherlands, and Switzerland. Experimental facilities have been established in several locations; the largest are at Kirkcudbright in Scotland (33 MJ), Unterluss in Germany (30 MJ), and St. Louis in France (10 MJ). Smaller facilities are available in the other countries. Several of these facilities use power supplies based on capacitors that were supplied by U.S. manufacturers.[10] TNO in the Netherlands also used a refurbished U.S. homopolar generator, and Magnet Motor GmbH in Germany is developing flywheel systems with permanent magnet generators that can serve as MW power sources to charge superconducting, inductive, pulsed GW systems. Research in Britain and France has been on rail guns and electro thermal chemical (ETC) guns. Germany, Israel, and Sweden have concentrated solely on ETC gun technology.

The Former Soviet Union. During the latter years of the Soviet Union, considerable R&D was undertaken on EM launchers for military applications, although relatively little was published in the West. Russia and the Ukraine were the primary developers, and several significant systems were built. Perhaps because capacitor technology is less well advanced in these countries, greater use seems to have been made of rotating machines. One notable Ukranian system that was installed in a transportable trailer used four homopolar generators, powered by helicopter gas turbines, that had 60 MJ stored energy. Other rotating machine system designs were for even larger energies. Based on published reports, there appears to have been more emphasis on achieving very high velocities in Russian research than in the United States, with several reports of 6 or 7 km/s with small pellets of a few grams and possibly up to 10 km/s with milligram masses.

East. One of the early efforts in developing rail guns was undertaken at the Ministry of Defense in Australia in the mid-1960 s. The availability of a very large (550 MJ) homopolar generator at the Australian National University (ANU) and interest in the effects of micrometeorite damage on spacecraft led to a larger effort at ANU in the early 1970s. Experiments were undertaken at velocities close to 6 km/s with gram-sized projectiles. This work ended after the two main researchers moved to the United States in the late 1970s.

During the late 1980s and early 1990s, several programs on EM launchers were funded at a modest level by industrial companies in Japan. In most cases, capacitor banks were used that were purchased from U.S. companies. Several innovative solutions were developed with modest investments. In the related area of high-speed transport, Japan, like Germany, has strong research programs and a national commitment to improved high-speed transit technology. This could form a good foundation for induction launcher research for higher velocities.

Serious Chinese studies started in the late 1980s, but publication occurred only in Western conferences and journals in the mid-1990s. A wide range of technical interests and level of technical sophistication are evident in recent publications, that show interest in both EM and ETC technology. The work builds on what has been undertaken in the West but with its own variations. Summaries of Western work have been prepared by Chinese authors and are available as a foundation for further research.

South Korea began to take an interest in this technology in the mid-1990s, and there are now several technical organizations involved with their Ministry of Defense in this research, especially on ETC guns. A Korean Conference on this technology was held in 1997.

[10] In some cases, through cooperative arrangements with the U.S. Department of Defense.

ELECTROMAGNETIC QUANTITIES, BASIC, MEASUREMENT OF. Electromagnetism consists of relationships between two fields, electric and magnetic. Therefore, two independent electromagnetic units must be defined in terms of the meter, kilogram, and second to ensure that the electrical units are part of the International System of Units (SI). These units are now used universally for practically all scientific and engineering measurements. The necessary two connections between the electrical and mechanical units are made at present by

1. implicitly defining mechanical and electrical power to be equal by using the same unit (watt) for both, and
2. explicitly defining the ampere as "the constant current which, if maintained in two straight parallel conductors of infinite length and negligible circular section placed 1 m apart in a vacuum, will produce between these conductors a force equal to 2×10^{-7} N per meter length." (This definition of the ampere is equivalent to defining the magnetic permeability of free space μ_0 as $4\pi \times 10_7$ H/m exactly.)

These abstract definitions have to be put into practice (or realized, in the jargon of metrology). See also **Metrology**. Realizations are carried out by more than one method and in more than one national measurement laboratory as a guard against error and to secure confidence in their correctness. To realize an electrical unit it is necessary to assume the complete accuracy of Maxwell's electromagnetic theory and to use an apparatus in a way that is, according to this theory, consistent with the definitions of the watt and ampere. Up to about 20 years ago the two apparatus that realized the two independent electrical units were

1. some form of current balance in which the force between circular current-carrying coils was weighed as a direct extension of the ampere definition, and
2. a mutual inductor whose carefully measured dimensions established a link between the meter and the ohm.

Neither the current balance nor the mutual inductor are accurate enough for the present-day routine needs of science and commerce at the highest level of accuracy of a part per million (ppm) or better. They have been replaced by electrometers (see **Electrometer**) or moving-coil apparatus that realize the volt or watt and the Thompson–Lampard calculable capacitor that realizes the ohm via the farad (Thompson and Lampard, 1656). The correctness of these realizations has been confirmed by examining relationships between those fundamental physical constants whose measured values involve mass, length, and time as well as electrical quantities.

Once they have been realized by these difficult and time-consuming measurements (each of which may take many years), the electrical units are preserved for everyday use in national standardizing laboratories by ascribing values to the constants that govern the Josephson (1962) and quantum Hall effects (von Klitzing et al., 1980). These precise effects of quantum physics that occur at cryogenic temperatures reproduce voltages and resistances very exactly (to 0.005 ppm at present).

Values of standards to represent other, derived, electrical units must then be determined in terms of the ohm and volt. There is usually only one preferred method of establishing each derived unit. This will be the method that yields the most accurate measurement in volts and ohms of a concrete standard representing the derived unit.

At present the stability and reproducibility of volt and ohm units preserved by means of the Josephson and quantum Hall effects greatly exceed the accuracy with which these units can be realized in terms of the meter, kilogram, and second. This situation suggests a possible future scenario: The present link to the meter, kilogram, and second could be replaced by a pair of basic electrical units (voltage defined in terms of the Josephson effect and impedance in terms of the quantum Hall effect) and then the kilogram could be derived from these. μ_0 would become an experimentally measurable physical constant, rather than a defined quantity, and the present prototype kilogram, which is the last unit based on a material artifact, would become a maintained standard whose value would have to be realized from these new definitions of the volt and ohm via an electromechanical apparatus.

ELECTROMAGNETIC RADIATION. Energy propagated in the form of an advancing electric and magnetic field disturbance. The term *radiation*, alone, is commonly used for this type of energy, although it actually has a broader meaning. Also called *electromagnetic energy* or simply *radiation*. In the classical wave theory of light (or electromagnetic theory) the propagation is thought of as a continuous wavelike disturbance of the electric and magnetic fields, which oscillate in planes orthogonal to each other and to the direction of propagation. The quantum theory of electromagnetic radiation adds the perspective that these disturbances also have particle-like attributes, being quantized into photons of minimum energy that have finite momentum. The observable properties and physical effects of various portions of the electromagnetic spectrum are of considerable importance in meteorology and are discussed under their respective names.

See also **Cosmic Rays**; **Electromagnetic Spectrum**; **Gamma Radiation**; **Infrared Radiation**; **Microwave Radiation**; **Ultraviolet Radiation**; and **X-Ray**.

ELECTROMAGNETIC SEPARATION. Separation of isotopes, especially those of uranium, by first accelerating them by means of an electrostatic field and then passing them through a magnetic field. The effect of this is to cause all the particles to take a curved path; the heavier ones, having higher kinetic energy, describe a wider arc than the lighter ones. Thus, two isotopes of closely similar masses can be separated and collected.

See also **Magnetic Separation**; and **Mass Spectrometry**.

ELECTROMAGNETIC SPECTRUM. The ordered array of known electromagnetic radiations, extending from the shortest cosmic rays, through gamma rays, X-rays, ultraviolet radiation, visible radiation, infrared radiation, and including microwave and all other wavelengths of radio energy.

The division of this continuum of wavelengths (or frequencies) into a number of named subportions is rather arbitrary and, with one or two exceptions, the boundaries of the several subportions are only vaguely defined. Nevertheless, to each of the commonly identified subportions there correspond characteristic types of physical systems capable of emitting radiation of those wavelengths. Thus, gamma rays are emitted from the nuclei of atoms as they undergo any of several types of nuclear rearrangements; visible light is emitted, for the most part, by atoms whose planetary electrons are undergoing transitions to lower energy states; infrared radiations are associated with characteristic molecular vibrations and rotations; and radio waves, broadly speaking, are emitted by virtue of the accelerations of free electrons as, for example, the moving electrons in a radio antenna wire.

See also **Absorption Spectrum**; and **Gamma-Ray Astronomy**.

ELECTROMETER. An instrument for measuring electric charge, usually by mechanical forces exerted on a charged electrode in an electric field. It consists, therefore, of a sensitive voltmeter operating on the principles of electrostatic attraction and repulsion. Thus, if the movement of the gold leaf in an electroscope is observed through a microscope whose ocular is provided with a calibrated scale, the instrument becomes an electrometer, capable of measuring potential differences in millivolts. (Some forms of electrostatic voltmeters operate on the same principle.) If the capacitance of the charged system is known, the rate of movement of the electrometer index may be used to measure the current from the discharging body; ionization currents are often thus measured.

The quadrant electrometer has a thin, oblong, metal plate suspended horizontally in the interior of a flat, circular metal box cut into four quadrants. One pair of opposite quadrants, and the suspended strip, are connected to the source of potential, while the other pair of quadrants is grounded. This causes the strip to turn toward the grounded pair against the torsion of the suspending wire (see Fig. 1, *left*). Several electrometers have been designed, depending upon the lateral deflection of a lightly stretched, silvered or platinized quartz fiber in an electric field; they are called string electrometers. The Wulf electrometer employs two such fibers side by side; on being charged, they bulge apart (see Fig. 1, *right*). The displacement of the fibers is observed in a micrometer microscope. Some of the special electrometers used for work with cosmic rays are of this type.

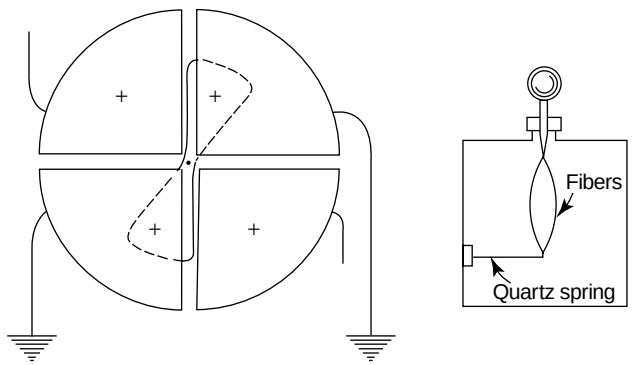

Fig. 1. Electrometers: (*Left*) Quadrant electrometer showing quadrants. (*Right*) Quartz fiber electrometer.

Vacuum tube electrometers, which are specially designed amplifiers with high input impedance, have been replaced by quadrant and string electrometers to a large extent.

See also **Electrical Instruments**; and **Electroscope**.

ELECTROMOTIVE FORCE. The electric potential difference (emf) between the terminals of any device which is used or may be used as a source of electrical energy, i.e., to supply an electric current. More strictly, the limiting value of that potential difference which is found as the current flowing from the source approaches zero. To avoid ambiguity, the strict sense of the term is often indicated by the use of the qualifying term "open circuit" or "no load."

The open circuit electromotive force of a cell is identical with its reversible potential difference. That of a rotating electrical machine is the potential difference existing across its terminals when the machine is neither receiving nor delivering electric power, i.e., when it is at the transition point between being a generator and being a motor. When a potential source of electrical energy, such as a capacitor, an inductor, or a rotating machine, is receiving energy from the external circuit, it is said to develop a counter-electromotive force. See also **Kirchoff Laws Of Networks**.

Counter-electromotive force is the emf generated by a running motor, by virtue of its generator behavior, or by an inductive circuit element through which the current is increasing with time. The total emf in the circuit is the impressed emf minus the counter emf; the current is given by the ratio of this total emf to the resistance in the circuit. The counter-electromotive force is sometimes called the back electromotive force. The *impressed emf* is the open-circuit (no load) emf of a source connected into a network.

Effective or root-mean-square electromotive force is the effective value of an alternating electromotive force and is the square root of the mean value of the squares of the instantaneous values. Where the variation of voltage with time can be expressed by a mathematical function, the value of the effective current can commonly be expressed in terms of the maximum value of the emf. Thus, for a sine wave relationship,

$$E_{\text{eff}} = \frac{E_{\max}}{\sqrt{2}}$$

ELECTROMOTIVE SERIES. See **Activity Series**.

ELECTROMYOGRAPHY. The recording of action potentials from muscles in the living subject by means of a needle electrode inserted through the skin into the muscle and connected to a suitable amplifier and cathode ray oscillograph. Normal resting muscle shows no changes in potential; contraction gives rise to large numbers of monophasic or diphasic spikes, indicating changes in potential of up to 1 millivolt, each lasting from 5–10 milliseconds. Various diseases and injuries of muscles and their nerves of supply give rise to characteristic and distinct departures from these normal patterns. Hence, electromyography is of value in assessing the extent of damage in diseases of the nervous system in which muscle is involved and in estimating the probability, progress and degree of recovery.

ELECTRON. An elementary particle of rest mass

$$m = 9.107 \times 10^{-31}$$

kilogram, a charge of 1.602×10^{-19} coulomb, and a spin quantum number $\frac{1}{2}$. Its charge may be positive or negative, although the term electron is commonly used for the negative particle, which is also called the negatron. The positive electron is called the positron. The electron is a constituent of all matter, thus the normal atom consists of a positively charged nucleus surrounded by a sufficient number of electrons so that their total charge is equal to the positive charge on the nucleus. The electron also has wave characteristics, with a frequency and a wavelength. According to wave mechanics, an electron traveling with speed v is associated with a "de Broglie wave" train of wavelength $\lambda = h/mv$ (in which m is the electronic mass and h is Planck's constant).

Bonding Electron. An electron in a molecule that holds two adjacent nuclei together.

Conduction Electron. An electron which plays an important part in electrical or thermal conduction by solids, i.e., by metals or semiconductors, e.g., the electrons in the conduction band, which are free to move under the influence of an electric field.

Electron Donor. 1. When a valence bond between two atoms is that type of covalent linkage in which both the electrons of the duplet are supplied by one atom, then that atom, or portion of the molecule of which it forms a part, is called the electron donor. The other atom in the linkage is called the electron acceptor. 2. A donor is also an impurity added to a pure semiconductor to increase the number of free electrons.

Electron Duplet. A pair of electrons shared by two atoms; it is equivalent to a single, nonpolar chemical bond.

Electron Octet. A group of eight valence electrons which constitutes the most stable configuration of the outermost, or valency, electron-shell of the atom, and hence the form which frequently results from electron transfer or sharing between two atoms in the course of a chemical reaction.

Electron Pair. The negatron and positron that result from the pair-production process or interact to initiate an annihilation process.

Electron Shell. The structure of a neutral atom consists of a positively charged nucleus with a number of electrons moving about it — the number being such that their total negative charge is equal to the positive charge on the nucleus. These electrons may be assigned to various shells, characterized by different principal quantum numbers.

Electron Spin. The intrinsic angular momentum of an electron, independent of any orbital motion. Spin ($= h/2$) contributes to the total angular momentum of the electron and is quantized. It gives rise to multiplicity in line spectra, which may be characterized by introduction of the spin quantum number.

Electron Transfer. The process of the shifting of an electron from one electrical field to another, as in the formation of an electrovalent bond, in which an electron moving in an orbit about one atom shifts to move in an orbit around the two bonded atoms.

Free Electron. An electron that is not held in the immediate neighborhood of an atom or molecule.

Orbital Electron. An electron remaining with a high degree of probability in the immediate neighborhood of a nucleus, where it occupies a quantized orbital.

Photo Electron. An electron ejected from a substance by the action of a single photon of light or other electromagnetic radiation.

Secondary Electron. An electron deriving its motion from a transfer of momentum from primary radiation, which may be either particulate or electromagnetic.

Valence Electron. The electrons in the outermost shell of the structure of an atom. Since these electrons are commonly the means by which the atom enters into chemical combinations — either by giving them up, or by adding others to their shell, or by sharing electrons in this shell — these outermost electrons are called valence electrons.

Additional Reading

Warwick, A. and J.Z. Buchwald: "Histories of the Electron," *The Birth of Microphysics*, The McGraw-Hill Companies, Inc., New York, NY, 2001.

ELECTRON AFFINITY. 1. Degree of electronegativity, or the extent to which an atom holds valence electrons in its immediate neighborhood, compared to other atoms of the molecule.

2. The work required to remove an electron from a negative ion, and hence to restore the neutrality of an atom or molecule, is called the electron affinity of the atom or molecule.

ELECTRON AVALANCHE. The process in which a relatively small number of free electrons in a gas that is subjected to a strong electric field accelerate, ionize gas atoms by collision, and thus form new electrons to undergo the same process in cumulative fashion. All streamers in a lightning discharge propagate by formation of electron avalanches in the regions of high electric field strength that move ahead of their advancing tips. Particularly in the case of the intense return streamer, avalanche processes are enhanced by formation of photoelectrons as a result of ultraviolet radiation emitted by the excited molecules in the region just behind the tip. An avalanche cannot possibly begin until the local electric field strength is high enough to accelerate a free electron to the minimum ionizing speed in the space and time interval corresponding to one mean free path of the electron, for upon collision, the electron usually loses its forward motion in the direction of the field. Maintenance of an avalanche requires a large reservoir of charge, such as accumulates more or less periodically in active thunderstorms.

ELECTRON BEAM. Specifically, a focused stream of electrons used for neutralization of the positively charged ion beam in an ion engine. Also used to melt or weld materials with externally high melting points.

ELECTRON BEAM LITHOGRAPHY. In chip making, the processing cost is only indirectly related to the amount of circuitry on a chip and thus it is an economic advantage for the semiconductor industry to increase the amount of circuitry per chip. This can be accomplished in either of two ways: (1) increasing the size of the chip, or (2) reducing the size of the circuits themselves. The latter approach, which has other advantages in terms of circuit performance and the application of chips by electronic equipment manufacturers, commercial and military, has predominated integrated circuit technology, with a target for the year 2000 or earlier of one billion transistors on a single chip. In passing, it should also be pointed out that larger chips exhibit poorer manufacturing yields and less mechanical stability. Hence, increasing circuit density can best be accomplished by reducing the circuit dimensions. There are physical limitations, of course, to the width of lines and separations in an intensely crowded chip. Over the last couple of decades, these dimensions rapidly dropped from the millimeter dimensions of the very early days of solid state electronics to micrometers (microns) as circuits proceeded from medium- to large- to very-large-scale integration. As of the late 1980s submicron dimensions were affecting the industry.

Earlier optical lithography methods were limited by diffraction and optical aberrations, a situation that occurs at feature sizes below about 2 micrometers.

Electron beam lithography entered the scene in the late 1970s as a means to fill the gap.

Principles of Electron Beam Lithography. Typically, an electron beam lithography system accelerates and focuses an intense beam of electrons to draw precise circuit patterns on suitable substances. Electron beam instruments, unlike optical instruments, require a high-vacuum environment for both the electron beam path and the substrate.

An intense beam of electrons from a high brightness source, such as lanthanum hexaboride, is focused to a size of about 0.2 micrometer or less by electromagnetic lenses. Patterns are generated by moving the beam across the substrate and turning the beam on and off with a blanking system. Two methods are employed to move the beam: (1) small movements are accomplished by deflecting the beam with electromagnetic coils; (2) large movements are made by moving the wafer by a mechanical stage. Positioning precision is achieved in the first case by using high stability electronics of high numerical precision, while in the second case it is achieved by employing a laser interferometer to monitor the stage motion. Because the beam must move at rates of two to ten million steps per second, a computer is required to control the position. Few computers are capable of the necessary data rates and, therefore, specific custom hardware is usually included in the interface to reduce the required amount of data.

The technique used in writing with an electron beam is similar to that used for tracing figures on cathode ray tubes in computer graphics displays. Two distinct methods have been developed for this purpose: (1) raster scan,

and (2) vector scan (sometimes called *random draw*). Because specific and distinct hardware is required for each, electron beam instruments are designed to use either one method or the other, but not both.

Raster Scan Method. In the raster scan method, the beam is moved across the entire chip using a television-type raster. It is unblanked only where exposure is desired. One system moves the stage continuously in one direction, X, while scanning the beam in an orthogonal direction, Y. In this way, a narrow strip is exposed, and the entire wafer is covered by exposing a large number of these strips. As the beam is scanned in the Y direction, the hardware must turn it on or off at each point. Currently available computers are not capable of supplying data at the required high rates and, therefore, a large block of information is stored in the hardware and used repeatedly to expose each of many identical areas on the wafer. This method results in fast exposure, but only if many identical chips are to be exposed. The raster scan method is shown in Fig. 1.

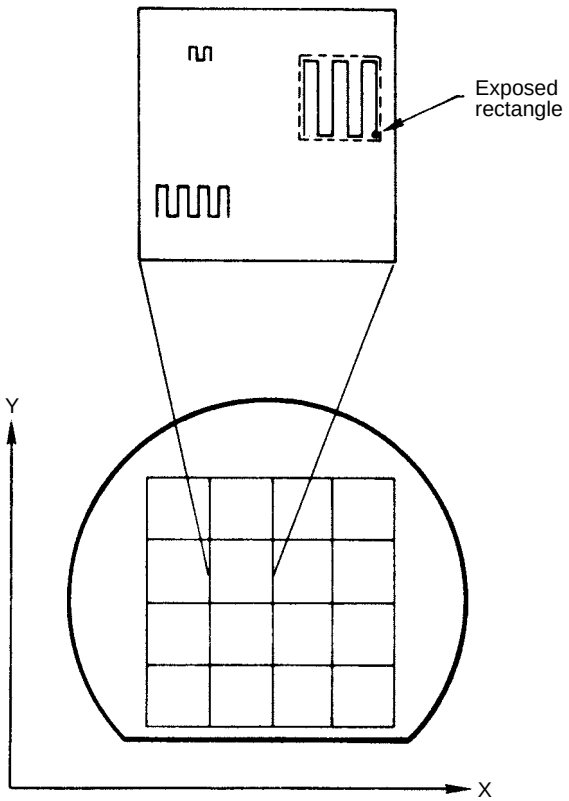

Fig. 1. Exposure of wafer by raster scan method.

Advantages of the raster scan method include less stringent requirements on the electronics and on the electron optics. In some cases, it is possible to achieve faster exposures. Deflection of the beam in the X direction is limited to that necessary to correct for minor errors in the position of the stage. In the Y direction, the beam deflection required is significantly less than the deflection required for the vector scan method. At these small beam deflections, field distortion is normally not a problem. Processing times are short if there are many identical chips to be made from a single wafer, but increase as the size of the chip increases.

These advantages are offset by a number of disadvantages. The necessity of "stitching" together many small fields places stringent requirements on the precision of the mechanical stage. The entire wafer must be scanned, and this is time consuming if it is necessary to expose only a small fraction of the area. Furthermore, corrections for the exposure effects of adjacent fields and for wafer distortion are difficult, if indeed possible.

Vector Scan Method. In the vector scan method, the beam is moved only to locations where exposure is desired. The beam is moved over a serpentine path to cover an entire basic element, the portion of the chip that can be exposed by a single computer command. The element is constructed of a series of parallel lines, each line consisting of a row of exposed points. Because the spacing of the points is of the same order as the width of the beam, the entire area is exposed. The maximum point rate is 5 or 10 megahertz, and, because most computers are unable to give commands at this rate, hardware is normally included to move the beam over an entire clement. The beam is blanked only for a short time between the tracing of adjacent lines and while moving from one element to another. The vector scan method is shown in Fig. 2.

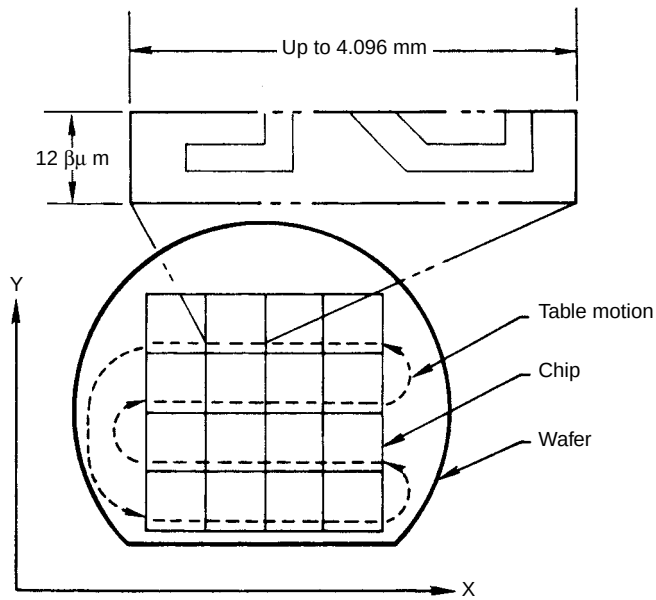

Fig. 2. Exposure of wafer by vector scan method.

The vector scan method has the advantage of not using up time moving the beam over areas that are not to be exposed. In addition, it is relatively easy to make corrections for scan field distortions, for the effect of adjacent exposed areas, and for wafer distortion. The necessary size of the scan field, however, is significantly larger than that used in the raster scan method. Consequently, more stringent requirements are placed on the quality of the electron optics, the scan coils, and the amplifier that drives them.

A computer is used to drive an interface, which implements the vector scan method. The interface contains a series of electronic counters and digital-to-analog converters, which determine the position of the beam. The output from this circuitry is fed to an amplifier, which drives the deflection coils. See Fig. 3.

Each pattern consists of a group of geometrical elements. The hardware stores the information, which defines the coordinates of the lower left corner of each element and also its height and its length. The hardware counts the height vector either up or down to expose a single line and decrements the length vector between lines to expose the entire element. The most commonly used element is a rectangle, but the hardware has the additional capability of drawing parallelograms and triangles.

The circuit designer defines the patterns, using another computer, usually one with graphics capabilities. The pattern definition is then placed on a magnetic tape, which can be read by the machine's computer. The software in the latter machine then interprets the tape and produces the commands to drive the instrument. This software is capable of accepting control information related to scaling, exposure, and position, either from the magnetic tape or directly from the operator.

The customizing of the system maximizes flexibility in order to facilitate the engineering prototyping of circuits. A single wafer may contain either many identical or many different chips, and exposure and scale may be varied from chip to chip. The reduced number of steps in the process, as compared with optical methods, reduces the time necessary to make a modification and to obtain a finished circuit ready for testing. The result is a shorter turnaround time in the design of new circuits.

Fabrication Techniques. Electron beam techniques of fabricating devices are in many ways similar to conventional optical techniques. Processes common to both include growing and removing oxides, depositing metal conductors, and doping the semiconductor. Each process requires that a different pattern be exposed and positioned accurately (registered) relative to previous ones.

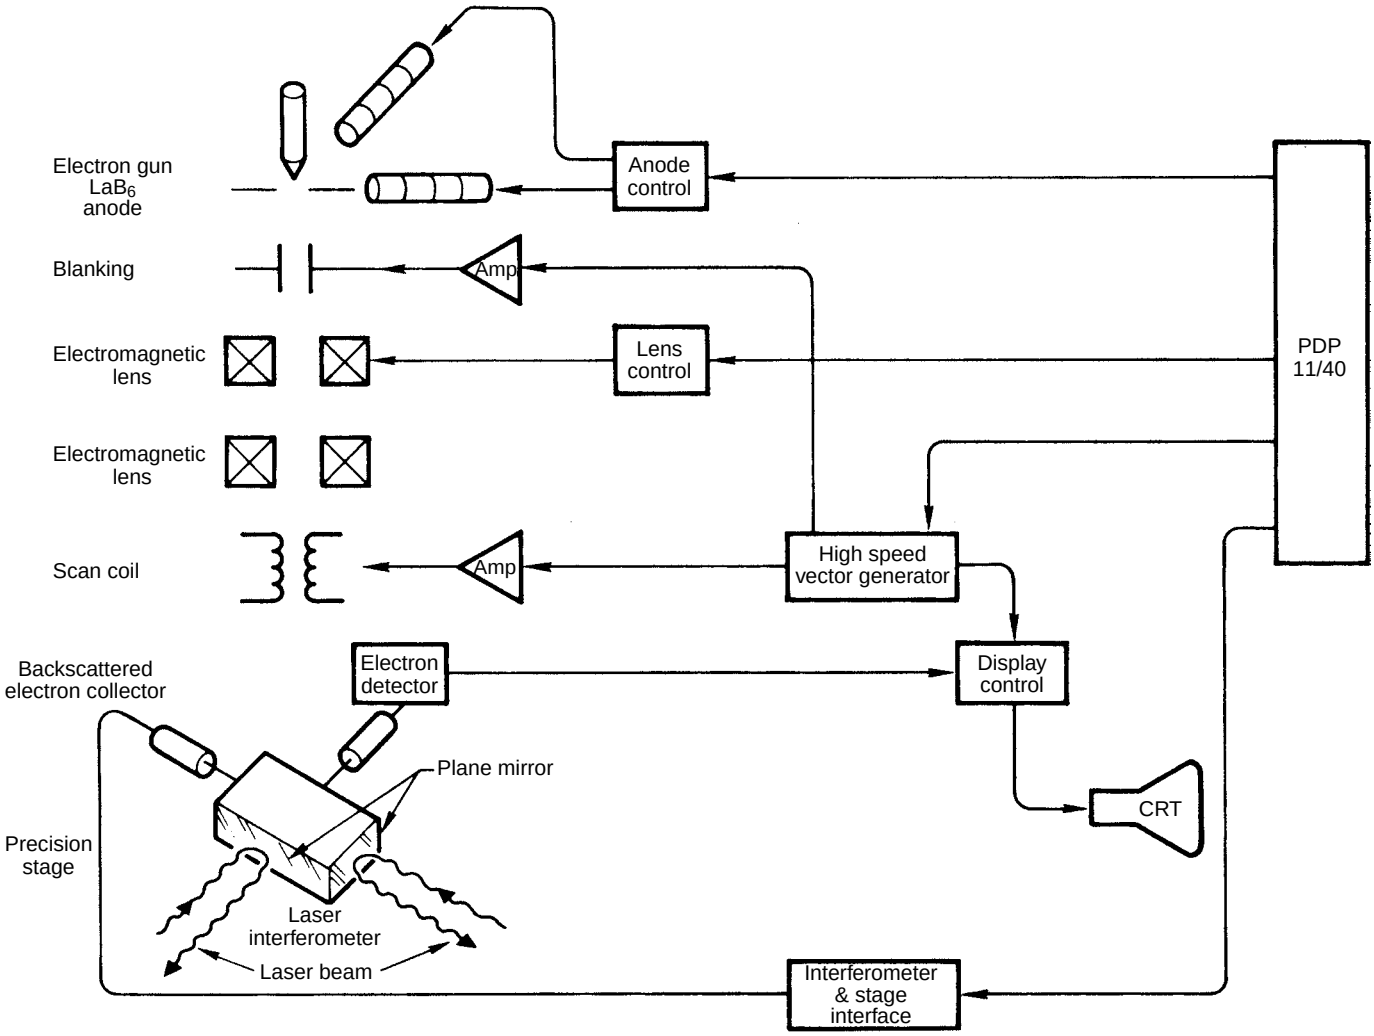

Fig. 3. Early 1980s electron beam instrument. (*GTE Labs*.)

Traditional methods of device fabrication define this pattern by a set of masks fabricated by optical techniques, usually using more than one processing step to manufacture each mask. The masks are then used to expose a photosensitive emulsion on the wafer, again by optical techniques.

Electron beam techniques make possible two improved methods of fabrication. (1) In the first, the electron beam instrument is used to make a mask. The masks are then used to expose the resist on the wafer with radiation. (2) The second electron beam technique is direct fabrication. Here the wafer itself is coated with an electron-sensitive polymer (resist), which is exposed directly by the electron beam. The wafer is then removed from the instrument, the resist developed, and the wafer processed. Each processing step requires that this sequence be repeated. In some cases, direct fabrication increases the processing time, but the technique has significant advantages, which include flexibility, greater ease of registration, and higher resolution. The devices commonly fabricated by direct electron beam methods have smaller dimensions and, therefore, require greater positioning accuracy. The accuracy is achieved by the use of registration marks consisting of heavy metal deposits or of holes in an oxide layer. The instrument uses electrons scattered from these marks to locate accurately the position of previous patterns. This technique achieves a positioning precision of 0.1 micrometer.

The process used to fabricate registration marks is similar to that used to fabricate the pattern. The device is covered first with a polymeric material and then with a thin aluminum coating which is used to drain charge from the device. Irradiation increases the degree of polymerization in some polymers and it reduces it in others. Chemicals are then used to develop the pattern by removing the unpolymerized material. The remaining polymer is used as a mask to protect areas not to be covered with metal, or not to be doped. Finally, the polymer is dissolved, and any excess metal or dopant is removed. This method is known as the "lift off" technique and is shown in Fig. 4.

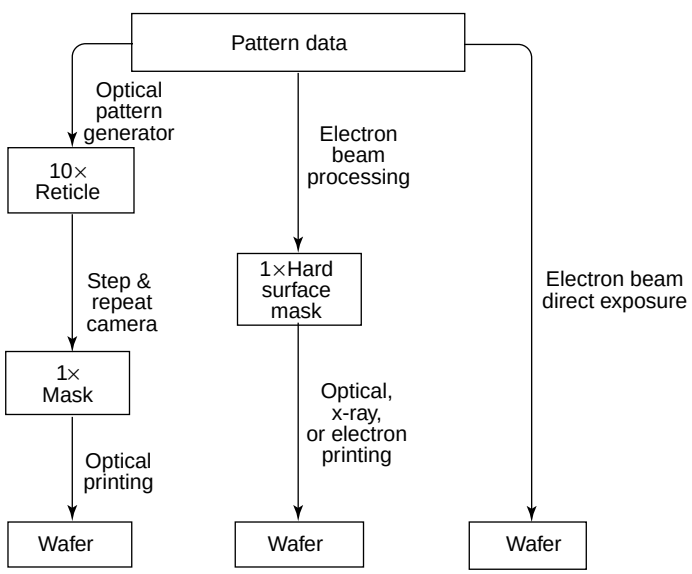

Fig. 4. Comparison of optical and electron beam fabrication.

The polymeric material used can be either of two general types: (1) In the first, positive resist, the exposed portion is depolymerized and therefore removed by the developer; while (2) in the second type, negative

resist, the unexposed area is removed. The electrical charge per unit area (coulombs per square centimeter) that is required to depolymerize or to polymerize the resist is a definition of its sensitivity. The resolution of the resist describes the minimum feature size that can be usefully exposed. Poly(methylmethacrylate), PMMA, is an example of a well-known positive resist with high resolution, but poor sensitivity. Poly(butene-l-sulfone), PBS, and Poly(glycidylmethacrylate), PGMA, are well-known negative resists with higher sensitivity, but less resolution than PMMA. Resolution is degraded by electron scattering from the resist and from the substrate. Because the area exposed by the scattered electrons is much larger than the minimum area of the electron beam, the scattering is the limiting factor in determining the minimum possible feature size.

Because of the complexity of electron beam instruments, a substantial investment in equipment is required. These instruments, however, provide increased flexibility and automated control which are extremely useful in the design and prototyping of circuits.

ELECTRON BEAM VACUUM-EVAPORATION PROCESS. For decades, various coating processes have been developed to provide metal parts, fundamentally selected for their strength, with protection required to resist corrosion and to provide additional performance characteristics, such as tolerance of high surface temperatures. Frequently, gas turbines are cited as an example of such needs. High-temperature processes, such as dipping (zinc galvanizing, cadmium coating, etc.) have been used for steel pipes and fittings, and numerous articles have been electroplated with nickel, chromium, gold, silver, etc., to deter corrosion and tarnishing. Because of extremely demanding operating conditions, however, traditional coating processes no longer suffice. The gas turbine blade is an example, but this problem also arises in other industries, notably in the manufacture of electronic components, where thin films must be created.

The need for coating purity and in film formation has become extremely demanding. Where alloy components of coatings, for example, must be melted and vaporized, conventional heating processes introduce undesired impurities. Electron beam heating under vacuum creates the needed melting and vaporizing temperatures without introducing any impurities. See Fig. 1.

A typical batch-coating cycle for coating aircraft gas-turbine blades consists of:

- Loading blades into the processing chamber. During the coating process — wherein such alloy metals as chromium, aluminum, and yttrium form a coating of a basic material such as iron, cobalt, and nickel — the parts are manipulated to orient all surfaces so that a uniform coating can be maintained. This operation, of course requires automation under vacuum conditions.
- The chamber is evacuated to a pressure of about 2 Pa (0.02 mbar). Approximately five minutes are required to reach this condition.
- Parts must be preheated to 960–980 °C (1760–1795 °F), depending on the part alloy. Preheating is carefully controlled so that the condensing vapor particles are sufficiently mobile to promote the formation of compact grain structures and, consequently, dense films.
- In an average situation, a 0.1 to 0.2 mm (0.004 to 0.008 inch) thick film is deposited on the parts. This requires about 10 minutes. Depending on how the evaporation sources are arranged, the coating chamber will contain two or three electron beam guns, each with a beam-power rating of 200 KW max.
- Coated parts are returned to a load-lock chamber and allowed to cool below 300 °C (570 ± F). The locked chamber is vented to atmospheric pressure and parts are unloaded.

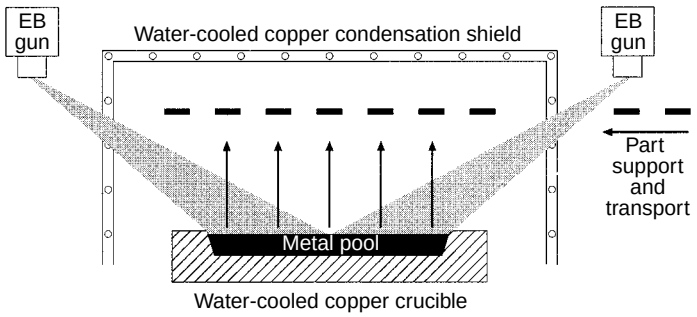

Fig. 1. Sectional view of electron-beam vacuum-evaporation process. Desired alloy ingots are melted in a copper crucible by energy from two focused electron-beam guns, causing metal vapors to rise and coat parts in the upper part of a water-cooled chamber. Nearly all types of materials can be evaporated. For parts which require corrosion resistance at high-temperature operating conditions (such as gas-turbine blades), numerous alloy components (such as nickel, cobalt, chromium, aluminum, and yttrium among others) can be deposited on parts. The chamber is evacuated, parts are preheated, and the time of part exposure is in the five-minute time range. Films of 0.1 to 0.2-millimeter (0.004 to 0.008 inch) are deposited on the parts.

As pointed out be Lämmermann and Kienel, "The composition and microstructure of the deposited film are the two major factors that determine its corrosion resistance. The typical composition of a MCrAlY film is 20 Cr, 10 Al, 0.3 Y, ball M (Fe, Co, or Co-Ni). In a typical situation, the chromium, aluminum and yttrium contents of a NiCoCrAlY deposit are 80%, 60%, and 60%, respectively, of acceptable tolerance ranges. Similarly, the cobalt, chromium, aluminum, and yttrium contents of a CoCrAlY deposit are 60%, 45%, 60%, and 60%, respectively.

The hot-corrosion (and oxidation) resistance of coated parts can be improved further by applying a layer of thermal insulation. This coating must be sufficiently thick, have a low thermal conductivity, and high thermal-shock resistance. Internal voids in the thermal coating also are helpful and can reduce the thermal conductivity of the material to a value well below that of the bulk material. The temperature difference between the outer surface of the coating and the outer surface of the underlying corrosion-resistant material can be as high as 150 °C (260 °F). In addition to reducing the temperature at the surface of the superalloy, the coatings also reduce thermal-shock loads on the parts, and rapid changes in ambient temperature are moderated and attenuated before they reach the substrate.

Zirconium oxide (ZrO_2) stabilized by an addition of about 7% yttrium oxide (Y_2O_3) can be quite effective. Any oxygen deficit due to partial dissociation is compensated for by adding metered amounts of oxygen during the coating process. The crucibles used are considerably smaller than those used for evaporating metals. The evaporation temperatures of ZrO_2 and Y_2O_3 are so high that the EB guns are not sufficiently powerful to maintain a uniform temperature at the surface of a large-area melt pool.

Thermal spraying in the form of low-pressure plasma-spraying (LPPS) is another method for providing the high coating purity and strong coating-to-substrate bond needed by some products. See also **Thermal Spraying**.

ELECTRON DEVICE. A device in which electricity is conducted principally by electrons moving through a vacuum, gas, or semiconductor.

ELECTRON DIFFRACTION. Beams of high-speed electrons exhibit diffraction phenomena analogous to those obtained with light, thus showing the wave-like character of electron beams. Such patterns are useful in the interpretation of the structure of matter.

See also **Electron Microscope**.

ELECTRONEGATIVITY. This term refers to the relative tendency of an atom to acquire negative charge. This tendency is not precisely defined because no exact theoretical or experimental method of evaluation has been devised. Electronegativity exists because the electronic cloud that

surrounds each atomic nucleus is inadequate to block off the nuclear charge completely at the periphery. In other words, although every complete atom is electrically neutral as observable from a distance, a small fraction of the total nuclear positive charge can be detected at any point near the surface of the atom. This "effective nuclear charge" at the surface is relatively insignificant in the absence of low energy vacancies capable of accommodating a foreign electron, as in the atoms of M 8 elements (commonly called the *inert* or *noble gases*). However, wherever a low energy electron vacancy occurs in the outer shell of an atom's electronic cloud, the effective nuclear charge as manifest within that vacancy is of major importance. Indeed, it constitutes the cause and means of chemical bond formation, and largely determines both polarity and strength of the bond. Electronegativity is a measure of the force of this effective nuclear charge within an orbital vacancy at the distance of the atomic radius.

Evaluation of relative electronegativity was first accomplished by Pauling. He considered the energy of a heteronuclear single covalent bond to consist of the geometric mean of the homonuclear single bond energies of the two elements, *supplemented* by an electrostatic or ionic energy resulting from uneven electron sharing in the bond. This he attributed to an electronegativity difference between the two elements. He used the difference between the observed bond energy and the average of the homonuclear energies as a measure of the ionic energy. From such differences for various pairs of atoms he established a relative scale in which the most electronegative element, fluorine, has the value 4.0, and within the same period are O 3.5, N 3.0, C 2.5, B 2.0, Be 1.5, and Li 1.0.

Mulliken defined electronegativity as the average of the "valence state" ionization energy and electron affinity. Gordy suggested that electronegativity is a measure of the electrostatic potential at the surface of an atom, expressed as the effective nuclear charge, $Z_{eff}e$ divided by the radius. Allred and Rochow modified this concept by considering the electrostatic force, $Z_{eff}e^2/r^2$, as the measure of electronegativity. Electronegativities have also been estimated from work functions of metals, from force constants determined by infrared spectroscopy, from nuclear magnetic resonance spectroscopy, and by other methods. When adjusted to the same arbitrary scale, conventionally that established by Pauling, these methods give values in surprisingly good agreement, with only a few minor discrepancies that remain controversial. The principal application of *Pauling scale electronegativities*, which are those almost universally given in textbooks, has been qualitative prediction of bond polarity. That is, a given bond between atoms initially differing in electronegativity is polar with a partial negative charge on the initially more electronegative atom. The degree of polarity increases with increasing electronegativity difference.

Far more valuable applications of electronegativity have been made using a different scale based on the relative compactness of the electronic clouds of atoms. Electronegativities thus derived are approximately a linear function of the square root of the Pauling scale values, and in this sense in generally good agreement. They (see Table 1) have been used for quantitative estimation of the partial charges on combined atoms, which in themselves permit correlation of a vast quantity of chemical data and interpretations of many chemical phenomena. The partial charges in turn have been applied to the quantitative calculation of bond energy. Furthermore, more recently, a simple quantitative relationship between homonuclear covalent bond energy and electronegativity has been demonstrated. Experimental homonuclear bond energy can be used to calculate electronegativity, or vice versa.

TABLE 1. RELATIVE ELECTRONEGATIVITIES OF SOME ELEMENTS (Relative Compactness Scale)[a]

H	3.55	K	0.42	Rb	0.36	Cs	0.28
Li	0.74	Ca	1.22	Sr	1.06	Ba	0.78

[a] Values for the transitional elements are tentative estimates only.

Space does not permit a detailed description of the concepts and methods mentioned here, but an example of the results obtainable may illustrate the principles involved. Silica, SiO_2, consists of silicon atoms initially of 2.84 electronegativity, tetrahedrally surrounded by oxygen atoms, initially of 5.21 electronegativity, each of which bridges two silicon atoms. The principle of electronegativity equalization states that when two or more atoms initially different in electronegativity combine, their electronegativities become equalized to the geometric mean. For SiO_2 the electronegativity of the compound is $(2.84 \times 5.21^2)^{1/3} = 4.26$. The equalization is brought about through the uneven sharing of the bonding electrons. The oxygen being initially more electronegative, attracts more than a half share of the bonding electrons. By spending more than half time more closely associated with the oxygen, the bonding electrons impart a partial negative charge on the oxygen, expanding the cloud through increased repulsions and decreasing the electronegativity. Simultaneously the silicon atoms shrink because of reduced repulsions, and increase in electronegativity because of reduced shielding between nucleus and bonding electrons. The decrease in oxygen electronegativity from 5.21 to 4.26 is 0.95. If oxygen had acquired an electron completely the electronegativity would have dropped by 4.75. The partial charge on oxygen is defined as the ratio $0.95/4.75 = -0.20$ (minus because the electronegativity decreased). The silicon is left with a partial positive charge of 0.40.

The silicon-oxygen bond, like all heteronuclear bonds, can be treated *as if* its energy were partly covalent and partly ionic. Instead of ionic energy supplementing the covalent energy, as suggested by Pauling, the ionic energy *substitutes* for a part of the covalent energy. The ionic weighting coefficient is half the charge difference: $(0.40 + 0.20)/2 = 0.30$. The covalent weighting coefficient, $1.00 - 0.30$, is 0.70. For the covalent energy one takes the geometric mean, 59.7, of the homonuclear bond energies of silicon (53.4) and oxygen (66.7, as calculated from the O_2 molecule), multiplies by 0.70, and corrects for bond length by the factor (covalent radius sum)/(observed bond length) $= 1.90/1.61$.

This calculation gives 49.1 kcal/mole of bonds. The ionic energy is simply the conversion factor (to kcal/mole) 332, times the weighting coefficient 0.30, divided by the bond length 1.61, or 61.8 kcal/mole of bonds. The sum, 110.9 kcal, is the Si−O bond energy. Atomization of SiO_2 requires the rupture of four SiO bonds per formula unit; $4 \times 110.9 =$ 443.6 kcal/mole for the atomization energy of SiO_2(c). Subtraction of the atomization energies 108.9 for Si and 119.2 for two O gives −215.5 kcal/mole for the calculated standard heat of formation of SiO_2(c). The experimental value is −217.7.

Electronegativity thus permits a quantitative interpretation of the bonding in SiO_2 or any other compound for which appropriate data are known. The same principles allow a superior alternative to the "ionic" model of nonmolecular solids, and offer high hope of eventually elucidating the thermochemistry of mineral substances in general.

ELECTRON EMISSION. The liberation of electrons from an electrode into the surrounding space. Quantitatively, it is the rate at which electrons are emitted from an electrode.

ELECTRONEUTRALITY. If one describes the properties of electrolytic solutions in terms of ionic species, one has to take account of the fact that the concentrations of all species are not independent because the solution as a whole is neutral.

One generally uses the symbol z_i to denote the charge on an ion measured in units of the charge of a proton (for example, for Na^+, $z = 1$; for La^{3+}, $z = 3$; for PO_4^{3-}, $z = -3$); z is also called the *charge number* of the ion.

If n_i is the number of moles of the ionic species i, the condition of electrical neutrality is

$$\sum_i z_i n_i = 0 \qquad (1)$$

Alternatively if one uses the subscript + to denote positively charged ions or *cations* and − to denote negatively charged ions or *anions*, then one may write (1) in the form

$$\sum_{+} z_{+}n_{+} = \sum_{-} z_{-}n_{-} \tag{2}$$

ELECTRON GAS. The term electron gas is used to denote a system of mobile electrons, as, for example, the electrons in a metal that are free to move. In the free electron theory of metals, these electrons move through the metal in the region of nearly uniform positive potential created by the ions of the crystal lattice. This theory when modified by the Pauli exclusion principle, serves to explain many properties of metals, especially the alkali metals. For metals with more complex electronic structure, and semiconductors, the band theory of solids gives a better picture.

ELECTRON GUN. An electrode structure which produces and may control, focus, and deflect an electron beam.

ELECTRONIC DATA PROCESSING. A few decades ago, when digital computers were introduced into the business and scientific fields for data processing, the term *electronic data processing* (EDP) was widely used. Today, use of the word *computer* in some form, such as *computer processing*, essentially has replaced EDP in the English business and technical language. See also **Digital Computer Systems**.

ELECTRONICS. An all-inclusive type of term embracing the study, design, and application of devices whose operation is dependent fully or partially upon the characteristics and behavior of electrons. Since electricity is a fundamental quantity, in nature comprising electrons and protons at rest or in motion, any phenomenon or device of an electrical nature would also be covered by the umbrella term, electronics.

The word *electron* was first used in a paper by George J. Stoney in the July 1891 issue of *The Scientific Transactions of the Royal Dublin Society*, entitled, "On the Cause of Double Lines and of Equidistant Satellites in Spectra of Gases." The word *electronics* (Ger. *Elektronik*) was first used to describe the branch of physics now generally called physical electronics. That usage dates back almost to the discovery of the electron in 1897, as witness the names of two early journals in the field, *Jahrbuch der Radioaktivität und Elektronik* (founded in 1904) and *Ion: A Journal of Electronics, Atomistics, Ionology, Radioactivity and Raumchemistry* (1908). In the currently prevalent technological context, the adjective *electronic* and the noun *electronics* (Ger. *technische Elektronik*) date back only to the 1920s.

The discovery of thermionic emission and the utilization of this effect in vacuum tubes set the stage for a new field of technology which, although basically electrical in character, nevertheless differed from the traditional spheres of electrical engineering and the science of electricity and magnetism. Invention of the triode by De Forest in 1907 and the development of new uses for vacuum tubes (or valves), with their particular attributes, notably amplification and oscillation, and with their unique solutions for problems, notably in the communications field, markedly differentiated these devices from prior run-of-the mill electrical and magnetic hardware. Designers of the early 1900s were able to develop practical and important electrical equipment without benefit of formal knowledge of electron theory. In Marconi's experiments of the late 1800s, using magnetic detectors for radio waves, and his dramatic accomplishment of spanning the Atlantic with radiotelegraphy in 1901, there was a definite pointing toward what is now considered modern electronics. This was given further emphasis with the first application of the three-electrode vacuum tube to radio in 1912. The Radio Corporation of America was formed in 1919 to pursue radiotelegraphy developments for the United States, which, at that time, enjoyed cable communications with only two nations in Europe — Great Britain and France. It was at about this time that the ever increasing and tight bond between electronics and communication was formed, which continues to the present and into the foreseeable future.

The first of the "modern" digital computers, the Mark I, was completed in 1944 for the U.S. Navy by Dr. Howard H. Aiken of Harvard University, assisted by International Business Machines Corporation. This was an electromechanical machine controlled by electromagnetic relays, two-position devices developed by Bell Telephone Laboratories as switches for the telephone industry. Other Bell Labs products used in the Mark I were punched paper tape equipment teleprinters and other components developed for communications systems. In today's parlance this machine might be called "electronic," but in its day it did not meet the requirement of incorporating vacuum tubes. However, the ENIAC (Electronic Numerical Integrator and Calculator), also built during the early 1940s by Dr. John Mauchly and Dr. J. Presper Eckert at the Moore School of Electrical Engineering at the University of Pennsylvania in Philadelphia, did meet the test, and it was commonly referred to as the first true electronic computer. Instead of electromagnetic relays, some 18,000 flip-flop vacuum tubes originally designed for radar and television were used. And thus the firm and everlasting association between electronics and computing was established.

The close association between electronics and the vacuum tube persisted for many years, until the development of semiconductors. In the 1941 edition of *The Encyclopedia Americana*, the entry on *Electronics* was largely confined to thermionic emission, applications of diodes, grid-controlled thermionic tubes, and triodes as detectors and amplifiers. The definition of electronics given was, "the term applied to a wide variety of applications of the electron theory to engineering practice," which, in retrospect, was an excellent definition for its time.

Specialized publications for the field of electronics commenced in the 1940s. The American Institute of Electrical Engineers and the Institute of Radio Engineers combined in 1962 to form the Institute of Electrical and Electronics Engineers. The new organization was composed of 34 specialized groups, most of them pertaining to some aspect of electronics. In a way, this merger of two professional groups recognized somewhat belatedly the existence of an electronics technology, but also perpetuated some demarcation of electronics from other aspects of electrical technology.

In an excellent, short review of electronics, Pierce suggested that "electronics has come to mean all electrical devices for communication, information processing, and control." Pierce points out that this would include pre-vacuum-tube devices such as the electric telegraph, which replaced such light-wave communication as semaphore telegraphs, signal flags, and heliographs. It would include the telephone. And, thus, according to this definition, electronics was born nearly 150 years ago with the first electric telegraphs (*Science*, **195** , 1092–1095, 1977).

As of the late 1980s, the foregoing definition of electronics has expanded even further. Although all classifiers of industrial activity may not agree, the *electronics industry* is now considered to include the following activities and end products:

1. Semiconductors — discrete semiconductors, integrated circuits, and optoelectronic devices.
2. Circuit Components (electric and electronic) — capacitors, character displays, connectors, crystals, electron tubes, magnetic and microwave components, filters and networks, power supplies, printed circuits, relays, resistors, switches, keyboards, transducers, cable, and wire.
3. Data Processing Equipment — computers (all types and sizes), data storage devices, data terminals, input/output peripherals, automated office equipment (copiers, typewriters, word processors), and optical disk drives, among numerous others.
4. Communications Equipment — message switchers, modems, multiplexers, facsimile terminals, fiber-optic systems, radar equipment, radio, television, and telecommunications equipment.
5. Industrial Measurement/Control Equipment — process controls, including sensors, valve and motor controls, displays, etc. — discrete-piece *manufacturing controls*, including numerical controls, programmable controllers, robots, machine vision, and testing equipment, among many other categories.
6. Computer-Aided Design and Engineering Systems (CAD and CAE).
7. Consumer Equipment — radios, stereo systems, television receivers, time pieces, microwave ovens, telephones, games and toys, personal calculators and computers, among others.
8. Software — to support many of the foregoing activities and products.

Scores of entries in this encyclopedia relate to electronic phenomena and electronic products. Consult alphabetical index.

ELECTRON LENS. An electron moving in an inhomogeneous electric or magnetic field in general follows a curved trajectory. It may be shown that the trajectories in certain fields are such that all electrons which pass through a given point subsequently pass through, or close to, a second point, whose location is fixed by the field strengths, and by the position of the first point. The paths of electrons in such a system therefore bear a striking resemblance to the light rays which pass through a lens, and the set of electrodes or of conductors which establish the necessary fields is known as an electron lens. The focal length of the lens is defined in the same way as is the focal length of an optical lens; it may be varied by changing the field strengths. As an example of an electron lens, a slit or hole in a conducting sheet acts to converge or diverge electrons if the electric fields on the two sides of the sheet differ in strength.

ELECTRON MICROSCOPE. The concepts that eventually led to the development of electron microscopes came out of the discovery of the wave nature of the electron in 1924. The effective wavelength of the electrons varies with accelerating voltage and is less than 1 Å: $\lambda = \sqrt{(150/V)}$Å. This short wavelength makes possible far better resolution and higher magnification in the electron microscope as compared with the optical microscope.

The lenses used in electron microscopes act on the beams of electrons in much the same way that ordinary glass lenses act on beams of light. Most electron microscopes have electromagnetic lenses, although electrostatic lenses also can be used. Application of a uniform axial magnetic field causes the electrons to travel in a spiral path and return to the axis as shown schematically in Fig. 1. Except for the spiral part of the motion, this behavior is just like that of a simple glass lens, and the equations for optical lenses apply, as shown in Fig. 2:

$$\frac{1}{a} + \frac{1}{b} = \frac{1}{f}$$

$$\text{Magnification} = \frac{b}{a}$$

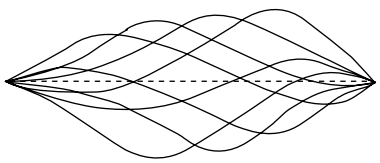

Fig. 1. Courses of electron beams in a homogeneous magnetic field.

However, in the electromagnetic lens, the angle of deflection and the focal length depend upon the strength of the magnetic field. This can be controlled by adjusting the current in the coils so that the magnification of the lens can be continuously varied over a broad range. See Fig. 3.

A simple electron microscope, as illustrated in Fig. 4, is operated by producing a beam of electrons from a heated filament, accelerating the beam with a high voltage applied to an anode, and then directing this beam of illuminating electrons onto the specimen. The specimen is in some respects similar to that used for optical microscopy, but

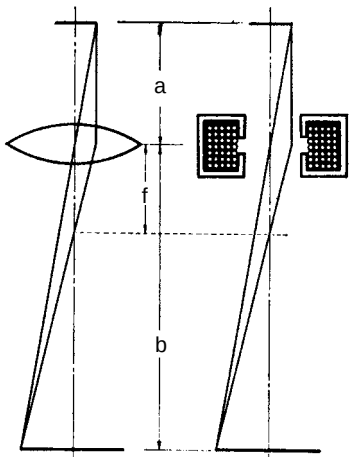

Fig. 2. Lens system used in transmission-type electron microscope. (*Left*) optical convex lens; (*Right*) electromagnetic lens.

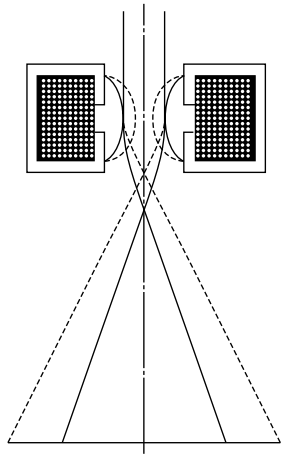

Fig. 3. Relation between magnetic field intensity and magnification in case of large magnetic field intensity (i.e., a large current flowing through the coil); or small magnetic field intensity (i.e., a small current flowing through the coil).

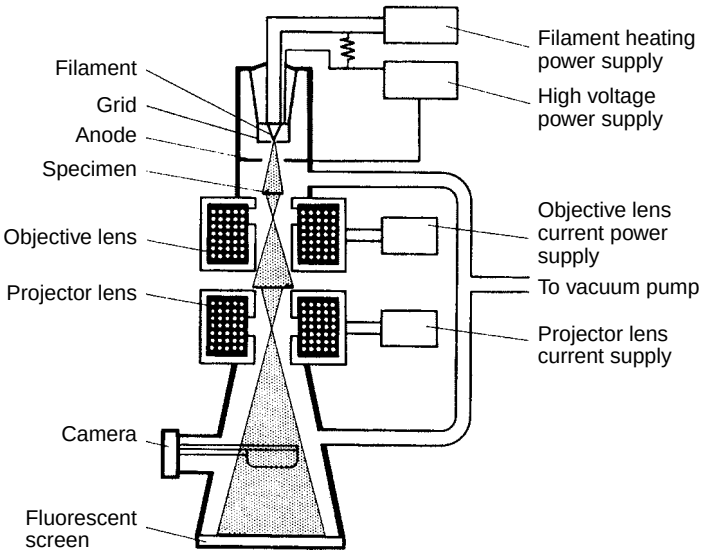

Fig. 4. Construction of a simple electron microscope.

because electrons are not so penetrating as light, the specimen must be much thinner (on the order of 1,000 Å or less for most materials). For biological materials, these thin sections are produced by ultramicrotomes. Many materials, especially metals, can be thinned chemically or electrochemically. Rough surfaces can be examined by evaporating carbon

on the sample and then removing it and using the carbon replica in the microscope.

The beam of electrons that passes through the specimen is then magnified by an objective lens and a projector lens and finally strikes either film held in a camera, or a fluorescent screen. The image seen on the fluorescent screen has varying shades of gray that depend upon the distribution of density and thickness of the specimen. This is most important for biological samples. For crystalline materials, the regular arrays of atoms aligned in critical directions can act like a mirror, diffracting the beam to another direction. This makes it possible to observe imperfections in the atomic arrangement of a material.

More complex electron microscopes use additional lenses, both above and below the specimen. The condenser lenses above the specimen concentrate the electron beam and increase the illumination. The addition of intermediate lenses below the specimen make it possible to go to higher magnification in the final image. Various alignment controls, apertures for the lenses, specimen handling devices, and suitable airlocks and anticontamination traps also are provided.

The central column of the instrument must be maintained as a vacuum because the electrons would be absorbed if any atmospheric gases were present. Typical resolutions obtainable by commercial instruments are on the order of 2 to 5 Å. Accelerating voltages from 20,000 to 1 million volts have been used. The higher accelerating voltages are useful for penetrating thick specimens (in some cases, up to 1 micrometer or more).

Scanning-Type Electron Microscope. This type of electron microscope is completely different in principle and application from the conventional transmission-type electron microscope. In the scanning instrument, the surface of a solid sample is bombarded with a fine probe of electrons, generally less than 100 Å in diameter. The sample emits secondary electrons that are generated by the action of the primary beam. These secondary electrons are collected and amplified by the instrument. Since the beam strikes only one point on the sample at a time, the beam must be scanned over the sample surface in a raster pattern to generate a picture of the surface sample. The picture is displayed on a cathode ray tube from which it can be photographed.

A block diagram of a scanning-type electron microscope is given in Fig. 5. Major elements of the instrument include the electromagnetic lenses that are used to form the electron probe, the scan coils that sweep the beam over the sample, the detector that collects the secondary electrons, and the amplifying means where the secondary electrons are amplified and fed to the cathode ray tube for display. Since the cathode ray tube is scanned in synchronization with the electron beam, the resulting picture corresponds to the area of the sample being examined.

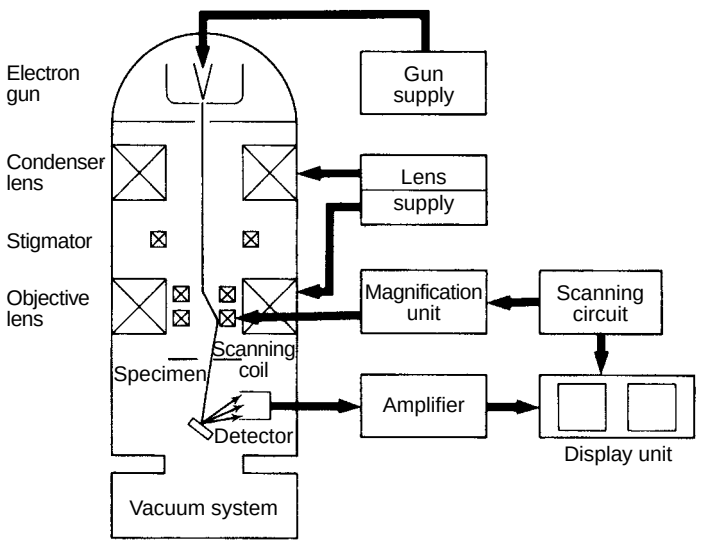

Fig. 5. Simplified diagram of scanning-type electron microscope.

The advantages of the scanning microscope as compared with conventional optical microscopes include superior resolution and depth of field. Resolution of 200 Å is obtained with a depth of field several hundred times that of a conventional optical microscope. The scanning microscope also makes possible the display of other kinds of data obtained from the specimen, notably cathodoluminescent photons emitted by fluorescing samples, electrical voltages generated in semiconducting samples by the passage of the electron probe, and characteristic x-rays that can be used to determine sample composition. Also see **X-Ray Analysis**.

The range of magnification of scanning electron microscopes generally is from less than 30 × to about 40,000 ×, limited by the resolution of the instrument. Most specimens can be examined without any special preparation, but nonconducting specimens usually are coated with 100 Å to 500 Å of metal to conduct away the beam current. A conventional diffusion pump vacuum system is used since a vacuum is required for operation of the electron beam. The image that is formed is easily interpreted as surface topography inasmuch as the illuminating and shadowing effects on the sample are similar to the appearance of large objects as they normally are seen by the unaided eye. The scanning electron microscope has found broad application in the transistor industry to show voltage distributions in such devices. Other uses include industrial quality control and a broad range of industrial and biological research.

High-Resolution Scanning Transmission Electron Microscope (STEM). The concept for constructing a STEM dates back to 1963, growing out of the techniques and practices of research in nuclear and high-energy physics, with minimal consideration given to the large record of experience gained with the STEM. The operating principles of the STEM reflect those of accelerator physics. As described by A.V. Crewe, a leading authority in the field, electrons from a field emission source are accelerated to a final potential V_0 and then focused on the specimen. Scattered electrons leaving the specimen normally are refocused by the magnetic field of the lens at some point farther down the column and then diverge. The elastically scattered electrons strike an annular detector; the inelastic and unscattered electrons are separated by a spectrometer. The beam is scanned across the specimen by using deflection coils; below the specimen, the scanning action is removed with additional deflection coils. The maximum scattering angle for the electrons is only 2° or 3°. Present resolution of the STEM is from 2 to 2.5 angstroms, still insufficient to resolve distances between atoms in most solids. A point resolution of 0.5 angstrom is needed to obtain images that will resolve such distances. See also **Scanning Tunneling Microscope**.

ELECTRON MULTIPLICATION. On bombarding certain surfaces by electrons it may happen that each impinging electron expels several electrons from the struck surface. If these electrons are caught in an electric field and driven against another similar surface, each of them may again give rise to several electrons. After several such stages of multiplication, an appreciable pulse may be obtained in this manner, starting with a single electron as beta radiation, or produced photoelectrically by gamma radiation. Quantitatively, the electron multiplication of a device such as a photomultiplier is the ratio of the number of electrons reaching the anode to the number emitted at the cathode.

An electron multiplier is a device for amplifying by a process of electron multiplication. In Fig. 1, electrons are emitted from the cathode and accelerated to an electrode called a dynode, maintained at about 100 volts positive with respect to the cathode. Secondary electrons knocked out of the dynode are accelerated to a second dynode at a higher potential, where they produce still more secondaries. The cathode, nine dynodes and final anode used in typical multiplier cells are so placed and shaped that the electron beams are efficiently focused at each stage. In typical multiplier cells, the gain per dynode is between four and five. The total gain is $(4)^9$

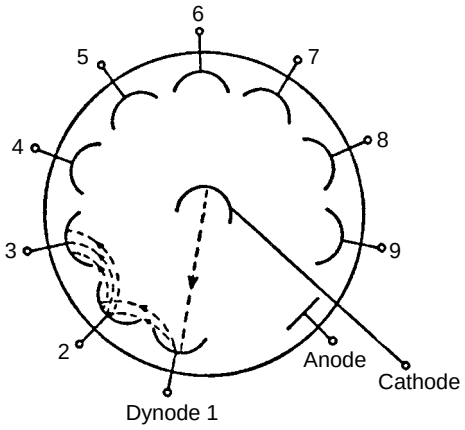

Fig. 1. Electron multiplier.

to $(5)^9$ or about 10^6. In addition to their use in photocells, multipliers are used in radiation detectors.

ELECTRON (Photoelectron) SPECTROSCOPY. A valuable research tool for conducting basic research in molecular chemistry and surface physics, in chemical characterization of atmospheric particulate matter in environmental studies, and in the analysis of the performance of catalysts in industrial processes. Electron spectroscopy is based on the high-resolution analysis of the kinetic energy distributions of electrons emitted from solid, liquid, or gaseous substances after they are irradiated with a beam of monoenergetic x-rays or ultraviolet radiation. Monochromatized synchrotron radiation has also become important as a tunable photo source. The physical quantity measured is the electron binding energy B, which is given by Einstein's relation $h\nu = B + K$, where $h\nu$ is the known photon energy and K is the measured photoelectron kinetic energy. Chemical information is obtained from chemically induced changes in the binding energies. In principle, all electron orbitals from the K shell out to the valence levels can be studied. When x-ray excitation is used, the technique is called x-ray photoelectron spectroscopy (XPS); when ultraviolet light is used, the term ultraviolet photoelectron spectroscopy (UPS) is used. The photoelectric effect was discovered by Hertz in 1883. K.M. Siegbahn, University of Uppsala, was awarded half of the 1981 Nobel Prize in Physics for his work in this field.

ELECTRON THEORY. In the 1830s, Faraday had tentatively suggested that his experiments in electrochemistry could be interpreted in terms of a small unit of charge attached to ions. This notion of individual "atoms of charge" was somewhat eclipsed, however, by the enormous success of Maxwell's theory of electromagnetism, which was generally interpreted, by 1880, as favoring a view that electrical phenomena were due to continuous charge distributions and motions. G. Johnstone Stoney, in 1874, and Helmholtz, in 1881, had suggested again an atomic interpretation of electricity, but it was not until the brilliant experiments of Perrin, J.J. Thomson, Zeeman, and others in the 1890s that the concept of the electron received firm experimental foundation. Later experiments and theory (Millikan, Bohr, etc.) established the constancy of the electronic charge and interwove the concept of an electron of definite charge and mass into the basic structure of the atom.

The Cathode Ray Controversy. After the discovery of the cathode ray in high-vacuum discharge tubes by Plücker in 1858, there developed, with the experiments of Goldstein, Crookes, Hertz, Lenard, and Schuster, a controversy over the nature of the rays. A predominately German school held that the rays were a peculiar form of electromagnetic rays. The British physicists thought they were negatively charged particles. The controversy provides a classic "case history" of the typical scientific controversy in which two quite different models both explain most, but not all, of the observable facts. For resolution of this controversy, see also **Cathode Ray**.

Thomson's Determination of e/m. In 1897 Thomson devised an apparatus in which he could deflect a beam of cathode rays with a magnetic field of induction B and also with an electric field of strength E. If the fields are perpendicular both to each other and to the original path of the beam, and if they occupy the same region, then (with proper polarities and magnitudes of fields) the electric force on the beam can equal the magnetic force. Thus, the beam hits the same point on a fluorescent screen as when no fields are applied. If e is the charge of a given particle, m its mass, and v its velocity, $v = E/B$. Thus, velocities of typical cathode ray beams could be measured. If the magnetic field is used alone, and the curvature R of the beam is measured, then one can equate centripetal and magnetic field forces $mv^2/R = Bev$, and then deduce $e/m = v/BR$. With v known from the previous experiment, e/m can be calculated. Thomson's early values were not very precise, but later experiments of a similar type gave values close to 1.76×10^{11} coulombs/kg. More recent experiments, drawing on measurements of many kinds, give $e/m = (1.75890 \pm 0.00002) \times 10^{11}$ coulombs/kg.

The Zeeman Effect. In 1896 Zeeman discovered the broadening of spectral lines when a light source was in a strong magnetic field. Experimental refinements by Zeeman and others, and theoretical work by Lorentz and Zeeman, permitted the interpretation of this effect as due to the influence of the magnetic field on oscillating or orbiting negatively charged particles within the light-emitting or absorbing atoms. From the spectroscopic data, the ratio of charge to mass of these hypothetical particles could be shown to be equal to that of cathode rays. The Zeeman effect thus provided the first experimental evidence that the negative particles emitted by atoms when heated (Edison effect) or subjected to high fields and/or ionic bombardment (cathode rays) or bombarded by short-wavelength light (photoelectric effect) were, indeed, actual constituents of the atoms and were probably responsible for the emission and absorption of light.

The Charge on the Electron. In the decade following 1897, many different methods were evolved for determination of ionic charges. Some methods depended upon measuring the total charge of a number of ions used as nuclei for cloud droplet formation. Other methods were more indirect experiments, for example, which, combined with the kinetic theory of gases, could give crude values for Avogadro's number, N. By dividing the Faraday constant (the charge carried in electrolysis by ions formed from one gram-atom of a univalent element) by N, one could determine the average charge per ion. Similarly, the constants in Planck's theory of blackbody radiation, when evaluated experimentally, could provide a numerical value for N, as could certain experiments in radioactivity. All such methods gave values of N of the order of 6×10^{23}, and hence 1.6×10^{-19} coulomb for the ionic charge. None of these methods measured individual charges; strictly speaking, the value for the ionic charge could be thought of only as an average value.

Millikan's experiments with single oil drops, beginning in 1906, provided a method for measuring extremely small charges with precision. He was able to show that the charge on his drops was *always ne*, with $e = 1.60 \times 10^{-19}$ coulomb (modern value) and n a positive or negative integer.

He observed the motions of very small charged oil drops in uniform vertical electric fields. The drops were so small that they moved with constant velocity (except for Brownian fluctuations) for a given force. The force in each case was due to gravity acting on the mass of the drop and to the electric field (if any) acting on the charge, q, on the drop. The charge on a given drop could be changed by shining x-rays upon it. Using Stokes' law (in a form modified to correct for the fact that the drops were *not* large in comparison to the inhomogeneities of the surrounding air) and the velocity of a drop in free (gravitational) fall, Millikan could infer the diameter and mass of a given drop, and then calculate its charge. The charge q always equaled *ne*. A few other physicists, in similar experiments, thought they had detected electric charges smaller than Millikan's e, but their experimental techniques were probably faulty.

Millikan's experiment did not prove, of course, that the charge on the cathode ray, beta ray, photoelectric, or Zeeman particle was e. But if we call all such particles electrons, and assume that they have $e/m = 1.76 \times 10^{11}$ coulombs/kg, and $e = 1.60 \times 10^{-19}$ coulomb (and hence $m = 9.1 \times 10^{-31}$ kg), we find that they fit very well into Bohr's theory of the hydrogen atom and successive, more comprehensive atomic theories, into Richardson's equations for thermionic emission, into Fermi's theory of beta decay, and so on. In other words, a whole web of modern theory and experiment defines the electron. The best current value of $e = (1.60206 \pm 0.00003) \times 10^{-19}$ coulomb.

The Wave Nature of the Electron. De Broglie had suggested in 1924 that electrons have in some respects the characteristics of waves, and deduced, for the wavelength equivalent to a moving electron, the expression $\lambda = h/mv$ in which m and v are the mass and speed of the electron and h is Planck's constant. If the electron is moving, for example, with a speed corresponding to 65 eV of energy, the corresponding "De Broglie wavelength" is 1.52 angstroms, which is in the X-ray range. This led Davisson and Germer to see whether electrons might be reflected from crystals after the manner of X-rays. They used a single crystal of nickel cut parallel to the (111) planes, and upon varying the electron speed at a fixed angle of incidence, they found not only a distinct "regular" reflection, but also a series of diffraction maxima strikingly similar to those obtained with the same crystal for X-rays of varying wavelength. The differences observed were satisfactorily explained as due to the refraction of the nickel for the electron waves.

G.P. Thomson independently reached the same conclusions in 1927. The hypothesis that matter exhibits both corpuscular and wavelike characteristics served as a stimulus for the formal development of quantum mechanics by E. Schrödinger, M. Born, W. Heisenberg, and others. Following the discovery, which eventually led to a Nobel Prize to Davisson and Thomson, electron diffraction was immediately utilized as a tool for the study of the structure of matter.

Other Characteristics of Electrons. In applying quantum mechanics to certain problems in atomic spectroscopy, in 1925 and 1926, Pauli, and Goudsmit and Uhlenbeck found that electrons must possess angular momentum of amount $\pm\frac{1}{2}(h/2\pi)$. Dirac's work on a generalized quantum theory of the electron showed that it possessed a related magnetic dipole moment of magnitude $eh/4\pi mc$. The ratio of the dipole moment to the angular momentum (e/mc) is larger than can be accounted for in classical terms with any homogeneous wholly negative model. The concept of electronic dipole magnetic moment is essential not only in spectroscopy but in theories of ferromagnetism. See also **Magnetism**.

One may speak of the "classical radius of the electron," $a = e^2/mc^2$, derived by setting the self-energy of the coulomb field of a charge e contained at a radius a equal to the relativistic rest energy, mc^2 of the electron. This $a = 2.82 \times 10^{-13}$cm, comfortably smaller than any atom, but larger than the usual estimates of sizes of protons and neutrons.

Positive Electrons. Dirac's paper in 1928 could be interpreted as predicting the existence of electrons that are positive. But until such particles were found experimentally by C.D. Anderson in 1932 in cloud chamber pictures of cosmic ray particle tracks, most physicists preferred other interpretations of Dirac's paper. Positive electrons, or positrons are now known (1) to occur as decay products from certain radioactive isotopes, (2) to be produced (paired with a negative electron) in certain interactions of high-energy gamma rays with intense electric fields near nuclei, and (3) to be the product of certain decays of certain mesons. In principle, positrons could form anti-atoms with nuclei made from anti-protons and anti-neutrons, but in practice almost all positrons produced in the observable universe quickly meet their end by annihilating themselves together with some negative electron. The end product of a positron-electron annihilation is a pair of gamma rays.

ELECTRON TUBE. A device in which electrons are freed from the restraints of a solid conductor, pass across a free space (vacuum or gas at low pressure) and are again collected by a solid conductor. During their passage across the free space, the electrons are controllable in manners that would be impossible if they had not been temporarily freed. Also known as valves (British), electron tubes were, until the perfection of semiconductor devices in the late 1940s and 1950s, the major components of nearly all electronic circuits and equipment. Although electron tubes continue to be used for certain applications, particularly involving specially designed tubes, a massive replacement or substitution of transistors and other solid-state devices and approaches for electron tubes has taken place. Whereas early in the period of conversion from tubes to transistors, one would assume that a piece of electronic equipment incorporated electron tube circuits unless otherwise denoted, the assumption now is that electronic equipment circuitry will be solid-state unless otherwise specified.

The remarkable circuit and packing densities now obtainable in microelectronic devices have further deemphasized the electron tube. Nevertheless the technology built around electron tubes is classical and merits the brief condensation presented here.

The "revolution" in electronics required a number of years to achieve, recalling that the point-contact transistor was invented by J. Bardeen and W.H. Brattain (AT& T Bell Laboratories) as early as 1948. The earlier semiconductors were quite costly to produce and their mass production under very closely controlled conditions was difficult to achieve. Good yield and quality control continue to be major problems among semiconductor manufacturers.

An electron tube consists of a heater for kinetic energy excitation of electrons, a cathode which acts as a transfer electrode source of electrons, controlling grid electrodes, and an anode that is maintained electrically positive with respect to the cathode. These elements are insulated from each other and enclosed within an evacuated envelope made of glass, or metal, or ceramic, or a combination of these materials. A getter is flashed within the tube to absorb any residual gas molecules, which could have a harmful effect, electrically and chemically, on the operation of the tube.

When the device has only two electrodes (a cathode and an anode), it is called a *diode*. With the anode maintained electrically positive with respect to the cathode, an electric field results. This causes the electrons to move toward the anode. In the external circuit, the electrons flow from the anode through the load impedance and then through the voltage source to the cathode, which acts as a low-work-function transfer medium, and so back to the anode. The work function can be considered to be the total amount of work necessary to free an electron from a solid.

Other electrodes are introduced in some designs between the cathode and the anode in the form of grids. By varying the voltages on these intervening electrodes, it is possible to modify the electric field between the cathode and the anode, and thus to control the current in the external circuit. Tubes having one grid in addition to the cathode and anode are called *triodes*. Tubes with two grids are called *tetrodes*; and tubes with three grids are called *pentodes*. Generally, tubes are labeled in accordance with the total number of active electrodes in a linear arrangement using a common electron stream. Sometimes, two or more sections are enclosed within the same envelope (e.g., a diode-triode or a triode-pentode); these tubes are not referred to in terms of the total multielectrode structure, but they are designated in terms of the respective tube units.

ELECTRON VOLT. This is a convenient unit of energy for calculations in electronics and in connection with ionization or excitation of atoms or molecules. When an electric charge e is transferred from a region where the electric potential is V_1 to one where the potential is V_2, its potential energy changes by an amount equal to $e(V_1 - V_2)$. If the charge e is the electronic charge 1.602×10^{-19} coulomb (as it is when the transferred particle is an electron or a proton), and if the potential difference $V_1 - V_2$ is one volt, then the corresponding change in energy is equal to 1.602×10^{-19} joule or 1.602×10^{-12} erg, and this is called an electron volt. Thus if a doubly ionized positive oxygen molecule moves in an electric field through a potential drop of 500 volts, it receives $2 \times 500 = 1000$ electron volts or 1.602×10^{-9} erg of energy; and since the mass of the oxygen molecule is about 5.31×10^{-23} grams, this energy would give the molecule, if unimpeded, a speed of about 7.77×10^6 centimeters per second or 48.1 miles per second. The abbreviation for electron volt is eV. In x-rays, nuclear physics, and elementary particle physics, the use of higher energies is encountered and additional abbreviations in common use are keV for 10^3 eV, MeV for 10^6 eV, and GeV (sometimes BeV in the United States) for 10^9 eV.

ELECTROOSMOSIS. The movement of liquid with respect to a fixed solid (e.g., a porous diaphragm or a capillary tube) as a result of an applied electric field. See also **Drainage Systems**; **Electroendosmosis**; and **Solar Energy**.

ELECTROPHILIC REACTION. The reaction in which an electrophilic reagent attacks a nucleophilic compound. The reagent is taken to be the inorganic substance (in the case of reactions of inorganic and organic substances) or the simpler of two reacting organic compounds. The electron pair for the bond formed is furnished by the nucleophilic compound. The term *electrophilic* connotes *electron-seeking* and is applied, for example, to positively charged cations, or to reactions brought about by them.

ELECTROPHORESIS. Electrophoresis is a separation technique most often applied to the analysis of biological or other polymeric samples. It has frequent application to analysis of proteins and DNA fragment mixtures. See also **Nucleic Acids**. The high resolution of electrophoresis has made it a key tool in the advancement of biotechnology. Variations of this methodology are being used for DNA sequencing. See also **Genetic Engineering**. Isolating active biological factors associated with diseases such as cystic fibrosis, sickle-cell anemia, myelomas, and leukemia, and establishing immunological reactions between samples on the basis of individual compounds. Electrophoresis is an extremely effective analytical tool because it does not affect a molecule's structure, and it is highly sensitive to small differences in molecular charge and mass.

The term electrophoresis refers to the movement of a solid particle through a stationary fluid under the influence of an electric field. The study of electrophoresis has included the movement of large molecules, colloids, fibers, clay particles, latex spheres. See also **Latex Technology**. Basically anything that can be said to be distinct from the fluid in which the substance is suspended. This diversity in particle size makes electrophoresis theory very general.

The fundamental principle behind electrophoresis is the existence of charge separation between the surface of a particle and the fluid immediately surrounding it. An applied electric field acts on the resulting charge density, causing the particle to move, the fluid around the particle to move, or both. An applied electric field also generates heat, through resistive heating, and gases, through electrolysis reactions. Each is important in understanding and designing working electrophoresis equipment.

There are three distinct modes of electrophoresis: zone electrophoresis, isoelectric focusing, and isotachophoresis. These three methods may be used alone or in combination to separate molecules on both an analytical (μL of a mixture separated) and preparative (mL of a mixture separated) scale. Separations in these three modes are based on different physical properties of the molecules in the mixture, making at least three different analyses possible on the same mixture.

Distinction is also made among electrophoretic techniques in terms of the type of matrix employed for analysis. Matrices include polymer gels such as agarose and polyacrylamide, paper, capillaries, and flowing buffers. Each matrix is used for different types of mixtures, and each has unique advantages.

There are a variety of techniques for detecting separated sample compounds using chemical stains, photographic media, and immunochemistry. Each detection technique also gives different information about the identity, quantity, and physical properties of the molecules in the mixture. Detection is often the focus of electrophoresis, and usually yields basic information about the mixture being studied.

The electrodes in electrophoresis equipment are typically constructed from platinum wire, and sodium chloride generally carries the bulk of the current in any electrophoretic medium. This results in the reactions at the cathode of $2H_2O + 2e^- \rightarrow 2OH^- + H_2$, and $H_2O + OH^- \rightleftharpoons A^- + H_2O$ at the anode: $H_2O \rightarrow 2H^+ + 20.5O_2 + 2e^-$, $H^+ + A^- \rightleftharpoons HA$. That is, water is electrolyzed. The hydrogen gas produced at the cathode can be hazardous, especially because it is in the vicinity of an electrode that is also producing heat. For this reason, electrode chambers are usually open to the atmosphere so that gases can vent.

The other reactions at the electrodes produce acid (anode) and base (cathode) so that there is a possibility of a pH gradient throughout the electrophoresis medium unless the system is well buffered. See also **Hydrogen-Ion Activity**. Buffering must take the current load into account because the electrolysis reactions proceed at the rate of the current. Electrophoresis systems sometimes mix and recirculate the buffers from the individual electrode reservoirs to equalize the pH.

Modes of Electrophoretic Separations

Electrophoresis Equipment. Most electrophoresis equipment shares a basic design, a diagram of which is shown in Figure 1.

Zone Electrophoresis. In zone electrophoresis multicomponent samples are applied to an electrophoretic medium, most commonly a gel, an electric field is applied, and after a predetermined length of time or after a certain level of power, current, or voltage has been applied, the electrophoretic medium is inspected for resolution of the sample components.

Resolution in zone electrophoresis depends critically on getting sample components to migrate in a focused band, thus some techniques are employed to concentrate the sample as it migrates through the gel.

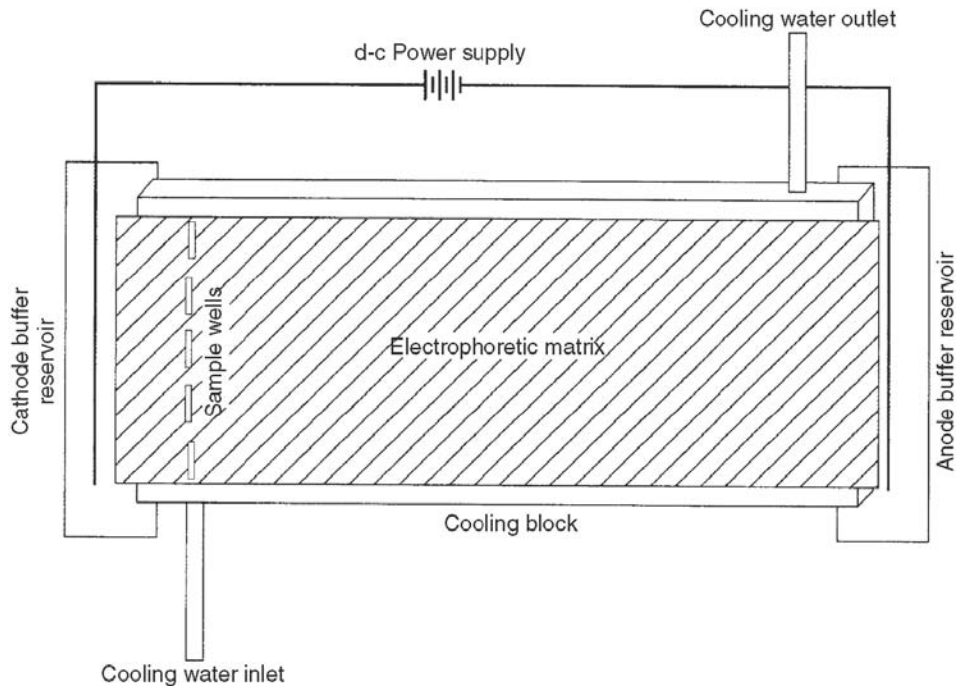

Fig. 1. Electrophoresis equipment

The most common technique is referred to as discontinuous pH or disc electrophoresis. Disc electrophoresis employs a two-gel system, where the properties of the two gels are different.

Two-dimensional electrophoresis, introduced in 1976, combines polyacrylamide (sodium dodecyl sulfate-polyacrylamide) gel electrophoresis with isoelectric (electrofocusing) electrophoresis. The method is attractive because it can separate large numbers of proteins. A more recent two-dimensional technique is called *electrophoretic titration curve analysis*. As reported by Maugh (1983) a pH gradient from 3 to 9 is established in a horizontal slab. A trough is then cut into the slab at a right angle to the gradient. The sample is applied to the trough and conventional electrophoresis is performed, perpendicular to the gradient to produce a classical titration curve. The latter provides useful information about the protein, including its stability and the binding of ligands. The data also predict behavior of the protein in ion-exchange chromatography.

Another recent technique, preparative electrophoresis, is *recycling isoelectric focusing* developed by Bier and colleagues (University of Arizona). See Fig. 2.

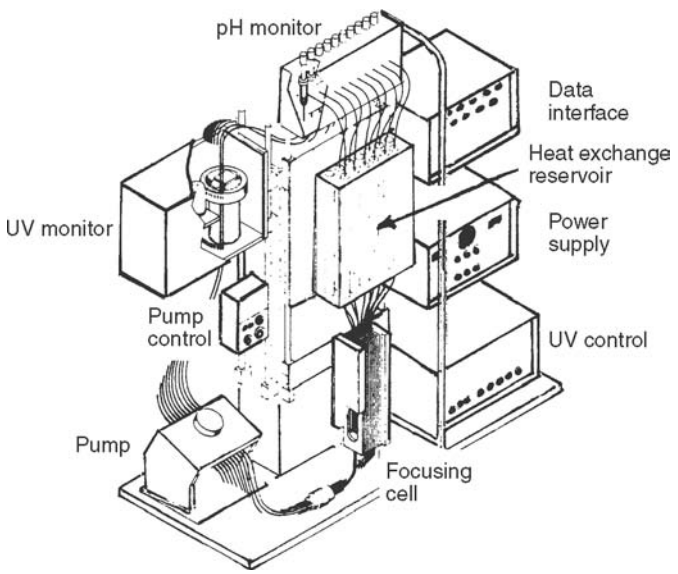

Fig. 2. Schematic representation of the recycling isoelectric focusing (RIEF) apparatus developed by Milan Bier (University of Arizona). In this preparative electrophoresis technique, no gel is used; instead the solution is recycled to be fractionated through a focusing cell and heat-exchange reservoir. The focusing cell is a series of parallel-flow chambers which are separated by monofilament nylon screen elements. The screens streamline the flow through the apparatus and avoid loss due to convection. The proteins are allowed to migrate from chamber to chamber exclusively under the influence of the electric field. Each chamber is connected to a separate glass channel in the heat-exchange reservoir. Capacity of the apparatus is determined by the volume of the heat exchanger and the cross-sectional area of the focusing chambers. A modular design permits scale-up to larger volumes. The pH gradient is established by the electric field itself, in the same manner as in analytical gel focusing. The apparatus has been used to process milligram quantities of antibodies to single-band purity within a period of 4 hours. (*M. Bier*)

A general trend in electrophoresis is to use thinner gels to provide better retention of nucleotides for DNA sequencing and, because of more efficient cooling, higher voltages can be used for faster separations. Prior gels typically have been 2 mm in thickness; current gels are typically less than 0.3 mm thick. Numerous equipment and procedural advancements are continuing apace.

Capillary Electrophoresis. This technique, which appeared in the late 1980s, makes possible rapid and automated analysis of small volumes of complex mixtures with excellent resolution and sensitivity. The procedure is well described by M.J. Gordon et al. (see reference listed).

Native Zone Electrophoresis. In some cases, good resolution between sample species can be obtained with little or no sample pretreatment. In these cases, the gels are said to be native gels. In this method, the charge on the individual sample component is primarily responsible for its differential migration.

Pulsed Field Gel Electrophoresis. In pulsed field electrophoresis, the direction of the field is intermittently changed, either forward and backward or from side to side. A small molecule notices no real difference in its electrophoresis because it can completely reorient in each field direction. However, the redirectioning of the electric field causes larger molecules to travel in a zigzag pattern, putting kinks in to the length of the molecule. The longer the molecule, the more kinks in its length, and the slower it travels down the length of the gel. The larger molecule finds itself traveling backward along some sections of its length with respect to the direction of the electric field. This has allowed resolution of megabase size strands of DNA, and has made the Human Genome Project feasible.

Isoelectric Focusing.

Isoelectric focusing is a technique used for protein separation, by driving proteins to a pH where they have no mobility. Resolution depends on the slope of a pH gradient that can be achieved in a gel.

Ampholytes or Zwitterions. An ampholyte is a molecule that can be either positively or negatively charged, depending on the pH. These molecules are also called zwitterions. All amino acids and proteins are ampholytes, or amphoteric.

A special class of ampholytes has been synthesized for the purpose of isoelectric focusing. These ampholytes have an amino end and a carboxyl end that are separated by varying numbers of methylene groups. The further apart the amino and carboxyl groups, the less one affects the ionization of the other; thus a different isoelectric point (pI) is established for each molecule. These ampholytes, which may be added to an electrophoretic medium, migrate in one direction or another, under the influence of an applied electric field, until they reach a zone in which the pH is the same as that ampholyte's isoelectric point. The ampholyte molecules buffer themselves and establish the local pH as they migrate through the gel. As the ampholytes reach an isoelectric pH, they establish a stationary spatial pH gradient in the electrophoretic medium.

Isotachophoresis. Isotachophoresis takes advantage of the fact that electroneutrality must be maintained in an electrophoretic system in order to support an electric field. If a current passes through a medium, that current must be constant from one electrode to the other, regardless of the local ion concentration or mobility; i.e., dilute ions must move faster to keep up with a zone of more concentrated ions. Electric fields compensate for this because the electric field strength does not have to be constant along the length of the medium. The electric field strength is lowest where the ions are most concentrated and most mobile. Isotachophoresis takes advantage of this phenomenon by lining up the ions of interest, fastest (most mobile) to slowest. This is a highly specialized technique that requires detailed knowledge of the properties of the sample to be separated, and is generally not applicable to analytical separations.

Electrophoretic Materials and Matrices

Agarose Electrophoresis. Agarose is produced from the processing of red seaweed. To prepare a gel for electrophoresis a combination of agarose and buffer is heated until the agarose solid is dissolved and boiling. The solution is cooled sufficiently and then poured into a warmed gel casting apparatus which forms the shape of the gel as it cools. After the cooled solution is poured into the casting apparatus, it is allowed to gel and can then be used in an agarose electrophoresis method.

The use of agarose as an electrophoretic method is widespread. The advantages of agarose electrophoresis are that it requires no additives of cross-linkers for polymerization, it is not hazardous, low concentration gels are relatively sturdy, it is inexpensive, and it can be combined with many other analytical methods.

Polyacrylamide Electrophoresis. Polyacrylamide gels are synthesized through the combination of acrylamide, $CH_2=CHCONH_2$, monomer and a cross-linking comonomer. Cross-linking comonomer of choice is *N*, *N*′-methylenebisacrylamide.

The most commonly used combination of chemicals to produce a polyacrylamide gel is acrylamide, bisacrylamide, buffer, ammonium persulfate, and tetramethylenediamine (TEMED).

Polyacrylamide gel electrophoresis is one of the most commonly used electrophoretic methods. Analytical uses of this technique center around

protein characterization, for example, purity, size, or molecular weight, and composition of a protein. Polyacrylamide gels can be used in both reduced and nonreduced systems as well as in combination with discontinuous and isoelectric focusing (ief) systems.

Paper Electrophoresis. Besides being easy to obtain, paper is a good medium because it does not contain many of the charges that interfere with the separation of different compounds. Two types of paper employed in this type of electrophoresis are Whatman 3 MM (0.3 mm) and Whatman No. 1 (0.17 mm).

In paper electrophoresis, the sample is placed directly onto chromatographic or filter paper and then exposed to a buffer solution at each end and an electric field is applied. As in most electrophoretic techniques, charged dyes are combined with samples and standards to see the progress of the electrophoresis.

Capillary Electrophoresis. The glass capillaries used are typically 20 to 200 μm in diameter, may be filled with buffer or gel, and are frequently coated on the inside. Capillaries are used because of the high surface-to-volume ratio which allows high voltages without heating effects. The only limitations associated with capillaries are limits of detection and clearance of sample components.

Capillary electrophoresis is a commercially available technique, and has been integrated with most automated lab equipment such as autosamplers, computer peak analysis (the charts generated are called electropherograms), temperature control, and recirculating buffers. The use of capillaries as a support medium for electrophoresis is advantageous because it avoids the effects of heating that occur in a gel, can be very rapid, and produces a chart recording rather than a stained gel for archiving.

Free-Flow Electrophoresis. Free-flow electrophoresis is the most common technique for scaling up electrophoresis for commercial application. In this technique, sample compounds are injected into a curtain of buffer which flows between two flat plates, with electrodes parallel to the flow at each end. The electric field is then applied perpendicularly to the flow direction, so that as compounds flow down between the electrodes they separate horizontally and exit the flow field at different locations.

Detection Techniques. Most sample components analyzed with electrophoretic techniques are invisible to the naked eye. Thus methods have been developed to visualize and quantify separated compounds. These techniques most commonly involve chemically fixing and then staining the compounds in the gel. Other detection techniques can sometimes yield more information, such as detection using antibodies to specific compounds, which gives positive identification of a sample component either by immunoelectrophoretic or blotting techniques, or enhanced detection by combining two different electrophoresis methods in two-dimensional electrophoretic techniques.

ELECTROPHORUS. The simplest of all static machines; devised by Volta in 1816. It consists of a slab of some resinous substance, such as sealing wax or vulcanite, which is negatively charged by rubbing with fur. A metal plate provided with an insulating handle is placed upon the electrified slab. The contact is localized at a few points, so that instead of taking the negative charge off the slab, the metal plate becomes charged by induction, positively on the under side and negatively on the upper. The negative induced charge is now removed by grounding with the finger, and upon being lifted by means of the handle, the plate becomes positively charged all over, often strongly enough to yield bright sparks. Very little of the negative charge on the slab is removed in this process, and it may thus be used over and over to induce an indefinite number of positive charges. The energy is of course furnished by the operator in pulling the metal plate away from the slab. If a slab of glass is used, and rubbed with silk, it becomes positive and the induced charges on the plate are then negative. The instrument is useful in lecture-table demonstrations.

ELECTROPLATING. The coating of an object with a thin layer of some metal through electrolytic deposition. The process is widely used, either for the purpose of rendering a lustrous or noncorrosive finish on some article. In electroplating, the general object is to employ the article to be plated as the cathode in an electrolytic bath composed of a solution of the salt of the metal being plated. The other terminal, the anode, may be made of the same metal, or it may be some chemically unaffected conductor. A low-voltage current is passed through the solution, which electrolyzes and plates the cathodic articles with the metal to the desired thickness. In this way, table utensils are silver plated, various parts are made weatherproof by cadmium or chromium plating, and a high finish may be imparted through nickel plating. Copper, zinc, and gold are also plated. As the plating proceeds, the strength of the solution must be kept up by the addition of crystals of the plating salt, or a renewal of the anode if it is of the plating metal. A firm bond between the anode and the deposited metal is to be secured when the two metals are of a type that tends to alloy. If this is not the case, some intermediate metal, which will alloy between the base and the plate, is first deposited. For example, in silver plating on steel, the iron would otherwise form a poor bond with the silver, so a thin layer of copper is first deposited on it.

Because of the excellent conducting properties of a metallic salt solution, only a low voltage is required. As this must be D.C. the process of electroplating calls for a supply of current from special low-voltage D.C. generators or rectifiers. The voltage will be of the order of 6 volts or less between anode and cathode.

Some of the solutions used to place various metals are as follows: for silver or gold plating, double cyanide of the metal and potassium; copper plating, copper sulfate; nickel plating, nickel ammonium sulfate. The articles to be plated must be thoroughly and effectively cleaned of all grease and dirt by washing in caustic or acid solutions. While the above is a brief outline of the process of electroplating, in commercial operations there are many troublesome angles which would not be suspected from the foregoing. Irregularity of the plate, poor surface graining, "trees," insufficient bond, and other troubles develop. The overcoming of these requires the use of various expedients, such as careful control of temperature, or the addition of certain colloids and other compounds which have been found effective in preventing formation of defects on the plated articles. See Table 1.

As will be noted from the table, in order to plate out the metals above hydrogen from an aqueous solution, the concentration of the hydrogen in the cathode film must be low. Hence a basic solution, such as provided by a cyanide bath, may be required. A cyanide bath also may be used to provide a smooth adherent plate.

TABLE 1. METALLIC IONS COMMONLY ELECTROPLATED

Ion	E^0	Ion	E^0
Zn^{+2}	−0.762	Cu^{+2}	+0.345
Cr^{+3}	−0.71	Cu^{+1}	+0.522
Cd^{+2}	−0.402	Ag^{+1}	+0.800
Ni^{+2}	−0.250	Au^{+3}	+1.42
Sn^{+2}	−0.136	Au^{+1}	+1.68
(H^{+1}	0.000)		

To plate out an alloy, that is, to codeposit at least two kinds of metals, the plating bath must be so designed that the electrodeposition potentials of the two metals in the cathode film are equal or nearly so.

Four typical electroplating baths are:

Copper:	CuCN 26 g/l, NaCN 35 g/l, Na_2CO_3 30 g/l $KNaC_4H_4O_6 \cdot 4H_2O$ 45 g/l, NaOH to give pH of 12.6
Copper:	$CuSO_4 \cdot 5H_2O$ 188 g/l, H_2SO_4 74 g/l
Tin:	Tin (as tin fluoborate concentrate) 60 g/l, free fluoboric acid 100 g/l, free boric acid 15 g/l.
Zinc:	$Zn(CN)_2$ 60 g/l, NaCN 23 g/l, NaOH 53 g/l

The bright, hard, ornamental chrome so popular on automobiles and household and office articles is produced by electroplating. In this process, the chromium is not present in the bath as a positive metal ion, but rather as part of the anion of chromic acid, H_2CrO_4. The object being plated is made the cathode. Usually the article will have previously been plated with copper and then with nickel. Sulfuric acid serves as a catalyst. The final chromium plate ranges from 0.00001 to 0.0005 inch (0.025–0.127 mm) in thickness. Although improvements have been made in recent years for certain chromium-plating applications, the traditional bath is an aqueous solution of chromic trioxide, CrO_3, and sulfuric acid, with a ratio of approximately 100 to 1 (wt). Fluosilicate catalysts are also added to some chromium-plating baths. See also **Chromium**.

The voltage for electrodeposition under ideal conditions would be:

$$E = E^0 + \frac{RT}{VF} \ln A$$

where E is the required voltage relative to the solution as measured by a hydrogen electrode in a unit molal activity hydrogen ion solution. E^0 is the electrolytic potential, in volts, of the metal being plated when immersed in a solution containing its ions at unit molal activity (approximately unit molal concentration). $R = 8.31$ joules per degree mole; T is the Kelvin temperature; F 96,500 joules per gram-equivalent; V is the valence of the ions which are depositing out; ln A is the natural logarithm of the activity of these ions (approximately the natural logarithm of their molality).

In actual practice the concentration and therefore the activity of the ions soon after the electroplating process starts is different in the solution just next to the cathode, called the cathode "film," than in the main body of the bath. The foregoing equation must in practice be modified to read:

$$E = E^0 + \frac{RT}{VF} \ln A - P,$$

where A is the molal activity in the cathode film of the ions being electrodeposited and P is the extra potential required to keep the plating going. A and P depend on temperature, current, density, concentration, valence, pH, and ion mobility.

P.R. ALBRIGHT

ELECTROPOLISHING. Production of a smooth surface on metals by electrochemical means.

In all electroplating processes, metals (and hydrogen) are deposited on the cathode and dissolved from the anode, except when insoluble anodes are used in which case oxygen is liberated at the anode. Electropolishing is the reverse of electroplating. The work is made the anode and tends to be dissolved. The operating conditions are controlled so that atomic oxygen forms continuously and reacts with the metal surface. Part of this oxygen may be liberated as gas. According to one theory, the high points of the metal surface are most readily oxidized and this oxidized material is thereupon dissolved in the electrolyte or otherwise removed. In any case, selective solution of the high points of the surface tends to give a very smooth finish comparable or superior to a mechanically buffed surface. A wide variety of electrolytes is used. A typical one for stainless steels contains phosphoric acid and butyl alcohol.

All mechanical methods of polishing, including those used for metallographic samples, produce a thin surface layer of work-hardened metal. Electropolishing produces a strain-free surface that is especially suitable for microscopic examination.

An important commercial application of the process is the polishing of stainless steel parts of irregular contour which would be difficult or impossible to buff. Copper and its alloys, Monel metal, aluminum, and many other alloys can be electropolished.

ELECTROSCOPE. An instrument for detecting small charges of electricity, or for measuring small voltages, or sometimes, indirectly, very small electric currents, by means of the mechanical forces exerted between electrically charged bodies. One of the earliest sensitive electroscopes consists of two narrow strips of gold-leaf hanging together in a glass jar. Upon being charged, they stand apart on account of their mutual repulsion. One leaf may be replaced by a stiff strip of brass, so that only the remaining leaf can move. See also **Electrical Instruments**; and **Electrometer**.

ELECTROSOL. A colloidal solution produced by electrical means, as by passing a spark between metal electrodes in a liquid.

ELECTROSTATIC GENERATOR. Any apparatus that generates electrostatically a voltage between two terminals. If a sufficiently large electrostatic charge can be accumulated on a particle large enough to be seen visually, it can also be accelerated to measurable speeds by an electrostatic generator. Such acceleration of particles provides a means for laboratory studies of the effects of collisions in space between satellites and micrometeoroids. A particle of mass m (in kilograms) carrying a charge q (in coulombs) and accelerated through a potential difference of V volts attains a speed $v = (2Vg/m)^{1/2}$ meters/second. Carbonyl iron spheres one micrometer in diameter, and carrying a charge up to about 3×10^9 volts/meter, have been accelerated to speeds in the 5 to 6 km/sec range in a 2 million volt accelerator. Improvements in particle charging techniques are expected to bring on increases in particle speeds into the hypervelocity range attained by real micrometeoroids.

One type of electrostatic generator is known as a Van de Graaff® generator, in which a moving belt is charged by a low-voltage supply, such as a battery, and this charge is deposited onto a hollow, spherically shaped shell, on which a voltage can be developed that is 100 times or more the voltage of the primary supply, depending on the radius of the shell and the electric field at which voltage breakdown occurs. Positive ions or electrons, depending on the sign of the charge on the shell, can then be accelerated from a source inside the shell down an evacuated tube to strike a target at the grounded end of the tube. These charged particles strike the grounded terminal with an energy eV equal to the voltage applied at the source.

ELECTROSTATIC LENS. An arrangement of electrodes so disposed that the resulting electric field produces a focusing effect on a beam of charged particles.

ELECTROSTATIC PRECIPITATOR. The concept of the electrostatic precipitator for the removal of particulates from smoke and industrial emissions dates back to the late-1800s and the pioneering work of Frederick Gardner Cottrell. Some of the earliest work in connection with electrical precipitators was directed to copper smelting in the early 1900s. Quoting briefly from reports, "In the first decade of the century there were three well-publicized and classic examples of smelter smoke injury in the United States — at Ducktown, Tennessee, at Salt Lake City, and at Anaconda, Montana. Some indication of the scope of the problem can be seen from a study that was eventually made at the latter and which revealed some startling figures. In a normal day's operation, up and out the stack

of that copper smelter went the amazing total of 3,200 metric tons of sulfur dioxide, 200 metric tons of sulfur trioxide, 30 metric tons of arsenic trioxide, 3 metric tons of zinc, and over 2 metric tons each of copper, lead, and antimony trioxide. The marvel is that anything remained, but nothing could more clearly demonstrate that here in full bloom was a cardinal essence of successful invention: a need existed. . . . The emissions from the low stacks of an old plant operated at a neighboring location had killed all vegetation, and losses of livestock by arsenical poisoning had been heavy over the near-lying area. Years after the plant was dismantled, the topsoil of a large area centering at the old site was stripped off, sent through concentrators, and smelted at the new plant with a reported recovery of over $1 million in copper and other metals."

But despite the need and the invention, Cottrell had considerable difficulty over a number of years in gaining acceptance of the electrical precipitator by industry. Today, and for a number of decades past, the electrostatic precipitator has been a major device for combatting air pollution. Since the precipitator functions only against particulates, numerous other items of air pollution control equipment, such as absorbers, scrubbers, and filters, are required and are described elsewhere in this volume.

Operating Principle. The basic operating principle of the electrostatic precipitator is demonstrated by the familiar experiment in which a glass rod is rubbed with a silk cloth; the action gives the rod an electrostatic charge, making it capable of attracting uncharged bits of paper, lint, or cork. In the electrostatic precipitator, it is the collecting surfaces that are grounded, while the charge is created on the particulates to be collected.

The power supply is a transformer-rectifier set that steps up ordinary 220-V AC supply to the high level necessary for precipitator operation, and rectifies it to direct current. The DC voltage is applied to discharge electrode wires suspended in the gas flow path. See Fig. 1. In the most common industrial type of precipitator, the discharge electrodes hang between rows of collecting electrode plates, which form a series of parallel gas flow ducts. The high potential on the discharge electrodes causes a corona discharge, from which electrons migrate out into the gas. These create gas ions, which attach themselves to particulates in the gas and give the particles a charge.

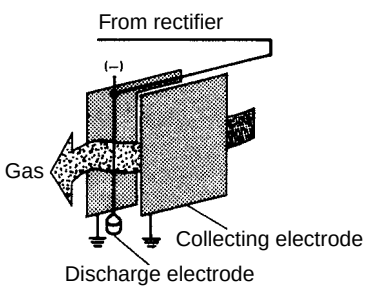

Fig. 1. Arrangement of electrodes in electrostatic precipitator.

The collecting electrodes are grounded, so that the high potential difference between them and the discharge electrodes creates a powerful electric field through which the gas must flow. According to Coulomb's law, such a field exerts a force on charged particles in the field. In the precipitator, this force moves particles out of the gas stream to the collecting electrodes. In a typical precipitator, the force on a particle 0.5 micrometer in diameter is several thousand times the force of gravity on such a particle.

At the grounded collecting electrodes, the particulates lose their charge. They drain off, if liquid, accumulate until washed off or, more commonly in the case of dry dust, are dislodged by mechanical agitation of the electrodes. In a few applications, the collecting electrodes are vertical pipes, instead of parallel plates, each pipe with a discharge electrode wire hanging down its axis.

ELECTROSTATICS. That branch of electromagnetism that deals with the effects of stationary (as opposed to moving) electric charges. The basic law of electrostatics is the Coulomb law. Materials are conveniently classed as conductors and nonconductors. In the former, charges are free to move within the conductor and any charge placed on a conductor will so distribute itself over the surface that the electric field within the conductor is zero and so that the conductor is an equipotential. When an uncharged conductor is placed in an electric field, produced, for example, by a neighboring charged body, a separation of charge on the surface will occur. A charge placed on a nonconductor will remain where it was placed. No material is a perfect nonconductor, but may approximate one very closely. When a non conductor is placed in an electric field, electric dipoles are induced within it.

Static electric charges may be built up on a body by friction, by electrostatic induction, and by other means.

The laws of electrostatics are expressed in terms of electric charges, q, charge densities $\rho = dq/dV$, electric field strengths $\mathbf{E} = \mathbf{F}/q$, and electrostatic potentials $\phi = -\int \mathbf{E} \cdot ds$. The basic law of electrostatics is the Coulomb law of force between charges:

$$\mathbf{F} = \frac{q_1 q_2 \mathbf{r}}{4\pi\varepsilon_0 r^3}$$

with the resulting field due to a single point charge q:

$$\mathbf{E} = \frac{q\mathbf{e}_r}{4\pi\varepsilon_0 r^2} \text{(rationalized mksa units)}$$

where $\mathbf{e}_r$ is a unit vector pointing in the direction of increasing $\mathbf{r}$. The field due to a number of discrete charges is the vector sum

$$\mathbf{E} = \frac{1}{4\pi\varepsilon_0} \sum_i \frac{q_i (\mathbf{e}_r)_i}{{r_i}^2}$$

while that due to a continuous distribution of charges is

$$\mathbf{E} = \frac{1}{4\pi\varepsilon_0} \int \frac{\rho e_r dV}{r^2}$$

The potential at some point in space due to a single point charge, referred to an origin of potential at infinity, is $\phi = q/4\pi\varepsilon_0 r$, while the potentials respectively due to a number of discrete charges or to a continuous distribution of charges are

$$\phi = \frac{1}{4\pi\varepsilon_0} \int \frac{\rho\, dV}{r} \text{ and } \phi = \frac{1}{4\pi\varepsilon_0} \sum_i \frac{q_i}{r^2}$$

again referred to an origin of potential at infinity. If the potential function ϕ has been determined, then the electric field may be determined from $\mathbf{E} = -\nabla\phi$ where $\nabla\phi$ is the gradient of ϕ. Alternatively, if the field $\mathbf{E}$ has been determined, the potential ϕ may be obtained from $\phi = \int_\infty^R \mathbf{R} \cdot d\mathbf{s}$.

The basic law of electrostatics, the Coulomb law, may alternatively be expressed either as the Gauss law or as the Poisson equation. In the absence of local charges, the Poisson equation reduces to the special case of the Laplace equation.

The electrostatic field is a conservative field, which leads to the fact that is possible to set up a potential function ϕ. This fact may be alternatively stated in terms of the closed line integral $\oint \mathbf{E} \cdot d\mathbf{s} = 0$, or in terms of the curl of $\mathbf{E}$: $\nabla \times \mathbf{E} = 0$.

ELECTROSTRICTION. The variation of the dimensions of a dielectric under the influence of an electric field.

ELECTROVALENCE. See **Chemical Elements**.

ELECTROVISCOUS EFFECT. The change in viscosity of a liquid when placed in a strong electrostatic field. The effect is very small and occurs only in polar liquids.

ELECTRUM. Electrum is a native alloy of gold and silver in which the latter metal may be present in quantities up to 40%. Electrum from the Urals is said to carry 20% copper. The color of electrum is a pale yellow or yellowish-white and the name is derived from the Greek word mentioned in the "Odyssey," meaning a metallic substance consisting of gold alloyed with silver. This same word was also used for the substance amber, doubtless because of the pale yellow color of certain varieties.

ELEMENT. 1. Smallest entity that is capable of possessing chemical characteristics and that cannot be changed into smaller neutral units by

chemical reaction. Elements in their pure form may exist in atomic forms, for example, He, Ne, or may be associated into molecular units such as H_2, O_2, graphite, or diamond.

2. Any one of the properties or conditions of the atmosphere that together specify the physical state of weather or climate at a given place for any particular moment or period of time; the climatic elements, meteorological elements.

3. The smallest definable object of interest in a scene.

ELEMENTARY PARTICLES. See **Particles (Subatomic)**.

ELEMENT (Graph). A *circuit element* is an element of a graph G that is contained in some circuit of G. A *noncircuit element* is an element of a graph G that is not contained in a circuit. The removal of a noncircuit element from a connected graph G leaves G unconnected. The removal of a circuit element leaves the connectivity and the number of vertices invariant. An *oriented element* of a graph is an element with an orientation assigned by ordering the vertices of the element. If the vertices β_1 and β_2 of element ε_1 are ordered as (β_1, β_2), ε_1 is said to be oriented away from β_1 and toward β_2. See also **Graph (Mathematics)**.

ELEPHANTIASIS. See **Filariasis**.

ELEPHANT *(Mammalia, Proboscidea).* Like most orders of hoofed animals, excepting the even-toed ungulates, Elephants or Proboscideans (order *Proboscidea*) are dying out and are past their zenith. During the Tertiary and the Ice Age there were many proboscidean species, distributed almost throughout the world. They are now represented by just two genera, each with one species, the last survivors of a large group related to hyraxes and sirenids that developed from primitive ungulates in the Lower Tertiary and have evolved as an independent line since the Eocene (50 million years ago). Although elephants are highly developed animals, they seem, with justification, to be primitive organisms. Their extinct predecessors were among the most distinctive mammals of earlier periods of the earth's history.

Trunk. The most striking feature of elephants, besides their great size, is their trunk, which not only substitutes for a hand as a grasping instrument but is also used for touching objects and for smelling. The trunk develops from the upper lip and the nose, and differs structurally in the two extant elephant species. See Fig. 1. Having arisen from the nose, the trunk of course functions in perceiving odors and in respiration, the latter being particularly evident when elephants swim. However, the trunk's most important function is to obtain food and water. When an elephant drinks, it sucks about a bucketful of water 40 centimeters (16 inches) up its trunk, closes the tip of the trunk with the fingerlike structure at the tip, and squirts the water into its mouth. The trunk is also a formidable weapon. It is likewise a highly sensitive tactile instrument, as we see when an elephant picks up a coin from the floor or tugs great loads about. Large motor-nerve fibers extend up and down the trunk, corresponding to the pyramidal tracts in humans.

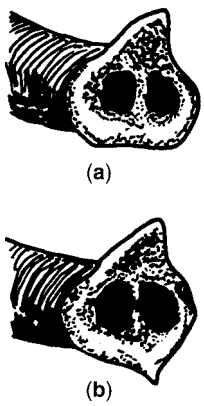

Fig. 1. Tip of the trunk of the (**a**) Indian elephant, (**b**) African elephant.

Skull. The powerful skull bears huge ears, especially in the African elephant. The skull bones have spongelike parts, which makes them weigh less than they would if they were solid bone. They are lined with mucous membranes like those found in the nose. The spongelike system reduces the massiveness of the skull in favor of increased mobility, an important compromise since with increasing age the large tusks would become useless if the skull were extremely heavy. The tusks are not elongated canine teeth. They are actually modified upper incisors, and they grow continuously.

Tusks, Teeth, and Ivory. Even at birth, elephants have so-called "milk tusks," which can be up to 5 centimeters (2 inches) long. Permanent tusks erupt when the animal is one year old. One third of each tusk is embedded in the upper jaw bones. Since they are incisors, they have a substantial enamel covering, and over a period of years they develop a strong, sharp tip within which the dental cavity is completely filled. Ivory is a mixture of dentine, cartilaginous material, and calcium-salt deposits on the incisors. The other teeth are also quite distinctive structures. Each of the four jaw halves bears six molars, but not simultaneously. No more than two of these molars are present in a jaw half at any one time. Newborn elephant calves possess the first and second molars; the first is as large as a match box, while the second is about the size of a cigarette pack. The molars wear down as a result of chewing action, and since they also rub against the front of the jaw, they break off in lamellae (in layers). The first molar disappears at the age of 3 to 4 years, while the second molar remains for 6 or 7 years. The third molar becomes functional between the age of 3 to 13, the fourth between 6 and 26 years, and the fifth between the age of 16 and 43. The last molar, which is the size of a small brick, begins to erupt when the animal is 33 years old.

Ivory as already mentioned, is largely the dentine of teeth, a material similar to bone but harder and of different minute structure. It is deposited outside of the layer of cells that produce it in the form of small tubules extending toward the outside of the tooth. The chief sources of ivory for commercial purposes are the tusks of various animals. Elephants' tusks have only a little enamel at the tip and are solid ivory except where the pulp cavity invades the base. The tusks of walruses have also been an important source of ivory, although they are inferior to elephant ivory. The material is used extensively for carved ornaments.

Species Endangerment

Because of the value of their ivory, for many years elephants have been slaughtered by the multi-thousands. Even after the Convention on International Trade in Endangered Species Pact was signed in 1990, by 105 of 110 participating nations, poaching continues at a rampant rate. Malawi and Zambia refused to sign. On the claim of having ample healthy herds, South Africa, Zimbabwe, and Botswana also refrained from signing. The latter three nations have had extensive conservation programs for a number of years. Also, their argument stressed that the ban would only result in rising values for ivory and thus encourage poaching. Essentially, this has been the case in recent years. Estimates indicate that the number of elephants killed for their ivory doubled between 1979 and 1988. Because counting wild elephants is indeed extremely difficult, statistics must be approximate at best. But some experts in the field estimate that the total elephant population, including Africa and Asia, shrank from 1.3 million in 1979 to 608,000 in 1989.

Prior to the 1990 ban, the majority of elephant tusks were shipped to Hong Kong and Japan for processing into jewelry, figurines, and piano keys. Advocacy programs to discourage the purchase of ivory items have enjoyed some success by way of public education. Nevertheless, poaching continues at a high rate. Numerous policing techniques have been proposed and developed, but have enjoyed only marginal effectiveness. For example, DNA fingerprinting has been under investigation by J.C. Patton (Washington Univ.) and others. In recent years, poaching has been extant in Kenya and Tanzania.

Another major factor in the elephant's plight is human population pressures on the elephant's natural environment.

Elephant Species

The African elephant is the largest of the existing terrestrial animals. The Indian elephant is the third largest, being somewhat smaller than the African Ceratothere or White Rhinoceros. The elephant is characterized

by massive structure and by the elongation of the nose and upper lip to form a long prehensile proboscis or trunk. The two upper incisors develop into long tusks in the male and the broad grinding molar teeth grow into position gradually as they are worn off during the life of the animal.

Two species of elephants are recognized: The Indian (*Elephas maximus*); and the African (*Loxodonta africana*). The Indian elephant averages 8 to 9 feet (2.4 to 2.7 meters) in height, but the record is 10 feet, 8 inches (3.2 meters). The African elephant averages about 10 feet (3 meters) in height, with a record of 12 feet, 8 inches (3.8 meters). Adult elephants weight as much as 6 tons (5.4 metric tons). An African elephant may consume up to a half-ton (0.45 metric ton) of grass, twigs, leaves, and fruit in a single day. The African elephant has much larger ears of the two species and the tusks of the African beast are also larger and heavier. See Fig. 2. Numerous extravagant claims have been made from time to time concerning the size of elephant tusks. Reasonable records indicate that the largest tusk from an Indian elephant measured 8 feet, 9 inches (2.6 meters), versus a dimension of 11 feet, 5 inches (3.5 meters) for an African elephant. The tusks weighed 161 and 293 pounds (73 and 133 kilograms), respectively. It is interesting to note that ivory from extinct Mammoths, predecessors of modern elephants, has been dug from the frozen tundra of Siberia and offered to the market.

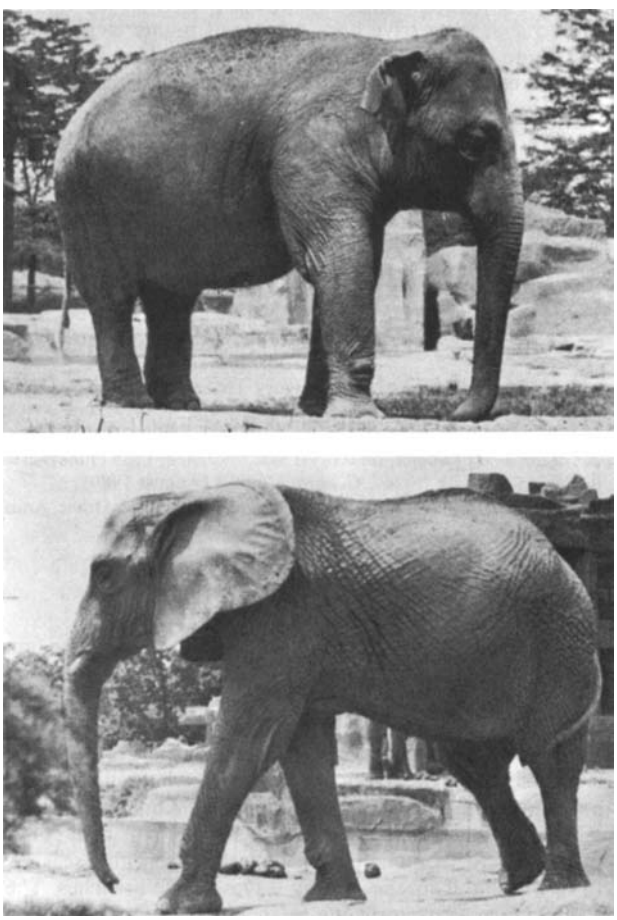

Fig. 2. Elephants: (*Above*) Indian; (*below*) African. (*A.M. Winchester*.)

The life span of the elephant is estimated at about 60 years, although records indicate that some specimens have lived longer. The elephant is fully grown at 25 years, but may breed at 15 to 20 years. The gestation period of the elephant is from 20 to 21 months. The young are weaned at 5 years. The average speed of an elephant is less than 15 miles (24 kilometers) per hour, although it can achieve a charging speed of 17 to 20 miles (27 to 32 kilometers) per hour. The elephant tends to socialize in herds with 100 or more beasts ambling slowly through their habitat. The animal, because of its tremendous capacity for food, must spend a great deal of its time in browsing and foraging. The tusks are used for fighting and can cause terminal destruction to most would-be attackers. The Big Cats are the elephant's main natural threat, particularly in catching and killing baby elephant calves. Over the years, the elephant has steadfastly resisted domestication.

The mother of an elephant calf is not the only individual to care for the infant; other group members join in, their assistance beginning even before the birth of the calf. Elephant calves are sporadically suckled and fed until the end of their second year, but they are capable of taking solid food shortly after birth. However, they are not able to masticate food at this time. Older herd members help them by collecting and cleaning grass, breaking off branches for them, and cutting the food into small pieces. Young elephants even snatch half-chewed food from the mouths of adults. Newborn elephants sleep more frequently and for longer periods than adults. They often interrupt their play fights to lean against each other and sleep. Since elephant calves are curious and playful, they do not pass up any opportunity to observe nearby buffaloes or deer or to chase a hare, a monitor lizard, or another small animal. Their behavior often creates difficulties for the adults.

Elephant mothers cannot continually watch over their youngsters, but this problem is overcome by keeping the young in "kindergartens," groups of infants that use the best feeding grounds in an area. The group is guarded by different adults. While most of the adults are off feeding, the "baby-sitter" insures that the young stay together and do not run off from the group. Baby-sitters also guard the young while they sleep and pre-chew their food. The baby-sitter role is apparently an unpopular one and is usually assumed, rather involuntarily, at water holes shortly before the group breaks up. Elephant infants have to be forced out of the water, since they tend to splash about and play with each other interminably when they are in the water. The lead cow usually begins moving off as the other mothers and half-grown animals try to get the youngsters out of the water. However, as the lead cow departs, other potential "baby-sitters" begin leaving the young, and the last cow to be with the infants assumes the role of baby-sitter. See Fig. 3.

Fig. 3. Elephant mother watching over calf.

Elephant's Sensory System

The extremely keen hearing of elephants has long impressed hunters and mahouts, but it was not scientifically studied until 1951. An elephant could distinguish one specific tone from six pairs of pure tones. In one case the various tones were just one note apart from each other. Elephants also learned simple melodies and rhythms that could be recognized independently of the instrument creating the music (i.e., whether the music was performed on violin, piano, organ, or xylophone).

Elephant cows call their young by slapping their ears against the head. When companions meet, they softly "peep" and "rumble." These greeting sounds are apparently understood by mahouts, too. Elephants trumpet when they are surprised by predators or by humans, and the shrill tones of a trumpet often initiate either fight or attack by the elephants. When they threaten, they often beat their trunks against the ground, producing a sound like that of automobile tires striking against a hard surface. Vocalizations either originate in the larynx (as in rumbling and roaring sounds) and are then amplified in the air columns of the trunk, or they are created in the trunk itself (trumpeting).

Olfactory signals undoubtedly play an important role in mutual recognition and in communication. When two elephants greet each other each one touches temporal and cheek glands and the mouth and genital region of the other. We do not know much about how important vision is. For a long time it was thought that elephants have poor eyesight, since their eyes are so small in proportion to the huge body. Furthermore, the field of vision is oriented downward and to the side in the normal head position, causing the elephant to have to lift its head to see in front. However, laboratory experiments have shown that the elephant's vision is as good as that of a horse. It is less able to adapt to changing illumination than humans are.

An observer of a procession of elephants definitely will detect that members of the group are communicating with each other, but at a sound pitch below the human's audible level. Research in Kenya, Namibia, and Zimbabwe indicates that elephants use infrasound for communication. In nature, infrasound is manifested during earthquakes, wind, thunder, volcanoes, and ocean storms, as reported in the Payne reference listed. Prior to some research on elephants, infrasound was not considered as a medium used by animals. This concept was tested by scientists of the Cornell Laboratory of Ornithology by recording elephant sounds at a zoo in Portland, Oregon. Experiments conducted showed that instruments had recorded some 400 calls (infrasound level), which was triple the number of sounds picked up by the researchers' ears. Audible elephant sounds include barks, snorts, trumpets, roars, growls, and rumbles. Part of the latter sounds seems to be infrasonic. Observation of the elephants revealed a fluttering and vibration as air passed through the elephant's nasal passage and the skin on the animal's forehead. This is tentatively considered as the source of the infrasonic vibrations. The researchers suspect that these very low sounds may account for at least some of the behavioral patterns of elephants, such as the female announcing estrus to receptive males.

Diet and Physiology

It seems unusual that the world's largest terrestrial animal makes relatively poor use of its food. Their diet consists of grasses, bamboo, roots, bark, wood, and fruits of specific plants. Some of the most popular items are tender bamboo shoots and the leaves. About half of the food swallowed leaves the body undigested. Elephants spend most of the day preparing and eating their food; adults spend 18 to 20 hours daily with this activity! Their short sleep period of just 2 to 4 hours is sufficient for their needs. Elephants, particularly older animals, often sleep standing up. Sleep is usually interrupted at 15 to 30 minute intervals, during which time the animals check the surroundings for danger. Even in deep sleep they become quickly aroused to any disturbances.

The intestines of an adult elephant exceed the length of those in any other mammal: an elephant has 25 meters (82 feet) of small intestine, 1.5 meters (5 feet) of appendix, 6.5 meters (21.3 feet) of large intestine, and 4 meters (15.1 feet) of rectum. An elephant must typically drink 70 to 90 liters (18.5 to 23.7 gallons) of liquid per day. In the wild and in work the elephant's liquid needs are satisfied during the course of several daily baths. Elephants choose their bathing water carefully, since they also drink where they bathe. Of course, an intake of such huge quantities of water means that elephants urinate impressive quantities. Elephants urinate ten to fourteen times every 24 hours. Wild elephants regularly interrupt their feeding and seek water holes or rivers, both for purposes of drinking and for bathing. They frequently slosh about in mud, which helps cool the body off. When the weather is extremely hot they fan themselves with their ears.

Since elephants are huge animals, they have relatively little surface area for heat loss compared to the internal heat-preserving mass. They only breathe 12 times per minute, and the heart beats 40 times per minute. The average body temperature is 39.9 °C (104 °F). The blood vessels are quite large: arteries leading to the head have a diameter of nearly 2 centimeters (0.8 inches), and the heart weighs about 12 kilograms (26.5 pounds). The great capacity of the circulatory system may be related to the small sleep requirements of elephants. Elephants in their native habitat tolerate cold better than heat, which they will actively avoid. During the day they avoid open sunny spots, instead withdrawing to the shaded jungles.

Hardly any other animal expends so much time and energy caring for its skin, bathing, massaging, and even powdering it (with dust). The thick skin is not nearly as insensitive as it looks, and it requires constant attention. In young elephants the skin is gray to blackish; with increasing age a pink-white appearance develops, beginning at the base and tip of the trunk, along the edges of the ears, the temples, and on the neck. Finally entire sections of skin have this pale color.

Temperature regulation through the sweat glands is apparently ineffective; elephants are unable to work during the midday hours in hot, tropical climates. Asiatic work elephants are usually rested from 10:30 A.M. to 3:30 P.M., since there is too much danger of overheating during these hours. The secretions from the sebaceous glands, at least in captive animals, are apparently of some help in reducing body temperature.

The Indian elephant is tamed for use as a beast of burden and for handling heavy materials, such as timbers. The elephant does not breed freely in captivity, hence wild herds are the source of supply. The animals are trapped in several ways.

Much has been written concerning the lore of the elephant and its behavior. It is well established that the elephant lives in accordance with certain customs. Apparently, sexual dueling is in order among younger males, but only in accordance with strict rules. The elephant is nomadic and apparently follows one of two plans. In the one case, a herd of animals will make a round trip between two locations during the course of a year; or they make what might be termed a "grand circle" tour that may last some ten years. Although traveling in herds is the norm, solitary elephants are sometimes found; or sometimes a very small group of male elephants. The solitary animals may be explained by the presence of illness or crippling, or just plain aging where an older male may not be able to keep the pace. It is known that elephants suffer from arthritis and rheumatism. An elephant may leave the herd for awhile and then return; or temporarily it may join another herd, but apparently the invitation is extended over only a limited time span. Female elephants of all ages generally are part of a large herd. It is well established that other female elephants assist at birth and in the early care of parent and calf.

Much has been written concerning the intelligence and memory of the elephant. The memory is considered exceptional, but not infallible. Like humans, elephants also forget. There is evidence that at least to some degree an elephant understands human language to a point exceeding that of — say — a dog obeying a command. A well-trained elephant can take verbal instruction from other than its regular trainer and thus obviously depends upon language sounds and to some degree of complexity. In other words, to some extent, the exact terminology need not be repeated each time or by the same person to achieve a desired reaction from the elephant.

In general terms, the elephant is nomadic, highly social, quite intelligent and, essentially as a result of this intelligence, quite temperamental, quite varied in personality from one specimen to the next, and extremely specialized. This places the elephant high if not at the top in the order of mammals in terms of advancement from the primitive state.

Over the years, there have been rumors of pigmy elephants. None have been found. The closest would be some of the Loxodonts found in parts of the former Congo territory in Africa, although these hairy races are far from the size of a pigmy animal.

At one time, the elephant, the rhinoceros, and the hippopotamus were classified in one group known as *Pachydermata* (thick-skinned beasts). These animals all have been reclassified, the elephant now in its own group *Proboscidea*.

ELEPHANT TREE. A relatively large, very noticeable tree found in the desert region of Baja California and Yuma, Arizona (see Table 1). Called copalqum locally, the tree has a smooth, light-colored bark reminiscent of the trunk of an elephant. Desert winds constantly prune the tree, this erosion frequently resulting in craggy, gnarled, and grotesque shapes. Foliage consists of small, compound, and somewhat pubescent leaves. Leaf production occurs after intervals of rain. Abundant, small pink flowers borne in panicles give the tree a slightly soft rose coloration when in full bloom. Sometimes, particularly during dry seasons, the tree will flower in the absence of any leaves on the branches. The elephant tree tends to prefer growing in ancient lava flows, where it becomes the predominant plant.

ELION, GERTRUDE BELLE (1918–1999). Gertrude Elion was an American chemist who developed a novel approach to the treatment of diseases in which antimetabolites are used as drugs.

Elion, born and educated in New York City, graduated *summa cum laude* in 1937 from Hunter College. The death of a beloved grandfather from cancer stimulated Elion to become a medical scientist. She obtained an MS in chemistry from New York University in 1941 but did not acquire a laboratory position until World War II forced the hiring of women. First employed in a food laboratory and then at Johnson & Johnson, Elion found herniche in George Hitchings' laboratory at Burroughs Wellcome in 1944. She spent the next 40 years synthesizing purine analogues for the treatment of an array of diseases. See **Hitchings, George Herbert (1905–1998)**.

In 1950 Elion experienced her first success, the discovery of 6-mercaptopurine, an inhibitor of leukemia cell multiplication. Many more beneficial compounds followed including: azathioprine (Imuran), which enables successful kidney transplantation; allopurinol, used in the treatment of cancer and gout; and acyclovir, an effective agent against herpes. In total, Elion is credited with 45 patents. Elion retired in 1983 but her legacy continued at Burroughs Wellcome with the synthesis of azidothymidine (AZT), a critical drug in the treatment of AIDS. During her retirement Elion remained active, serving as a research professor at Duke University and as an adviser to the World Health Organization and to the National Cancer Advisory Board. See also **Antiviral Drugs**; and **Drug Discovery (The History)**.

In 1988 Elion shared the Noble Prize in Physiology or Medicine with Hitchings and Sir James Black from the University of London. Elion also received many other accolades including 25 honorary doctorates, the National Medal of Science, and election in to the National Academy of Sciences. Additionally, in 1991 she became the first woman inducted in to the National Inventors Hall of Fame. To Elion, however, the greatest distinction was the knowledge that her work helped improve the health and well-being of many people. See also **Black, James Whyte (1924–Present)**.

ELLIPSE. A conic section obtained by a cutting plane parallel to no element of a right-circular conical surface. It is the locus of a point which moves so that the sum of its distances from two foci is a constant. Its eccentricity is less than unity. The standard equation may be taken as $x^2/a^2 + y^2/b^2 = 1$. The curve is a central conic for it is symmetric about both the X- and Y-axes. When placed in its standard position, the center of the ellipse is the coordinate origin, the major axis of length $2a$ is along the X-axis, and the minor axis of length $2b$ is along the Y-axis. The distance from the center to either focus is $\sqrt{a^2 - b^2}$; the eccentricity e is given by $ae = \sqrt{a^2 - b^2}$; the length of the latus rectum is $2b^2/a$; the equations for the directrices are $x = \pm a/e$. The distance from any point on the ellipse to a focus is a focal radius and the sum of two focal radii equals $2a$.

If the semi-major axis equals the semi-minor axis ($a = b$), the ellipse degenerates into a circle.

The polar equation of an ellipse is

$$r = \frac{a(1 - e^2)}{1 - e\cos\theta}$$

and its parametric equations are $x = a\cos\phi$, $y = b\sin\phi$. The equation for the evolute of an ellipse is $X^{2/3} + Y^{2/3} = 1$, where $X = ax/e^2$, $Y = by/e^2$. It is similar in shape to an asteroid and sometimes called that.

With reference to Fig. 1. the area of an ellipse $A = \pi ab$. Circumference $C = 4aE(k)$, where $k = 1 - (b^2/a^2)$ and $E(k)$ is the complete elliptic integral of the first kind. This is an approximation for the circumference $C = 2\pi\sqrt{(a^2 + b^2/2)}$.

See also **Asteroid (Mathematics)**; and **Conic Section**.

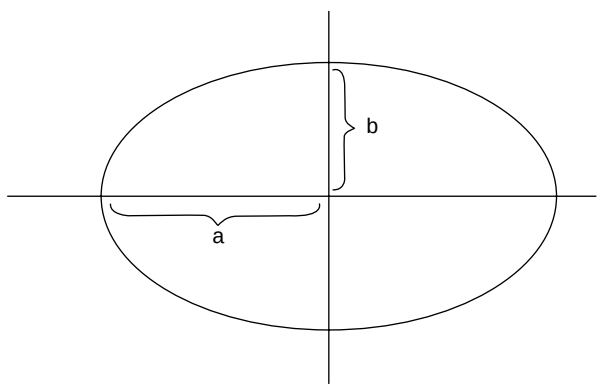

Fig. 1. Area of ellipse.

ELLIPSOID. A central quadric surface, given in its standard form with center at the coordinate origin, as

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1$$

where a, b, c are the semi-axes. Sections parallel to each of the coordinate planes are ellipses.

If two of the axes become equal, the surface is a spheroid, which can be generated as a surface of revolution. Consider an ellipse in the XZ-plane $x^2/a^2+z^2/c^2=1$, with $a>c$, so that its major axis is along the X-axis of the coordinate system and its minor axis along the Z-axis. There are then two possibilities: (1) rotate the ellipse about its major axis, and the result is a prolate spheroid with $a>b=c$; (2) rotate about the minor axis and obtain an oblate spheroid, $a=b>c$. Sections through the surfaces are circles in both cases: when taken parallel to the plane $x=0$ for the prolate case: parallel to $z=0$ for the oblate case.

In the final degenerate case, $a=b=c$, the surface is a sphere.

See also **Spheroid**; and **Surface (of Revolution)**.

ELLIPSOIDAL COORDINATE. A system based on confocal quadric surfaces. If λ, μ, ν are the three real roots of a cubic equation in a parameter describing such quadrics, they also locate the position of a point in space, for three mutually perpendicular quadric surfaces intersect at the point. If constants are taken so that $a>b>c$, the surfaces are: (1) ellipsoids, $\lambda=$ const., $c^2>\lambda>-\infty$; hyperboloids of one sheet, $\mu=$ const., $b^2>\mu>c^2$; (3) hyperboloids of two sheets, $\nu=$ const., $a^2>\nu>b^2$.

The relation between the rectangular Cartesian coordinates and the ellipsoidal coordinates of a point are

$$x^2=\frac{(a^2-\lambda)(a^2-\mu)(a^2-\nu)}{(a^2-b^2)(a^2-c^2)}$$

$$y^2=\frac{(b^2-\lambda)(b^2-\mu)(b^2-\nu)}{(b^2-a^2)(b^2-c^2)}$$

$$z^2=\frac{(c^2-\lambda)(c^2-\mu)(c^2-\nu)}{(a^2-c^2)(b^2-c^2)}$$

Since x, y, z occur as squares in these relations they give eight points symmetrically located in the Cartesian system. Some convention must then be adopted for the signs of the ellipsoidal coordinates in order to locate a point uniquely.

See also **Coordinate System**.

ELLIPSOMETER. See **Photometers**.

ELLIPTICALLY POLARIZED SOUND WAVE. A transverse wave in an elastic medium in which the displacement vector at any point rotates about the point and has a magnitude which varies as the radius vector of an ellipse. An elliptically polarized wave is equivalent to two superposed plane polarized waves of simple sinusodial form in which the displacements lie in perpendicular planes and are 90° apart in phase.

ELLIPTICAL POLARIZATION. The polarization of a wave radiated by an electric vector rotating in a plane and simultaneously varying in amplitude so as to describe an ellipse.

ELLIPTICAL SYSTEM. A tracking or navigation system where ellipsoids of position are determined from time or phase summation relative to two or more fixed stations which are the focuses for the ellipsoids. See also **Ellipsoid**.

ELLIPTIC CYLINDRICAL COORDINATE. A degenerate case of ellipsoidal coordinates where the surfaces are: (1) elliptic cylindrical with semi-axes $a=c\cosh u$, $b=c\sinh u$, $u=$ const.; (2) hyperbolic cylindrical with $a=c\cos v$, $b=c\sin v$, $v=$ const.; (3) planes parallel to the XY-plane, $z=$ const. A point in this system has rectangular Cartesian coordinates

$$x=c\cosh u\cos v$$

$$y=c\sinh u\sin v$$

and $0\le u\le\infty$; $0\le v\le 2\pi$; $-\infty<z<\infty$.

See also **Coordinate System**.

ELLIPTIC GEOMETRY. See **Geometry**.

ELLIPTIC INTEGRAL. Any integral of the type

$$\int f(x,\sqrt{R})\,dx$$

where f is a rational function of its two arguments and R is a third or fourth degree polynomial in x, with no repeated roots. It may be reduced, by suitable change of variable, to a sum of elementary integrals and one or more of the following types:

$$u_1=\int_0^x\frac{dt}{\sqrt{(1-t^2)(1-k^2t^2)}}=\int_0^\phi\frac{dw}{\sqrt{1-k^2\sin^2 w}}$$

$$u_2=\int_0^x\sqrt{\frac{1-k^2t^2}{1-t^2}}dt\int_0^\phi\sqrt{1-k^2\sin^2 w}\,dw$$

$$u_3=\int_0^x\frac{dt}{(t^2-a)\sqrt{(1-t^2)(1-k^2t^2)}}=\int_0^\phi\frac{dw}{(\sin^2 w-a)\sqrt{(1-k^2\sin^2 w}}$$

These are incomplete elliptic integrals of the first, second, third kind, respectively. When expressed in terms of $t=\sin w$, they are Legendre's normal forms. The constant $k(0<k^2<1)$ is the modulus and a is an arbitrary constant. If $\phi=\pi/2$, the integrals are called complete.

Series evaluation of the elliptic integrals may be made and numerical tables for them are available. They are called elliptic because they were first studied in order to determine the circumference of the ellipse. Their properties are best studied in terms of their inverse functions. See also **Jacobi Elliptic Function**; **Theta Function**; and **Weierstrass Function**.

ELLIPTICITY RATIO. 1. The ratio of the major axis to the minor axis of an ellipse. See also **Ellipse**.

2. As a measure of elliptical polarization, the power ratio of the maximum to the minimum electric vectors of an elliptically polarized antenna.

ELLIPTICITY (symbol e). The amount by which a spheroid differs from a sphere or an ellipse differs from a circle, calculated by dividing the difference in the length of the axes by the length of the major axis. Also called *compression*.

ELM TREES. Of the family *Ulmaceae* (elm family), there are close to fifty species of elm trees, notably of Europe and North America. It is estimated that 70% of the hedgerow trees in the English Midlands are elms. Of the species of elms, there are numerous hybrids, cultivars, and clones, and thus there is a resulting complexity of nomenclature.

The American elm (*Ulmus americana*), also called the white elm, has a natural range from Newfoundland to Florida and westward to the Rocky Mountains. Many of the choice specimens were created from grafting. The height of the tree normally ranges from 50 to 100 feet (15 to 30 meters), with a trunk from 20 to 30 feet (6 to 9 meters) in a circumference, and spread of about 70 to 100 feet (21 to 30 meters). About one-third of the way up the tree, the trunk usually divides into a number of very stout branches. The bark is grayish-brown and is furrowed. The leaf is 11/2 to 3 inches (3.8 to 7.6 centimeters) in length, alternately spaced, and sharp-pointed. The tree is essentially an ornamental shade trade and widely used for plantings in parks and along streets. Of course, in recent years, the elm disease, described later, has caused the removal of large numbers of these trees.

The cedar elm (*U. crassifolia*) is found mainly in the southern states, ranging westward from the Mississippi basin to Texas and parts of Mexico. The tree usually attains a height between 60 to 80 feet (18 to 24 meters) and a trunk diameter in excess of 2 feet (0.6 meter). The record cedar elm

TABLE 1. RECORD ELM TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
American elm (1997) (*Ulmus americana*)	282	716	112	34.1	115	35.1	Michigan
Cedar elm (1989) (*Ulmus crassifolia*)	127	323	100	30.5	44	13.4	Mississippi
Cedar elm (1994) (*Ulmus crassifolia*)	112	284	107	32.6	69	21	Florida
Florida elm (1985) (*Ulmus americana Var. floridana*)	117	297	56	17.1	60	18.3	Florida
Florida elm (1989) (*Ulmus americana Var. floridana*)	95	241	70	21.3	77	23.5	Florida
Rock elm (1988) (*Ulmus thomasii*)	202	513	117	35.7	122	37.2	Michigan
September elm (1985) (*Ulmus serotina*)	105	267	150	45.7	64	19.5	Alabama
Siberian elm (1997) (*Ulmus pumila*)	239	607	95	29	97	29.6	Colorado
Slippery elm (1988) (*Ulmus rubra*)	240	610	100	30.5	119	36.3	Ohio
Slippery elm (1995) (*Ulmus rubra*)	250	635	100	30.5	100	30.5	Ohio
Water elm (1983) (*Planera aquatica*)	183	465	106	32.3	96	29.3	North Carolina
Winged elm (1991) (*Ulmus alata*)	185	470	97	29.6	78	23.8	North Carolina

[2]At 4.5 feet (1.4 meters).

is listed in the Table 1. The tree is characterized by very small leaves, 1 to 2 inches (2.5 to 5 centimeters) in length, considering the other dimensions of the tree. The September elm (*U. serotina*), also known as the southern or red elm, prefers limestone regions and ranges from southern Kentucky westward into Arkansas and southward to the northern parts of Alabama and Georgia. The tree normally attains a height of about 50 to 60 feet (15 to 18 meters) although some specimens become larger. The leaves are 2 to 3 inches (5 to 7.6 centimeters) long and are of a narrower contour than found on most other elms. The slippery or red elm (*U. rubra*) has a rough bark, deeply furrowed, scaly, and of a dark-brown color. The leaf surfaces also are rough. The tree normally attains a height of about 70 feet (21 meters). The top is often formed in a broad, irregular manner. This species ranges from the lower Saint Lawrence River area westward to the Dakotas and Nebraska and south and southwestward from western Florida to Texas. The mucilaginous inner bark has been valued as a home medicine of demulcent qualities. The winged elm (*U. alta*), also called Wahoo elm or cork elm, is smaller than most elm trees, with an average height of 40–50 feet (12 to 15 meters). The tree can grow to much larger dimensions. The bark is of a light-gray-brown color and is close and fine, with perpendicular ridges. The leaves range from 1 to 2 inches (5 centimeters) in length, usually very narrow with sharp points, and of a deep olive-green color. The foliage usually is reasonably dense. The tree ranges southward from Virginia to western Florida and Westward to southern Indiana and Illinois and into Texas.

Other species of elm include: the rock elm (*U. thomasii*); the Florida elm (*U. americana var. floridana*); the Cornish elm (*U. angustifolia cornubiensis*), a large tree of the British Isles and France; the smooth-leaved elm of Europe and north Africa (*U. carpinifolia*); the Wych or Scotch elm of Europe and north and western Asia (*U. glabra*); the Camperdown, tabletop, Dutch, and Belgian elms, all relatives of U. glabra; the Chinese elm (*U. parvifolia*) of northern and central China, Korea, Japan, and Taiwan (disease-resistant); the English elm (*U. procera*); the dwarf or Siberian elm (*U. pumila*); the Jersey or Wheatley elm ($U. \times sarniensis$); and the Huntingdon or Chinchester elm ($U. \times vegeta$).

In recent years, the disease-resistant Chinese elm has been planted in the western United States. Its branches are long, delicate, and drooping and it makes an excellent park and street tree, especially for certain parts of California.

The characteristics of record elms in the United States are given in Table 1.

Dutch Elm Disease. The elm for many decades was a favorite for urban planting. Millions of these trees lined the streets of small villages, towns, and large cities. It has been estimated that in 1930 over 77 million elms were located within incorporated areas. It is attributed that Dutch Elm Disease was first noted in Cleveland, Ohio in 1930, when a relatively few trees displayed yellowing leaves in their upper branches, after which they mysteriously wilted and died. Because at first the disease spread slowly, the concern was not great. However, by 1976, approximately 54% of the elms in the United States had died, at which time the population was reduced to about 43 million trees. In New England, the loss of 75% was above average. A map showing the progression of the disease from Ohio in all directions is given in an informative article on "Dutch Elm Disease" by G.A. Strobel and G.N. Lanier [*Sci. Amer.*, 55–66 (August 1981)].

It is alleged that the Dutch elm disease was imported into North America, certainly unintentionally, when it was present in a shipment of elm logs. In early America, wood of the American elm and of the rock elm was used extensively for ship-building because it does not splinter. Also the wood bends well, but retains its strength, important characteristics for constructing a wooden ship. The fungus (*Ceratocysis ulmi*) carried by the elm-leaf beetle (*Galeruca scanthomelaena*) and the long-horned beetle (*Saperda tridentata*) grows in the new ring of wood, adjacent to the bark. The tree depends upon this for the flow of sap. In attempting to wall off infection, the tree creates a gummy substance, which ironically clogs tree fluids. Once the sap vessels are blocked, a branch dies and this process is repeated until the total tree is lost. Trees of 100 years or more in age can be destroyed in one season. Various insecticides attack the beetles and the sap-stream also has been injected with the insecticide. Unfortunately the process must be continued and, considering the hazards of effective chemicals, the large number of trees to be treated, and the time and money involved, this is not an ideal approach.

The aroma of rotting tree debris attracts the beetle. This aroma is not emitted by healthy elm trees. The beetles tunnel under the bark where they mate and lay eggs—later to fly away and feed in healthy elms. In so doing, the beetles transmit the fungus to healthy trees.

The most effective response to Dutch Elm Disease, after several decades of research, appears to be to develop resistant species. Well over a dozen

TABLE 2. SOME DUTCH ELM DISEASE RESISTANT ELM TREES

Identification	Developed By
Ulmus carpinifolia × *pumilia* "Urban"	National Shade Tree Laboratory, Delaware, Ohio
U. glabra × *U. carpinifolia* × *U. wallichiana*	(Cultivars are known as Lobel, Dodoens, and Plantyn)
U. laevis Pall	—
U. americana L (NPS 3)	National Capital Region of the National Park Service, Alexandria, Virginia
U. americana "Iowa State"	Iowa State University (Harold S. McNabb)
U. americana "Delaware II"	National Shade Tree Laboratory, Delaware, Ohio
U. japonica "Jacan"	Manitoba Agricultural Experiment Station, Morden, Manitoba, Canada
U. japonica × *pumila* "Sapporo Autumn Gold"	University of Wisconsin (Eugene Smalley)
U. japonica × *pumila* "44–25"	(Sister seedling from the cross that produced Sapporo Autumn Gold)
U. japonica × *pumila* (An unnamed upright European hybrid)	University of Wisconsin (Eugene Smalley)
U. hollandica "Groeneveld 494" (not hardy in upper Midwest)	The Netherlands (Hans Heybroek)
U. davidiana	National Shade Tree Laboratory, Delaware, Ohio
U. Wilsoniana × *japonica* (NPS-5)	(In the collections of the National Capital Region of the National Park Service; and the Arnold Arboretum)
U. × hollandica vegeta (Loud) "Huntingdon"	—
U. hollandica Mill (NPS-8)	National Capital Region of the National Park Service
Unnamed (NPS-36)	National Capital Region of the National Park Service

such species have been developed, as shown in Table 2, but they may not be easily obtainable. As pointed out by H.V. Wester (National Capital Region of the National Park Service), "Resistant elms are here. The need now is education. Nurseries haven't been growing elms, because people haven't wanted to plant trees that were going to die. But the American elm is the world's finest tree for its purpose. People will soon be planting the tree again with confidence that it will outlive them and their children and grandchildren. There are already the beginnings of nursery preparations to meet the impending demand."

Because resistant varieties are not effective in all areas, biological research continues to better understand Dutch Elm Disease and its vectors. Countermeasures range from the simple to the complex — from beetle trapping and the implementation of sanitation measures to the treatment of trees with fungicides and notably with antagonistic bacteria. *Pseudomonas syringae*, for example, has been used with some success.

EL NIÑO. Fishermen who ply the waters of the Pacific Ocean off the coast of Peru and Ecuador have known for centuries about the El Niño. Approximately every two to seven years during the months of December and January, fish in the coastal waters off of these countries virtually vanish, causing the fishing business to come to a standstill. South American fishermen have given this phenomenon the name El Niño, which is Spanish for "The Child," because it comes about the time of the celebration of the birth of the Christ Child.

An understanding of the complex processes at work to produce the El Niño requires information about phenomena occurring all across the tropical Pacific, not just its eastern boundary, the west coast of South America. Remote sensing, particularly from weather satellites, has been the source of data that finally has made it possible to understand the interactions between atmospheric winds and oceanic temperatures and currents that lead to the El Niño. See Fig. 1.

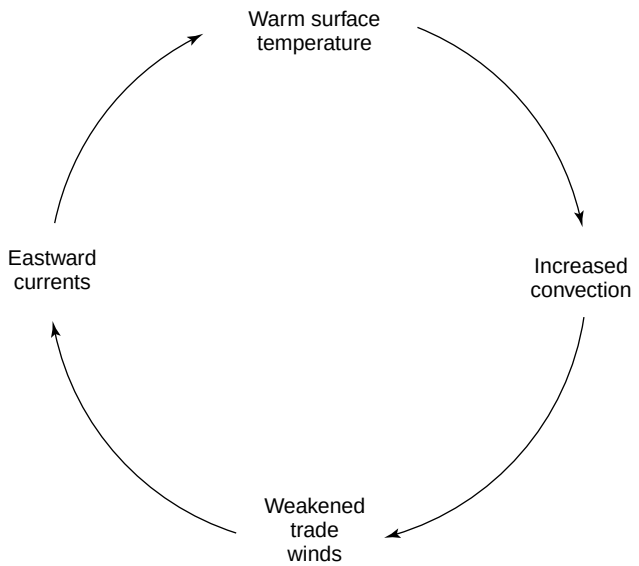

Fig. 1. Process that affect El Niño.

Worldwide Effects

El Niño effects are not limited to the disturbed areas off of Peru and Ecuador. They can be transmitted great distances. In many parts of the world, the disruption of normal climate can have tragic and/or profound economic consequences. El Niño has been shown to be related to the unusual flooding in Texas in the winter of 1991–1992 and to the anomalous warmth experienced in the southeast United States in the same period.

Nightly cloud images on television news from weather satellites show us the paths followed by the storms that cross the Pacific and travel northward from equatorial regions to the central lands of North America. Important indirect or secondary El Niño effects have been noted in other locations worldwide. During the 1997–1998 El Niño, drought and wildfires occurred in Indonesia and drier than normal conditions prevailed in Mexico and parts of Central and South America. A stronger than normal southern hemisphere jet stream contributed to wetter than normal conditions in Chile and in large portions of central and southern South America. Some locations in Chile received their normal annual rainfall total in a single day. In addition, El Niño's warm waters caused coral bleaching in the waters off the Pacific coast of Panama. Coral bleaching occurs as coral tissue expels zooxanthellae, algae that reside within the coral that are essential to the coral's survival.

Air/Sea Interaction

A key element of the El Niño phenomenon is the interaction between the winds in the atmosphere and the sea surface. Without this air/sea interaction, there would be no El Niño. Taking advantage of observations from the National Oceanic and Atmospheric Administration (NOAA) weather satellites, scientists have been able to track shifting patterns of sea surface temperatures. The pool of warm waters that normally resides in the western waters of the Pacific has been seen to drift eastward toward the western coast of South America. This foretells the advent of an El Niño.

The National Aeronautics and Space Administration (NASA) satellite images also help us see the shifting patterns of storms over the equator that are a consequence of the shifting locations of the warm water pool. Towering cumulus clouds, reaching high into the atmosphere with multiple regions of strong up-and-down vertical (convective) motions, form and move eastward across the Pacific as they are generated by the warm surface waters. This movement of the powerfully active convective regions alters the surface winds, and weakens the normally prevailing east-to-west trade winds. See Figs. 2 and 3.

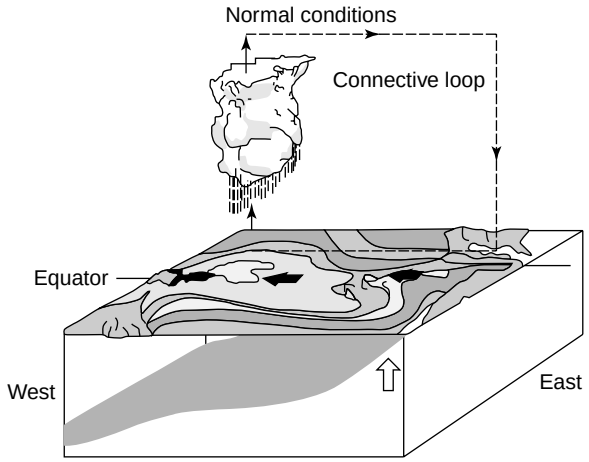

Fig. 2. Normal conditions over the Pacific basin.

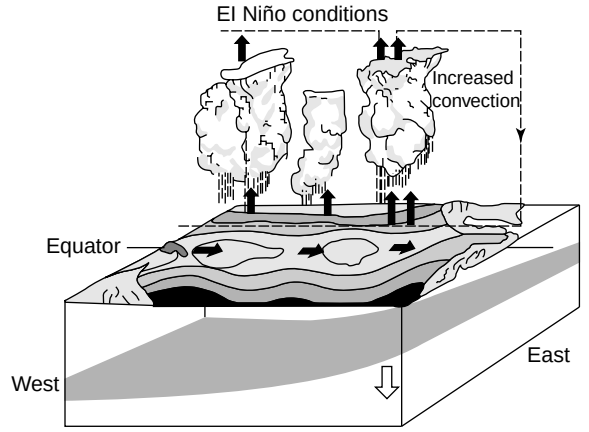

Fig. 3. Disturbed conditions over the Pacific basin during an El Niño.

Space Observations Pin Down the El Niño Phenomenon

Scientists at the Goddard Space Flight Center and elsewhere have used numerical models and theoretical studies to understand the processes that lead to El Niño. Comparison with data has shown the sequence of events leading up to El Niño.

In normal years, when there is no El Niño, the trade winds tend to blow from east to west across the waters of the eastern Pacific. They tend to drag the surface waters westward across the ocean. In turn, this causes deeper, colder waters to rise to the surface along the coast. The "upwelling" of deep ocean waters brings with it nutrients that otherwise would lie near the bottom of the ocean. The fish population living in the upper waters is dependent on these nutrients from below for survival.

During an El Niño, the westward trade winds weaken, causing the upwelling of deep water to cease. The consequent warming of the ocean surface further weakens the trade winds, and strengthens El Niño. Without upwelling, the nutrients from the deep water are no longer available. This signals a severe reduction in the fish population and fishing industry until the time that normal conditions return.

Prediction of El Niño events is now the focus of a major scientific initiative. The prediction of El Niño requires sophisticated numerical models to simulate: (1) the changes within the ocean that cause surface temperatures to warm; (2) the changes in atmospheric convection and clouds due to surface warming; and (3) the changes in surface winds that are caused by the convective disturbances. The societal impacts of accurately forecasting El Niño up to a year in advance are huge, allowing economic and agricultural policy makers to adapt to short-term climate fluctuations in a beneficial way. Satellite observations will continue to play a crucial role in ensuring the success of these forecasts, by providing accurate measurements of the present conditions in the region, an essential first task for prediction. See Fig. 4.

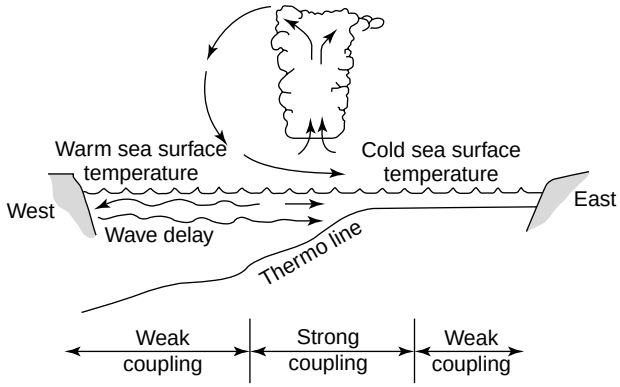

Fig. 4. Schematic of the main processes thought to produce *El Niño*. Abovenormal sea surface temperatures produce increased precipitation and changes in atmospheric circulation. These tend to maintain the warm temperatures by driving oceanic currents. Some of these effects are immediate; others act after the forced signal reflects from the western boundary and returns to the region of strong coupling.

NASA Missions to Study El Niño

Over the years, several NASA missions have studied the effects associated with El Niño, such as changes in sea−surface temperature (SST) and cloud cover changes. These studies are augmented by data from operational satellites of NOAA.

Initial efforts at mapping SST and cloud cover were conducted using data from NASA's Nimbus series of satellites. The four-channel Advanced Very High Resolution Radiometer (AVHRR), flown on NOAA's TIROS-N weather satellite in 1978 and on the NOAA-6 satellite in 1979, greatly increased the accurate measurements of El Niño effects. ("Four channel" means that the instrument views in four different parts of the electromagnetic visible and infrared spectrum.) Still further increases in accuracy resulted when a fifth channel was added to the AVHRR instrument flown on NOAA-7 in 1981, and on subsequent NOAA satellites. The fifth channel improved the measurement of SST by providing corrections for atmospheric water vapor that otherwise would have interfered with the temperature measurements.

The joint U.S.-French TOPEX/Poseidon mission was launched in 1992 and is providing global determinations of changes in ocean surface currents that are related to the El Niño phenomenon. The currents are determined from changes in ocean surface elevations measured by altimeters on TOPEX/Poseidon with accuracies of a few centimeters.

NASA has initiated a "Pathfinder Program" to make higher-quality data available from past and current missions. These efforts will lead up to the Earth Observing System (EOS), the main initiative of NASA's Earth Science Enterprise. The first in the series of EOS satellites will launched in 1999. Table 1. lists some of the missions that relate to the study of El Niño, and some of them are discussed briefly here.

The joint U.S.-Japanese Tropical Rainfall Measuring Mission (TRMM), launched November 27, 1997 uses for the first time, both active (radar) and passive microwave detectors from space to provide measurements of precipitation, clouds, and radiation processes in lower latitudes, including the portions of the Pacific Ocean where El Niño occurs.

A NASA scatterometer called NSCAT flew on the Japanese Advanced Earth Observing System (ADEOS) spacecraft, which was launched in August 1996. NSCAT provided very high quality data on the speed and direction of ocean-surface winds worldwide. Unfortunately, after nine months in orbit, a spacecraft failure brought to an end the stream of extremely valuable NSCAT data.

Recognizing the important contributions to Earth science made by NSCAT, NASA launched a copy of the new SeaWinds scatterometer in June 1999 as part of a dedicated mission named QuikSCAT to bridge the gap remaining before launch (planned for 2000) of the Japanese spacecraft designated ADEOS II, which will also carry a SeaWinds instrument.

In addition to the scatterometer measurements, which use active microwave radar systems to determine surface wind speeds and directions over the ocean, surface wind speeds are also being obtained from a passive

TABLE 1. EARTH SCIENCE ENTERPRISE

Mission	Launch	Scientific Objective
Nimbus Series	1964–1978	Initial global sea-surface temperature and cloud-cover mapping
TIROS-N/NOAA	1978-	Daily global sea–surface temperature and cloud-cover mapping (increased accuracy with addition of fifth channel on the NOAA-7/AVHRR in 1981)
Defense Meteorological Satellite Program (DMSP)	1987	Precipitation, ocean–surface winds from SSM/I
TOPEX/Poseidon	1992	Ocean topography and circulation
Advanced Earth Observing System (ADEOS) Japan	1996	Ocean-surface wind vectors from NASA Scatterometer (NSCAT)
SeaWiFS	1997	Ocean color, phytoplankton
Tropical Rainfall Measuring Mission (TRMM)	1997	Precipitation, clouds, and radiation processes in lower latitudes
Earth Observing System (EOS)	1999-	Advanced radiometers, sounders, altimeters, the SeaWinds scatterometer, etc., will provide the most-comprehensive data set for El Niño/La Niña studies
QuikSCAT	1999	Ocean-surface wind vectors from the NASA SeaWinds scatterometer
ADEOS II	2000	Ocean-surface wind vectors from the NASA SeaWinds scatterometer

microwave sensor on a Department of Defense spacecraft. The instrument is called the Special Sensor Microwave/Imager (SSM/I).

Key sources of Pathfinder data related to El Niño are data from the five-channel AVHRRs flown on NOAA-7, 9, and 11. These historic data sets cover the period 1981 through 1992 and beyond and will permit more-accurate SST determinations than were previously available. These data are important to the development and testing of a new generation of computer models in which the interacting processes of the land, the atmosphere, and the oceans are coupled. These coupled models will lead the way to an increased understanding of phenomena such as El Niño and the teleconnections that link El Niño with changes in weather patterns throughout the world.

NASA's SeaWiFS (Sea-viewing Wide Field of View Sensor) was launched on the OrbView-2 satellite in August 1997. The SeaWiFS sensor is designed to detect ocean color, which is an indicator of microscopic plant life in the ocean. The growth of such plants (called phytoplankton) is affected by the changes in sea surface temperature that are related to El Niño.

With the launch of the EOS satellites, we will have the means to collect and analyze the most-comprehensive data set ever acquired for the development of coupled models. This data set will increase markedly our understanding of the causes and effects of such large-scale ocean-atmosphere phenomena as El Niño.

See **Atmosphere-Ocean Interface**; **Climate**; and **La Niña**.

ELONGATION (Astronomy). The angular distance of a body of the solar system from the sun; the angle at the earth between lines to the sun and another celestial body of the solar system. The term is usually used only in connection with inferior planets. The greatest elongation of such a body is its maximum angular distance from the sun before it starts back toward conjunction. The direction of the body east or west of the sun is usually specified, as greatest elongation east. See also **Conjunction (Astronomy)**.

ELONGATION (Poisson's Ratio). See **Poisson's Ratio**.

ELUTION. In general, a process for extracting a solid substance from a mixture of solids by means of a liquid; as in the recovery of a vitamin adsorbed on an adsorbent by means of a solution. Specifically, elution is a process for the recovery of sucrose from molasses. Quicklime in the proportion of 25% of the weight of the molasses is added, the resulting mass is freed from much impurity by percolating (in "elutors") with 35% alcohol and is then decomposed by carbon dioxide, which liberates the sucrose. See also **Chromatography**.

ELUTRIATION. The separation of solids by the action of water or other liquids: hence, also the washing of a solid by decantation or a related process.

ELUVIUM. General term for unconsolidated, residual sediments.

EMANATION. See **Radon**.

EMBRITTLEMENT. A lowering of the ductility of a metal as a result of physical or chemical changes. Metals may be embrittled under many different conditions. Ordinary steel, wrought iron, and body-centered cubic metals generally, as well as zinc alloys and magnesium alloys suffer a reduction in impact toughness at subnormal temperatures. The effect is only temporary, full recovery of toughness occurring upon return to normal temperatures. Austenitic stainless steels, brasses and bronzes, nickel alloys, aluminum alloys, and lead alloys are not subject to severe embrittlement at low temperatures. Nickel additions to ordinary steels have a favorable effect.

Hydrogen embrittlement of iron and steel may be caused by absorption of atomic hydrogen in electroplating processes or in pickling baths. After such exposure the normal toughness can usually be restored by prolonged aging or a short period of heating at a slightly elevated temperature, as in a steam bath.

Season cracking of high zinc brasses is a severe form of embrittlement resulting in cracking or disintegration. Somewhat similar forms of stress-corrosion cracking occur in many other metals and alloys. Embrittlement of boiler plate, discussed below, may be considered a special case.

Steels and ingot iron may be embrittled by any heat treatment that deposits films of either oxides or carbides in the grain boundaries.

Caustic embrittlement is the development of brittleness in metals such as steel or ferrous alloys, upon prolonged exposure to alkaline substances, like caustic soda, in solution. Failures and explosions in boilers and evaporators have been caused by this action. Effective water treatment essentially has eliminated this condition in boilers.

See also **Corrosion Embrittlement**.

EMBRYO. The developing individual between the time of the union of the germ cells and the completion of the organs which characterize its body when it becomes a separate organism. The term is difficult to limit because some development occurs after birth or hatching and in some species a considerable period of growth intervenes between the completion of the essential structures of the individual and its assumption of separate life. In the latter stage, the organism is called a fetus if it is a mammal; but this term is not applied to the similar period of birds and reptiles. For the embryo in botany. See also **Seed**.

At the moment the sperm cell of the human male meets the ovum of the female and the union results in a fertilized ovum (*zygote*), a new life has begun. But before this new life is transferred from the inner, protected life provided by the mother, the new organism will have acquired an age which may vary from a premature 26 weeks to a postmature 46 weeks.

There is no exact procedure for computing the exact age of a child at birth, because the precise date of ovulation of the mother is not established. Although most authorities agree that ovulation occurs about 14 days prior to the beginning of menstruation, it is recognized that such an estimate is hardly more than an average, and that mature eggs (*ova*) may be liberated either sooner or later. Therefore, it is not known how long the new life inhabits the womb before birth, except in rare cases in which the exact occasion of a fruitful coitus is surely known.

But regardless of the length of time spent in the womb by the unborn life, it goes through six preparatory stages before becoming a full-term infant.

The first of these stages is fertilization within one of the Fallopian tubes, which extend from each side of the top of the womb (*uterus*). It is believed that fertilization takes place within the first 24 hours following sexual intercourse. Almost immediately after fertilization of the ovum, the second stage begins. This stage is concerned with the process of cell division. The single-celled zygote becomes a multicelled embryo. The term *embryo* covers the several stages of early development from conception to the ninth or tenth week of life. The early embryo is barely visible without the aid of a microscope; it is considerably smaller than the periods that end the sentence of a typical printed page. The initial series of cell divisions occur as the fertilized egg passes down the Fallopian tube.

Although cell division is still going on in the third stage, when the embryo reaches the womb, the cell cluster has not increased appreciably in size. Up to this time, the embryo is free in the uterus. By the end of the tenth day of development, the fertilized ovum begins to burrow its way into the wall of the uterus. See Fig. 1. This process is known as *implantation*, the fourth stage. It takes about two weeks for the embryo to begin to obtain food from the maternal blood vessels; during this time the developing embryo is probably nourished by the uterine substances it absorbs.

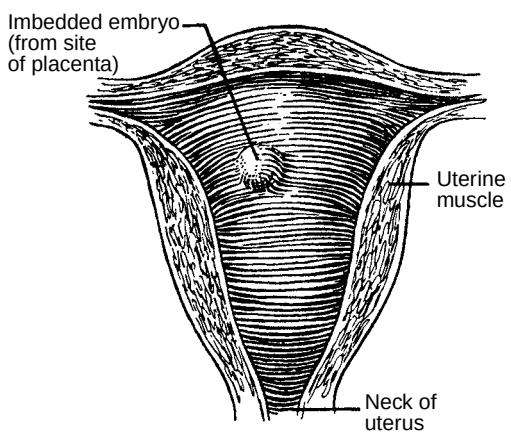

Fig. 1. The human embryo, on about 10th day, becomes embedded in the soft uterine wall. After about two additional weeks, the embryo will derive nourishment through a new placenta which will develop at the site of the attachment.

During the fifth stage the growing new life attains an age of eight to ten weeks, has definitive vital organs, as well as partial ability to balance itself within its fluid environment. When these organs are formed, the individual is called a *fetus*. In the sixth stage of prenatal development, the fetus is prepared for and experiences birth, at which time it is called an *infant*, fully capable of existing as a separate entity in the outer world.

The period of pregnancy begins with the union of the sperm and egg. At the moment of fertilization of the egg (*conception*), a new life begins. The period of pregnancy is also referred to as the period of gestation, and its duration from conception to full-term birth varies between 265 and 285 days in normal situations. See also **Pregnancy (or Cyesis; Gestation)**.

Early Days and Weeks of Life. During the fourth stage of development, which coincides with the first two or three weeks after conception, the new life is still not much taller than the capital letters upon this page. It can barely be seen and gives little evidence of its presence in the womb. By the third week after conception the embryo indicates its position in the womb by a small elevation. In the weeks since fertilization of the ovum, the weight of the resulting embryo has increased about 10,000 times, its length about 15 times.

Within the first weeks of growth, the outer layers of embryonic cells are undergoing development and providing nourishment; at this time, too, changes are taking place in the thick disc of inner cells (the *blastodisc*) which gives rise to the embryo proper. The uppermost layer of cells of this disc separates from the remainder to form a cavity known as the *amniotic cavity* and the upper layer thus becomes the *amnion*. The cavity remains filled with fluid throughout the prenatal period so that the developing child leads an aquatic existence during the entire period of prenatal life. The amnion is one of the important membranes covering the developing fetus. In this central cell mass, the outer layer of cells on the underside split off to form what is known as the *yolk sac*. The lowermost cells of the blastodisc become the *endoderm*. The embryonic structure now appears to be a flattened disc between two hollow sacs (*vesicles*). The upper of these vesicles is the amnion, and the lower is the yolk sac. The relationship of these structures is shown in Fig. 2.

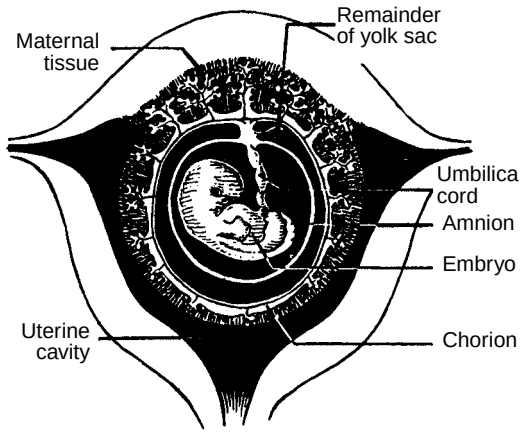

Fig. 2. Protection of developing embryo within the uterus by the chorion and the amnion. The growing child is completely surrounded by amniotic fluid and derives entire nutrition from maternal blood through umbilical cord which is connected to the placenta.

The cells of the embryonic disc segregate to give rise to three main layers of cells, which form the definitive organs of the body. The outermost of these cell layers is the *ectoderm*, the middle is the *mesoderm*, and the innermost is the *endoderm*. The middle germ layer, as it is called, rapidly sends out migrant cells, which line the entire sac. These mesoderm cells which migrate to the outside of the hollow sphere unite with the external layer to form the *chorion*, a part of which later becomes the *placenta* or the organ by which the fetus obtains food from the mother's blood. Another layer of mesoderm spreads out in a sheet-like fashion to surround the yolk sac. A relatively large amount of mesoderm adheres to the outer membranes to form the body stalk, which later will become the *umbilical* cord through which the fetus will receive its nourishment.

Between the second and eighth weeks after conception the three germinal layers differentiate, divide, and combine with each other to lay down the basic body structures, from which the more complicated organism grows. All of the infant body is derived from combinations of the three germinal layers of the embryonic disc. From the mesoderm come supporting structures — muscles, bones, and connective tissues — as well as kidneys, blood and blood vessels, the lymphatic system, and the organs of generation. From the ectoderm are derived the skin and its glands, the hair, the nails, the lens of the eye, the internal and external ear, the mouth and teeth, the mammary glands, the nervous system, and the lower part of the rectum. From the endoderm evolve the respiratory tract, except for the nose; the digestive tract and its glandular outgrowths, including the liver, the pancreas, and the gall bladder; the bladder, and portions of the reproductive organs.

Primitive Streak. During the early part of the third week, the embryonic disc changes shape, so that from the upper surface it appears as an elongated, egg-shaped structure. The cells in the central portion of this disc

thicken and form a slight ridge, which is known as the *primitive streak*. At one end of this streak, a small knob appears which marks the beginning of the head; in front of this knob the head process forms. The mesoderm is thought by many authorities to give rise to a solid, compact, elongated mass of tissue, the *notochord*. This structure grows forward as well as backward to form the beginning of the backbone. The notochordal tissue continues well into the head region, and on each side of it are formed the bones of the base of the skull.

The primitive streak with its head process divides the embryonic disc into right and left halves. This primitive streak is the first evidence of polarity — cells growing at opposite poles in opposite directions. In the postnatal human animal this polarity of development is clearly evident. An example is the manner in which muscles and tissues grow in opposite directions away from the axis of the spinal cord.

A groove soon courses along the primitive streak, deepens, and presently forms a connecting canal between the amniotic and yolk sac. This is the neurenteric canal, forerunner of the neural canal. The neural canal is the forerunner of the entire nervous system, including the brain and the spinal cord.

Having organized the area in which will lie the future head of the embryo, the primitive knot shifts, enlarges into an "end bud," and from this bud the lower half of the body arises.

During the third week of prenatal life the embryo is still a tiny organism the size of a large English pea, and the embryonic disc is about the size of the head of a pin. The body now begins to assume a cylindrical form instead of its previously flattened shape. This change is produced by the edges of the embryonic disc growing downward and enclosing the underlying structures. Concomitantly the underlying endoderm rolls itself into a tube which is to form the digestive system, or as it is properly called, the "gut." The mesoderm gathers itself into a number of small segmentally arranged bundles called *somites*, which later give rise to the deeper layers of the skin and to the muscles and bones. These somites are formed in rapid succession, so that sometimes they are used as an index to the age of the embryo. See Fig. 3.

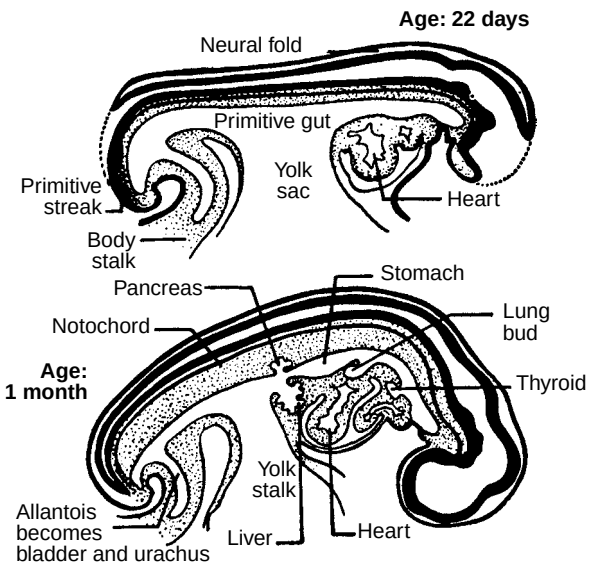

Fig. 3. By end of third week, embryo has commenced to fold over and assumes a more cyclindrical form as contrasted with prior flat form. During this early period, traces of most of the important body structures can first be observed.

Differentiation of Primitive Organ Systems. Near the end of the third week, the embryo has formed the beginnings of most of the important organ systems. The anterior or front end of the neural tube closes and the primitive brain starts forming. On either side of the brain, early in the fourth week, is to be found the first sign of the eyes. These are called the *optic vesicles*; they grow out from the brain and appear as bulges on either side of the early head. Back of or posterior to the future eyes are the *auditory vesicles*, which represent the beginning of the ears.

Toward the end of the fourth week of prenatal life, the original three divisions of the brain called the forebrain, midbrain, and hindbrain now become five divisions. By a symmetrical growth the brain makes a series of bends which cause the head region to curve downward with respect to the remainder of the body. The cranial nerves that later innervate the face begin their formation during this fourth week.

The spinal cord, which is formed from the neural tube, becomes thickened on the underside to develop the primitive nerve cells. Previously, when the margins of the neural tube had formed, there were left behind small clusters of cells. These clusters of cells, by uniting with the upper and lower sides of the neural tube, form the spinal nerves. These nerves grow outward from the spinal cord to innervate the organs of the body as they are being formed.

The heart is formed by the union of two blood vessels underneath the head. The united tube thus formed grows rapidly in length and bends around itself to form the letter "S." Thus by bending back upon itself the *ventricle*, or main pumping organ of the heart, is formed. Rapidly it changes into an incomplete, four-chambered structure. The heart begins to beat during the third week and continues beating throughout the life of the individual.

The lungs develop from endodermal tissue by forming a bud, which later branches into two lung buds. Each lung bud forms two *bronchi*, from which later are formed the *bronchioles* and finally the *air sacs*.

The primitive gut gives rise to some of the glands such as the thyroid, pancreas, thymus, and parathyroid. From the gut, a pouch grows downward and invades the circulatory system to form the liver. The hind part of the digestive system produces a pouch known as the *allantois*, which remains relatively undeveloped in human beings during most of embryonic life. The urinary bladder may be considered a remainder of part of the allantois. The limbs first appear during the fourth week as tiny buds from the midside region and from the hind region of the embryo. They later develop into the arms and legs of the fetus.

Early Fetal Development. After the first eight weeks, the embryo has become a fetus; that is, it now roughly resembles the ultimate adult human being. Prior to this time it would have been impossible to determine by observation whether the embryo was that of a human being, pig, goat, dog, or monkey.

During the third month, there is a rapid growth of the fetus so that by the end of the third month the weight has increased eight- to tenfold. The facial features have shown a marked change; the eyes have migrated inward so that they are no longer on the sides of the head. A bulging high forehead, a small slit-like ear, widely separated nostrils, and a large slit-like mouth characterize the earlier part of the third month's development. The upper limbs show sufficient development so that one may readily discern the fingers, wrist, and the forearm. The lower limbs are relatively smaller and less developed. The liver begins to function during this period. The intestine becomes a coiled structure. At the beginning of the third month the internal organs of reproduction have become sufficiently developed to enable one to distinguish between the sexes. The external genitalia, however, are still in the asexual stage, so that externally both sexes appear the same. Some of the bones are beginning to calcify.

See Fig. 4(a) through (f).

The Umbilical Cord. The unborn depends for its nourishment, oxygen supply, and the removal of its waste products, upon the mother's blood supply. From the original multicelled embryo, accessory arrangements have developed apace with the growth of the fetus. These, in conjunction with maternal contributions, provide mechanisms to give the embryo nourishment from the mother. From the larger sac which was contained within the covering membrane and surrounded by ectoderm cells, a two-way cord (umbilical cord) develops. This is the connecting structure between the embryo and the placenta. It is attached to the middle of the fetal abdomen.

The Placenta. The original covering membrane (chorion), in cooperation with certain accommodating cells of the womb, evolves the placenta, which is commonly known as "the afterbirth."

Through the placenta, the bloods of mother and fetus circulate independently, and in entirely separate channels. Maternal blood empties into pockets (*sinuses*) in the placenta, from which food materials are absorbed through the thin walls, to pass into the fetal circulatory system. By a reverse process, waste material is picked up by the maternal blood. In addition to providing oxygen and taking up gaseous and fluid wastes from the fetus,

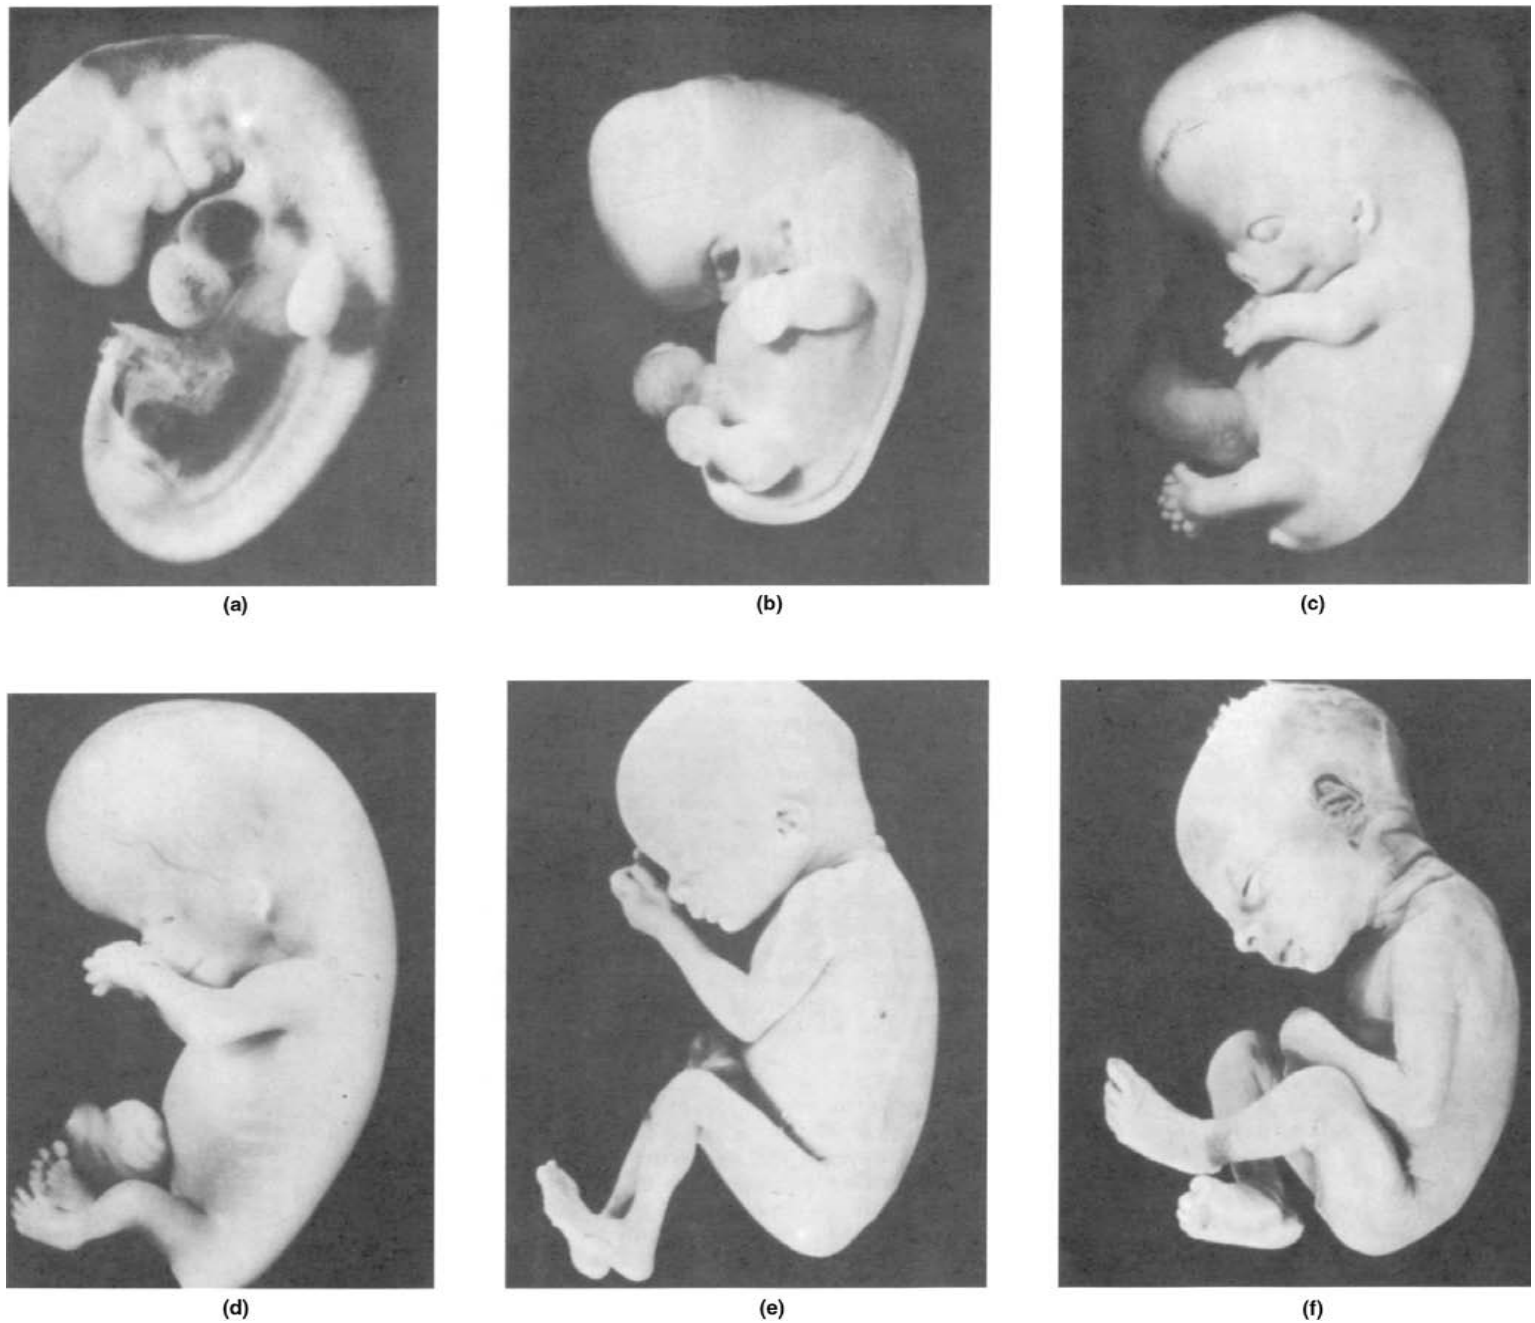

Fig. 4. Various stages in development of human embryo and fetus: (**a**) At 29 days, magnified 9 times; (**b**) at 37 days, magnified 4 times; (**c**) at 42 days, magnified 3.5 times; (**d**) at 56 days, magnified 2 times; (**e**) at 4 months (now called a fetus), reduced to about 1/2 of actual size (note disproportionate head size); and (**f**) at 6 months, shown from 1/2 to 1/3 actual size (note body of is now more proportionate to head); (**a**) through (**d**) *Carnegie Institution, Washington* , DC; (**e**), (**f**) *photographed by F.W. Schmidt.*

the placenta acts as a digestive area for adjusting foodstuffs in the maternal bloodstream to meet the absorption capabilities of the fetus.

The supportive role of the placenta is essential to fetal health and well-being. Besides keeping the fetus alive, the placenta has the additional function of preparing the uterus and birth canal for the delivery. Several hormones are manufactured by the placenta; these are for use sometimes by the mother and sometimes by the fetus. Should the placenta falter in any of its supportive endeavors, the fetus is in trouble.

If the protective functions of the placenta are impaired, noxious products of the fetal metabolism enter and cause disturbances in the maternal blood. The severe and continued vomiting sometimes experienced in pregnancy may be associated with the incomplete functioning of the placenta. In most cases, the placenta prevents infections from reaching the fetus, although sometimes it fails to protect against such diseases as syphilis, smallpox, and German measles. After the birth of the baby, the placenta is expelled from the uterus.

The Protected Fetus. When the placenta and the umbilical cord have been formed, during the first eight weeks of unborn life, the fetus rests within a closed membrane (amniotic sac) which fills the inside of the womb. This fluid-filled sac absorbs shock, equalizes pressure, prevents the fetus from adhering to its protective enclosure, and provides nourishment. After the first 8 weeks, the primitive, but fast-developing muscular and nervous system of the fetus allows it spontaneous movement. Within the amniotic sac, the fetus has room to rearrange its posture. During the seventh week, the middle vestibule of the ear becomes functionally alive. This development allows the embryo to balance itself. The semicircular canals of the middle ear are structures providing for maintenance of static equilibrium throughout life. At birth of the baby, they are of adult size.

Fourth Month to Birth. During the fourth month, there is considerable development of the abdomen so that the head is less out of proportion to the remainder of the body. Hair begins to appear on the head. During this time, the mother becomes aware of movements of the arms and legs.

During the fifth month the lower abdomen and legs become proportionately larger. The legs and arms show vigorous, active movements during this month. A thin silky hair, which disappears during the succeeding weeks, is deposited over the surface of the body. During the sixth month, the fetus increases in size and the organs in complexity. The embryo is lean, with little fat immediately beneath the skin. The skin is protected by a thick, oily secretion of the external glands. Eyelashes and eyebrows are present, and the eyelids have become separate.

The seventh, eight, ninth, and tenth lunar months are characterized by the maturation of the fetus. There is a layer of fat deposited beneath the skin during the last two months of unborn life. This fat protects and nourishes the infant during its early existence in the external world. During these last months before birth, the organs carry on their functions in much the same manner that they will in the external world. The fetus swallows amniotic fluid, which passes through the walls of the stomach and the intestine. The kidneys likewise may function slowly and discharge their contents into the amniotic fluid. Rhythmical movements occur in the intestine and the stomach, but their contents are not emptied into the amniotic fluid. During this period the mother's body is active in the elimination of waste material from the fetal body.

In the ninth lunar month, redness, which heretofore has been considerable in the fetal skin, now fades. The body becomes rounded; the nails project. Weight is from five and one-half to six pounds. The fetal infant is complete except for the finishing touches, which are accomplished in the tenth and last lunar month before birth.

As the fetal body produces glandular secretions and excretions in preparation for changes to be encountered through birth, the body becomes firm, sturdy, and round. By the time the baby is ready to be born, its many body functions — heartbeat, blood pressure, temperature regulation and, as it is being born, its breathing — have been correlated.

Studies of the Fetus

During the last few decades, there has been a great expansion of the knowledge of the fetus. Problems that have confounded obstetricians for centuries are being analyzed and it is becoming possible to treat the new life as a *patient*, along with the mother. This medical discipline is known as *fetology* and has been made possible mainly through the development of new instrumental exploring and measuring techniques.

Amniocentesis. This is the extraction and analysis of some of the amniotic fluid from the sac surrounding the fetus. Study of this fetal fluid yields clues to many obstetrical problems, for example, the complications that arise in the unborn children of mothers who are Rh-negative, diabetic, or hypertensive. An estimate of fetal age can be determined, as well as the sex of the fetus. In amniocentesis, a hollow needle is inserted through the mother's abdomen and the wall of the uterus into the amniotic sac. A small sample of the amniotic fluid is thus obtained. In certain situations, such as Rh incompatibility, a transfusion can be given to the child while in the womb. See also **Blood**. The amniotic fluid contains clues to numerous factors that determine the further development of the fetus and the infant. Because the fluid contains cells from the fetal skin, chromosomal analyses (*karotyping*) can be performed. Potentially dangerous genetic disorders may be diagnosed. Although there is tremendous interest on the part of the obstetrician and, of course, the parents in the state of the fetus, most authorities agree that the procedure should not be undertaken simply out of interest in the sex of the fetus. Rather, the technique should be reserved for those instances where family histories or other factors indicate distinct medical advantages to the obstetrician. Although the procedure is generally regarded as safe, it is nevertheless an *invasive procedure*.

Fiberoptic Camera and Endoscope. The *amnioscope* is an illuminated endoscope, which can be inserted through the cervix and placed directly against the cervical membrane at any time from the thirtieth week of pregnancy until delivery. The color of the amniotic fluid will be indicative of whether the fetus is in distress and/or ready for delivery.

The fiberoptic camera is a miniature camera connected to a needle that is inserted into the uterus. Within the needle are fibers that refract light into the lens. Although the instrument yields a picture only one square inch (2.5-centimeters square) in size, it does allow direct observation of the fetus.

Ultrasonography. This is a *noninvasive* procedure and considered by many to be essentially free of risk. The technique can be used to measure the size of the head of the fetus as well as other features. A pulsed beam of ultrasound passing through the fetal head is partially reflected by the skull margins and by the variable density within the brain. A given echo indicates the size of the fetal head. This can be an accurate aid in determination of fetal size and weight. The method can be used after six weeks of pregnancy to visualize the amniotic sac. Progressive ultrasonographic images will indicate the rate of fetal growth.

Maleness. From years of studies directed to understanding human sex-chromosome anomalies, it has been well established that sex determination is mainly a function of the presence or absence of a Y chromosome. The latter is both necessary and sufficient for male development. As observed by Kidd (see reference), exceptions to the foregoing rule have been the main resource for learning what specific genetic information on the Y chromosome is responsible for maleness. Even as early as 60 days of gestation, normal male development appears to require both the inhibition of the "female" (Müllerian) systems and the stimulation of the "male" (Wolffian) systems. These chemical changes are brought about by substances produced by the developing male gonads. Thus, the ultimate cause of sexual differentiation occurs very early, at the time when the gonads begin to differentiate. The search for the gene determining gonadal sex is now focusing on the small euchromatic short arm of the Y chromosome. Cytogenetic observations and DNA studies have implicated this region of the genome. As pointed out by Kiel-Metzger et al. (see reference), the region is sufficiently small and recombinant-DNA methods are sufficiently advanced that the steps of the search are clear. It is believed that within the near future, this entire segment is likely to be cloned. Once cloned, the DNA can be sequenced, and numerous new methods brought to bear — first to look for expressed sequences and then to determine the function of those genes. The ultimate cause of maleness may then be identified, thus providing one more answer to the many questions of human biology being answered by modern molecular genetic techniques.

Vulnerability of Unborn

Extensive studies have been made of the placenta, which serves as the interface between the fetal blood supply and the mother's blood. The placenta anatomically separates the circulatory systems of the fetus and the mother. Exchanges of substances take place across this interface. There are, however, important and sometimes tragic exceptions. In the early 1960s,

one of the most dramatic examples of how damaging influences from the outside can reach the fetus via the maternal bloodstream was discovered. In December 1962, a tranquilizing and sleep-inducing drug *thalidomide* was taken off the market and all samples were recalled. The drug had not been approved for use in the United States, but had enjoyed distribution in Germany, the United Kingdom, and a few other European continental countries.

This drug, which had been believed to be safe enough even to be given to babies, was causing a rare malformation in infants of mothers who took the drug during the sixth to eighth week of pregnancy, the period during which the limbs are forming. The most common malformation was *phocomelia* or "*seal limbs*," in which the arms and legs were often absent and there were seal-like "flippers" in their place. Phocomelia was also often accompanied by internal abnormalities, even some affecting the heart. About one-third to one-half of the babies died within a few days of birth.

Since that time, the medical profession and the drug manufacturers have exercised vigilance in this regard and various regulating agencies in different countries have exercised more aggressive controls over drug testing and approval for distribution, with safe administration during pregnancy being a major concern. Only a few examples of offending drugs can be given here. For example, adenine arabinoside, sometimes used to treat acute herpes simplex keratoconjunctivitis and recurrent epithelial keratitis caused by herpes simplex types 1 and 2, should not be given systemically to pregnant women because of its known teratogenicity and toxicity to the embryo (in experimental animals). Anticoagulants, if used during pregnancy, must be administered with extreme discretion. Although it has been shown that heparin does not cross the placenta and thus does not anticoagulate the fetus, it does increase the potential of maternal bleeding. Warfarin anticoagulants, on the other hand, do anticoagulate both the mother and the fetus. Serious problems have been reported as resulting from anticoagulant therapy during pregnancy, including nasal hypoplasia (incomplete development) and stippled epiphyses (parts of bone; see also **Bone**), particularly when warfarin was administered during the first trimester of pregnancy. See also **Anticoagulants**. Anticonvulsant drugs have been shown to increase the rate of malformations in the children of women who have been on chronic anticonvulsant drug therapy. There are many other examples. Much greater attention is also being given to the effects of chemicals found in the environment.

The effects of ingesting alcohol during pregnancy are mentioned frequently in the literature. In addition to those drugs which may be prescribed to nonpregnant women with full justification, but which may be contraindicated during pregnancy, there are the so-called hard drugs (street drugs) which poorly informed persons sometimes take. Drug addiction, of course, is an anathema to the pregnant woman. Smoking, a lesser form of addiction, is considered by most authorities in the field as probably harmful in pregnancy over and beyond the effects of heavy smoking on all persons as a precipitating factor of several diseases. The well-informed pregnant woman will avoid smoking throughout her pregnancy to assist her body in handling the exceptional demands of that period.

Infections. For many years, rubella (German measles) has been known to be capable of causing birth defects, especially deafness and mental retardation, in children whose mothers had the infection during the first trimester of pregnancy. This usually mild disease can produce devastating effects in the fetus. See also **Rubella (German measles)**.

In addition to the rubella virus, it is now known that other virus infections in the mother may lead to infection in the baby. Depending on the type and severity of the infection, abortion or stillbirth may result. Normal development of some of the organs may be prevented (for example, the deafness which often occurs in children of rubella-infected mothers), or the baby may be so infected that its first days or weeks of independent life are an uphill struggle against disease.

Apparently, viruses may infect the fetus at any time from the first few days after conception until immediately before delivery. The incidence of virus infections in fetuses is not known, but it is expected that such infections may account for some otherwise unexplained disorders of the fetus and newborn child.

EMBRYOLOGY. The science that deals with the development of the individual from the union of the germ cells to the completion of its bodily structure. Although the term embryo cannot be precisely limited, the science of embryology is concerned with all development prior to birth or hatching.

Development of the fertilized ovum begins with the process of cleavage. Following cleavage a process of gastrulation gives rise to two or three

germ layers and from this point the development of specialized tissues and organs goes on by gradual steps, all based on the subdivision and differentiation of many cells.

The processes of change by which germ layers give rise to other structures are varied. In some cases, masses of cells grow out in solid protuberances from an existing source. This process is called budding and is exemplified by the appearance of legs and other appendages on the surface of the body. Other structures are developed by the pushing in or out of layers of cells. If the new part pushes in the layer it is said to invaginate, and if it pushes out, to evaginate. Hollow organs may also be formed by the splitting of solid masses, and parts may separate by splitting from such masses; either process is delamination. A good example of evagination is the pushing out of a blind sac from the embryonic pharynx of vertebrates to form the respiratory system, and invagination is illustrated by the pushing in of ectoderm to form the stomodaeum, which becomes the oral cavity in part. The formation of the vertebrate excretory tubules as solid knots of tissue whose cavities arise by internal splitting is a case of delamination.

The details of development of any species or groups of animals are complex. Vertebrate embryology has been worked out in great detail and is fairly uniform, but the number of invertebrate forms is so great that their embryonic development cannot be concisely summarized. See also **Embryo**.

In the vertebrates, once the germ layers are formed their further development is the formation of organs and tissues and in some species extraembryonic membranes, with the exception of the mesoderm. This layer gives rise to diffuse mesenchyme and its compact portions differentiate into three regions, the dorsal, intermediate, and lateral or ventral mesoderm. The first subdivides into two longitudinal series of metameric masses, the mesodermal somites, flanking the middle line of the body where the notochord lies. This skeletal primordium is independently derived from the same source as the mesoderm. The lateral mesoderm splits to form an outer somatic layer associated with the body wall and an inner splanchnic layer, which envelops the viscera. The split forms the coelom or body cavity. From this point the mesoderm, like the other germ layers, gives rise directly to organs of the body. The organs and systems developed from each embryonic tissue are listed under germ layers.

In the field of experimental embryology an effort has been made to learn of the controlling factors in development by subjecting embryos and ova to various unusual conditions. By exposure to chemical stimuli, unusual temperatures, radiation, and the effects of centrifuging, many abnormal results have been recorded. It is evident from these results that the development of an organism, like the life of the organism itself, is conditioned by a delicate balance of environmental factors. The response of inherited potentialities to this balance in the development of normal organic structure links embryology very closely with the subject of heredity.

Although the word embryology is most commonly used to refer to the development of the embryo of the vertebrate animals, it also refers to the study of the development of embryos of invertebrate animals and plants.

EMBRYONIC FISSION. The subdivision of a single ovum at some stage in its development into parts which give rise to complete embryos. Polyembryony.

As a result of this process a single egg of many insects (parasitic *Hymenoptera*) and of some rotifers develops into several or many individuals.

EMBRYO (Yolk Sac). See **Yolk Sac**.

EMDE DEGRADATION. Modification of the Hofmann degradation method for reductive cleavage of the carbon-nitrogen bond by treatment of an alcoholic or aqueous solution of a quaternary ammonium halide with sodium amalgam. Also used as a catalytic method with palladium and platinum catalysts. The method succeeds with ring compounds not degraded by the Hofmann procedure.

EMERALD. This beautiful green variety of the mineral beryl has been known since ancient times and always prized as a gem, both because of its color and relative rarity. It is frequently cloudy or flawed, hence the expression "rare as an emerald without a flaw." The original source of emeralds seems to be the so-called Cleopatra's mines in Egypt, where in a range of low mountains about 15 miles (24 kilometers) from the Red Sea, they are found in schists. The quality of these emeralds is not high, but there is much evidence of considerable workings in a former period. See also **Beryl**.

Although emeralds are found in the Urals and to some extent elsewhere the most important locality for emerald is at Muso, Colombia, South America, about 75 miles (121 kilometers) northwest of Bogotá. These mines are believed to be in part at least the source of the emeralds that Cortez and the Spanish conquistadores ruthlessly seized and which were believed for a long time to have come from Peru.

The word emerald is probably derived from the Persian.

EMERY. See **Corundum**.

EMESIS. Commonly termed vomiting, this is the expulsion of the stomach contents through the mouth. This is accomplished by reversal of the direction of the normal waves of peristalsis in the gastrointestinal tract. Vomiting may accompany almost any disease, but in particular often accompanies viral gastroenteritis (intestinal flu), intestinal obstructions, kidney infections, intracranial pressures that may result from blood clots, concussions, meningitis, and tumors, and the ingestion of many offensive drugs and poisons. A person also may vomit when exposed to a particularly offensive odor or terribly unpleasant subject, as upon viewing an accident or other tragic event. Usually vomiting is preceded by nausea, an imminent desire to vomit, accompanied frequently be feeling of weakness, faintness, sweating, vertigo, headache, increased pulse rate, and salivation. Numerous drugs are available to encourage as well as to discourage vomiting.

EMETIC. A substance or drug that induces vomiting, either by direct action of the stomach or indirectly by action on the vomiting center in the brain.

EMF. See **Electromotive Force**.

EMISSION COEFFICIENTS (Einstein). In Einstein's derivation of the Planck radiation formula for a black body three coefficients were introduced which are of importance in the consideration of spectral intensities. Assume two quantum states m and n of a system such that the energy level E_m is higher than E_n, then transition from the upper to the lower state is accompanied by emission of radiation of frequency

$$\upsilon_{mn} = \frac{E_m - E_n}{h}$$

Assume further that there are a large number of identical systems (atoms or molecules) in equilibrium with black body radiation at a temperature T. Then the rate at which systems pass spontaneously from state m to n, by emission of radiation, is given by

$$-\left(\frac{dN_m}{dt}\right)_1 = A_m^n N_m$$

where A_m^n is known as *Einstein's coefficient of spontaneous emission*, and N_m is the number of systems in state m. But the rate at which systems can pass from the upper to lower state is also dependent upon the density of the radiation, $\rho(\upsilon_{mn})$, so that there is a second process defined by the relation,

$$-\left(\frac{dN_m}{dt}\right)_2 = B_m^n N_m \rho(\upsilon_{mn})$$

where B_m^n is known as *Einstein's coefficient of induced emission*.

Furthermore, the system can pass from the lower to the upper state by absorption of radiation, and the rate of this reaction will be given by

$$-\left(\frac{dN_n}{dt}\right)_2 = B_n^m N_m \rho(\upsilon_{mn})$$

where N_n = number of systems in quantum state n, and B_n^m is known as *Einstein's coefficient of absorption*. See also **Photoelectric Effect**.

EMISSION FACTOR. For air pollution produced during an industrial process, the ratio of output (air pollutants or other by-product such as waste heat) to some measure of productivity, such as input quantity of fuel or raw materials or amount of final product. As written by the U.S. Environmental Protection Agency, an emission factor is a representative value that attempts to relate the quantity of a pollutant released to the atmosphere with an activity associated with the release of that pollutant. These factors are usually expressed as the weight of pollutant divided by a unit weight, volume, distance, or duration of the activity emitting the pollutant (e.g., kilograms of particulate emitted per megagram of coal burned).

AMS

EMISSION (Photoelectric). Electron emission from solids or liquids resulting directly from bombardment of their surface by photons. See also **Black Body**; and **Planck Radiation Formula**.

EMISSION SPECTROSCOPY. Study of the composition of substances and identification of elements by observation of the wavelengths of radiation they emit as they return to a normal state after excitation by an external energy source. When atoms or molecules are excited by energy input from an arc, spark, or flame, they respond in a characteristic manner; their identity and composition are signaled by the wavelengths of incident light they emit. The spectra of elements are in the form of lines of distinctive color, such as the yellow sodium D line of sodium; those of molecules are groups of lines called bands. The number of lines present in an emission spectrum depends on the number and position of the outermost electrons and the degree of excitation of the atoms. The first application of emission spectra was identification of sodium in the solar spectrum (1814).

See also **Spectroscopy (Instrumental Analysis)**.

EMISSIONS. See **Acid Rain**; **Coal**; **Coal Conversion (Clean Coal) Processes**; **Petroleum**; **Pollution (Air)**; **Wastes and Pollution**; and **Water Pollution**.

EMISSIVE POWER. The emissive power of a body is equal to its emissivity multiplied by the emissive power of a black body at the same temperature. The emissive power of a black body (perfect or complete radiator) is the total radiation from the black body per unit area of radiating surface. See also **Wien Laws**.

EMISSIVITY. The ratio of the radiation emitted by a surface to the radiation emitted by a black body at the same temperature and under similar conditions. The emissivity may be expressed for the total radiation of all wavelengths (total emissivity), for visible light (luminous emissivity) as a function of wavelength (spectral emissivity) or for some very narrow band of wavelengths (monochromatic emissivity). Excepting for luminescent materials, the emissivity does not exceed unity.

EMISSION INVENTORY. A catalog or list of each emission source within a region, along with the location and emission height, type of air pollutants emitted, rate of emissions, initial emission characteristics such as buoyancy and initial momentum, and emission schedule if not continuous. Such a catalog often includes anthropogenic sources such as individual point sources from industry including some farming activities, line sources along roads, and area sources associated with quasi-uniform distributions of sources such as houses in a residential neighborhood. Biogenic area sources are also included, such as lawns, parks, farmland, pasture, and forests.

EMITTANCE. The radiant emittance of a source is the power radiated per unit area of the surface. This may be either the radiant emittance per unit range in wavelength, the spectral radiant emittance, or its integral over all wavelengths, the total radiant emittance. If the radiant emittance is evaluated by the standard luminosity function, it is called luminous emittance. For a perfectly diffusing surface, the luminous emittance is equal to p times the intensity luminance.

EMPHYSEMA. Distention of tissues by gas or air within the interstices. Emphysema is one of the most common disabling disorders of the respiratory tract, a condition characterized by overdistention of the lungs with air that cannot be expelled. At the microscopic level, the walls of the tiny alveoli stretch and eventually rupture, reducing the capacity of the lungs to exchange carbon dioxide and water. Chronic bronchitis of many years' duration almost always precedes the development of alveolar overdistension. Emphysema is a progressive disease that is most common in males over 40. Its cause is unknown, but excessive smoking and atmospheric pollution may be factors.

Obstructional emphysema is classified professionally as one of the chronic obstructive lung diseases (COLD). Others in the group include chronic bronchitis, bronchiolitis, cystic fibrosis, small airway disease, and Kartagener's syndrome. In obstructive emphysema, the lungs are sometimes called "floppy lungs," i.e., the lungs lack the important property of elastic recoil. The actual physiological cause of the disease is still poorly understood. Some researchers suggest that destruction of lung tissue may result from the actions of proteolytic enzymes. They have found that the plasma of emphysema patients lack certain substances (such as alpha globulin that is capable of neutralizing various proteolytic enzymes, including elastase) which are present in the plasma of a person without the disease. Some researchers have suggested that cigarette smoke may cause increased destruction of elastin by increasing the release of proteolytic enzymes from various lung cells.

X-rays of the chest of patients with emphysema indicate a number of characteristic features of the disease — hyperinflated chest, a low, flat diaphragm, wide interspaces, and small heart.

Symptoms of emphysema include a long history of cough and the raising of sputum, and shortness of breath. The shortness of breath is noticeable first on exertion and later with walking and other daily activities. Bouts of wheezing are not unusual. Weakness, lethargy, anorexia, and weight loss also may be present. In patients with significant emphysema, the chest is hyperinflated and at times fixed in the inspiratory position. On inspiration, the entire rib cage is lifted and accessory muscles of respiration are used. The diaphragm is flattened and hardly moves.

Although changes in the lungs are irreversible, it is possible to give the emphysema patient considerable relief and to increase the functioning capacity of the lungs. The patient should be encouraged to live a moderately active life, but to avoid any exertion that might increase shortness of breath. To control bronchospasm, patients should make regular use of bronchodilator aerosols. Thick and tenacious bronchial secretions can be thinned with sputum liquefiers, and deliberate coughing will help to bring them up. Exercises should be done to strengthen the abdominal muscles and permit more complete exhalation. Manual compression of the abdomen during expiration will aid in elevating the diaphragm. Elevating the foot of the bed will produce similar results.

Oxygen inhalation is sometimes necessary for relief of shortness of breath, but it must be used with caution. The safest method is with the intermittent positive pressure apparatus, which produces adequate ventilation and also removes carbon dioxide. A return to normal ventilatory function cannot be expected in patients with symptomatic emphysema. The normal course of events is relentless progression, and therapy is successful if it maintains the status quo or merely slows the downward trend. A patient with mild to moderate emphysema may live a long and comfortable life, provided all the factors producing bronchospasm and bronchial irritation are controlled. In contrast, the patient with severe emphysema has a greatly reduced life expectancy.

EMPRESS TREE. See **Catalpa Trees**.

EMPYEMA. Accumulation of pus in the pleural space, a condition known since the time of Hippocrates. Bacteria may enter the pleural space as the result of bronchopulmonary infections, such as pneumonia, lung abscesses, and bronchiectasis. Empyema may be a complication of thoracic (region between neck and abdomen) surgery. A direct injury to the chest region may be a cause. Rarely a rupture of the esophagus is a causative factor. Traditionally, pneumococcus was the principal infective agent (associated with pneumonia) seen in empyema, occurring in 5–10% of pneumonia cases. Early and effective antibiotic therapy in handling pneumonia cases has greatly diminished this cause. Today, *Staphylococcus aureus* is the major cause. *Pseudomonas aeruginosa, Klebsiella pneumoniae*, and *Escherichia coli* are also seen with some frequency. However, the possible causative agents are many, including anaerobes, *Bacteroides* species, *Fusobacterium*, and *Mycobacterium tuberculosis*, among others.

Present with empyema are fever, dyspnea, chest pain, and cough. With delayed treatment, weight loss usually will occur. Therapy is usually a combination of antibiotic administration and drainage. In acute empyema, thoracentesis or tube thoracostomy may be employed. Surgical drainage may be indicated in chronic empyema. The chronic form of empyema is less frequently seen because of advances in treatment of patients in the acute stage.

The appearance of the fluid from the pleural cavity in empyema varies. It may be watery (*serous*), pus-like (*purulent*), or a combination of the two (*seropurulent*). In deep wounds, in addition to the aforementioned procedures, irrigation (*lavage*) with saline solution may be indicated.

EMU *(Aves, Casuariiformes, Dromaiidae)*. The Emus are flightless inhabitants of Australian bush steppes. Three subspecies that lived on coastal islands were exterminated in the last 150 years. Ancestors of today's emus lived in the Upper Pleistocene (50,000–10,000 years ago) in Australia. See Fig. 1.

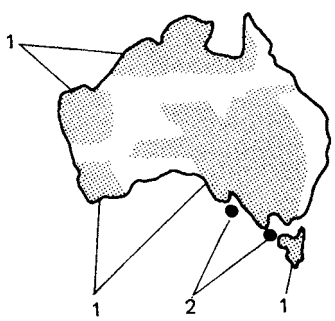

Fig. 1. Areas inhabited by the emu: (1) Emu (*Dromaius novaehollandiae*), Australia, extinguished in Tasmania and many parts of Australia: (2) black emu (*D. minor*), Kangaroo and King islands, extinct.

Externally they resemble the rhea. See also **Rhea**. They are about the same size but much more compact and heavier, weighing up to 55 kilograms (121 pounds). The main shaft and secondary shaft (aftershaft) are equal in length so that every feather appears to be double. The wings are small, and are hidden by the rump plumage. There are three toes. The gut and caeca are shorter than in rheas. Their food consists of fruits and seeds. There is no preen gland.

The emu is a fast runner; it can reach speeds of up to 50 kilometers (30 miles) per hour. Surprisingly, it also swims well and with endurance.

Incubation and raising young is the male's task, as in the rhea and cassowary. When two emus are paired they stand next to one another with lowered heads and bent necks. They sway their heads from side to side above the ground. Then the female sits down, the male sits down behind her, and he shuffles up and onto her and finally grasps the skin of her nape with his beak. At the same time he utters squeaking or purring sounds, and finally he runs away while the female remains sitting. The nest is a shallow depression located next to a bush. It is simply made with leaves, grass, and bark, and holds 15–25 eggs, which come from several females. Incubation takes 25 to 60 days; the great variability is due to pauses during which the male must leave to feed and drink for shorter or longer periods of time. At 2 to 3 years of age, the young are grown and capable of reproduction. See also **Ratites**.

ENAMEL. See **Paints and Coatings**.

ENAMELS, PORCELAIN OR VITREOUS. Porcelain enamel is a glassy coating applied to various metal substrates through a high (usually $>425\,^{\circ}C$) temperature fusion process. The resultant chemically bonded glass–metal composite exhibits properties which reflect the chemical, physical, electrical, and aesthetic properties of the glass while combining the strength, ease of fabrication, and durability of the metal. Porcelain enamels are formulated to develop specific properties on metals or alloys. See also **Conversion Coatings**; and **Composite Materials**.

The porcelain enamel is composed of various inorganic metal oxides fused between 1100 and $1400\,^{\circ}C$ to form an alkali borosilicate glass. The glass is rapidly quenched to produce either flakes by rapid chilling using water-cooled rollers, or glass granules by water quenching a narrow stream of molten glass. The resultant product is known as frit [CAS: 65997-18-4]. An enameled article is produced by applying either wet or dry finely ground frit particles to the metal substrate. The enamel is fired to form one or more glassy layers to achieve a desired surface finish and property group for the article. See also **Glass**.

Modern appliances were developed utilizing the chemical and physical properties of the glass-on-metal coatings on cast iron, sheet steel, and, more recently, aluminum. The wide variety of colors and textures and the long-term durability of porcelain enamel surfaces have been attractive to appliance producers as well as users. Enamels have been used on a wide array of kitchen utensils, cooking devices such as ovens and range tops, sanitary ware such as bathtubs and lavatories, water heater tanks, specially built industrial chemical vessels, cast-iron piping, storage silos for agricultural and industrial products, as well as architectural interior and exterior surfaces.

Porcelain enamels are used in modern mass transit facilities because of inherent fire resistance as well as ease of maintenance and durability in the face of highly corrosive atmospheres resulting from vehicular traffic. Newer applications of porcelain enamels include electronic substrates, pyrolytic self-cleaning oven interiors, microwave oven interiors, outdoor cookers, and fireplace liners as well as wood-stove exteriors, writing boards for erasable markers, institutional surfaces such as bathroom stalls and hospital operating room walls that need to be easily disinfected, and subway car interiors and elevator walls that are durable and easy to clean. Porcelain enamel surfaces are frequently used in food contact applications. The glassy nature of porcelain enamels has a significant effect on encapsulating and minimizing any solubility of constituents. Enamels can also be formulated to have specific acid, alkali, and abrasion-resistant properties.

The early history of enameling is associated with the craft of enameling art. Porcelain enamel provides a low cost, extremely pleasing, nonporous protective and corrosion-resistant surface, using mass production techniques. There are many excellent summaries of the history of porcelain enameling and artistic uses of enamels. Porcelain enameling art is a continuing form of expression for many artists. Although enameling has been known for at least four to five thousand years, only in the twentieth century has the widespread use of enamels on base metals such as cast iron, sheet steels, and aluminum alloys flourished.

Enameling Process

The frit-making process involves all the technology ranging from proper selection of raw materials through mixing and smelting to uniform production of frit. Box smelters, predating continuous smelters, are used for small quantity production. Electric smelting of porcelain enamel glasses has been carried out in the United States and abroad. The most prevalent method of making porcelain enamel glass is in continuous smelters. Continuous smelters may produce from 700 to 1200 kilograms of frit

per hour. First, the glass is smelted from raw materials. In a continuous furnace the thoroughly mixed raw batch is fed in at one end and molten glass flows out at the other end. Decomposition, gas evolution, reaction, and dissolution occur during smelting. Modern smelters, which are fired by natural gas and often pure oxygen, are equipped with pollution control equipment on the smelter exhaust system.

After the molten glass has become a homogeneous liquid, it is poured in a thin stream into water or between closely spaced, water-cooled rotating metal rollers. This quenched glass, termed frit, is a friable material easily reduced to small-sized particles by a ball-milling operation. Ball-milling the glass frit into small-sized particles can be carried out whether the frit is to be used wet or dry.

Ball-mill grinding of the glass is accomplished using porcelain or high alumina balls 1.5–5.0 cm in diameter. Mill size, speed, and charge, and ball size and charge are important parameters for the determination of the milling time required for optimum size distribution in prepared slip. Ground-coat enamels are ball-milled to a fineness of 95% of solids smaller than 74 μm (<200 mesh). Cover coats are ground more finely, to 98% of solids finer than 44 μm (325 mesh). Dry powders are used for dry process cast-iron enameling and for electrostatic application on sheet steel. Dry powders are also prepared and marketed for the subsequent preparation of slurries and slips used in wet-process application techniques.

For conventional wet processing of sheet steel, the porcelain enamel frit is ball-milled using clay, certain electrolytes, and water to form a stable suspension. This clay-supported slurry of small particles is called the slip and has the consistency of a heavy cream. The ingredients of the mill batch are carefully controlled. The amount and purity of all materials in the mill, including the clay and water, affect the rheological character of the slip as well as a number of the properties of the fired enamel such as chemical resistance, reflectance, gloss, color, and abrasion resistance.

Ground coats are applied to metal by spraying, dipping, or draining as well as electrostatically. Large articles (washing machine tubs and stove chassis) may be coated only by spraying or flow coating the slip, whereas small articles may be dipped into a tank of ground-coat slip. Cover coats may be applied by similar methods, by electrostatic spraying (wet and dry powder), or by electrophoresis. See also **Electrophoresis**.

The dry powder process has several additional advantages over the wet process. For example, much less waste of enamel occurs because the dry over-spray is airborne and recycled in a closed system. No-pickle ground coats have broadened the application of both wet-process and dry-process systems. These enamels are applied over cleaned-only metal. Thus, the problems of disposing of pickling acid wastes containing iron sulfates and nickel wastes are eliminated.

Dry-process cast-iron enameling involves the application of the cover coat by dusting or dredging the dry glass powder (using a long-handled vibrating sifter) onto the heated cast-iron article. The cast iron, which has been previously ground coated, is removed from the furnace (870 °C and higher) for the dusting operation and then is returned to the furnace to complete the fusion and maturation of the glass. Generally, two or more dusting and heating cycles are required for the development of an adequately thick and uniform coating.

Metals for Enameling

Sheet steel is usually bought in precut sheets or coils for subsequent stamping and pressing into shapes. The steels are chemically formulated to make them suitable for the fabrication and porcelain enameling operations. The ASTM has classified enameling-grade steels into Type I and Type II (A or B) as well as specifying various qualities such as commercial, drawing, and drawing quality special killed. Type I has an extremely low carbon level, commonly produced by decarburizing in an open-coil process. This material is suitable for direct cover coat enameling practice. The less expensive Type II has moderately low carbon and is suitable for ground coat enameling operations.

The basic steel types are undergoing gradual modifications to adapt the steels to the continuous casting process. This has led to changes in the minor constituents of steel such as boron, nitrogen, titanium, and other alloying elements. Titanium is used to tie up the carbon as titanium carbide [CAS: 12070-08-5], TiC, and the boron nitride [CAS: 10043-11-5], BN, and titanium nitride [CAS: 25583-20-4], TiN, provide void sites for hydrogen accumulation after firing. See also **Carbides**; and **Nitrides**.

Cast irons for enameling contain between 2.8 and 3.7 wt % carbon; the more usual content is between 3.25 and 3.6 wt %. The carbon is usually found in two forms: graphitic carbon and combined carbon. Some additional elements in the cast iron are silicon, manganese, sulfur, and phosphorus. The cast iron known as gray cast iron is the most widely used for enameling purposes. Before enameling, a casting must be cleaned, usually by abrasively blasting the surface with sand or steel shot.

The most commonly used aluminum alloys for enameling are 3003 P.E. grade and 6061 P.E. grade. It is important that the magnesium and copper contents of the alloys be kept to a minimum; otherwise, spalling of the enamel can occur.

Metals such as the austenitic series, Types 301–347, and the ferritic series, Types 409–446, of stainless steels may be enameled, as well as a number of other alloys. The metal preparation usually consists of degreasing and grit blasting. Copper, gold, and silver are also enameled. These metals are usually prepared for application by degreasing. Copper is pickled using either a nitric acid [CAS: 7697-37-2] or a sulfuric acid [CAS: 7664-93-9] solution, followed by a dilute nitric acid dip. Silver may be pickled in hot dilute sulfuric acid followed by a dip in a nitric acid solution.

Sheet-steel parts are formed by stamping, bending, and shearing. Many parts require welding, which needs to be carried out in a uniform, smooth manner so that the welded joint can be enameled without defects. Cast-iron parts are formed by the usual cast-iron foundry methods; however, additional care is given to prevent contamination of the surface. Surface contamination causes defects in the enamel, particularly blisters and bubbles. Aluminum metal can be formed in sheets, extrusions, and as castings.

Enameling cannot be successful unless the metal is thoroughly cleaned and kept clean until the final coat is fired. Simply touching the surface with a hand can cause defects. Cast iron, thick steel parts, and aluminum castings may be sand-blasted. The thickness precludes the danger of deformation resulting from metal loss. Sand, silicon carbide, and steel grit are satisfactory abrasives. Products made from thin sheet material are most satisfactorily and most economically cleaned by chemical methods that require alkali and soap solutions to remove grease and dirt, and acid solutions to remove oxidized metal.

Firing can be carried out in intermittent box-type furnaces or continuous furnaces. The dryer and the furnace form one continuous unit or function as separate units in the continuous firing process. Most industrial furnaces are fiber-lined (low thermal mass), which lowers cost and downtime between firing schedules. In a continuous tunnel-type furnace, each piece progresses through the furnace on a conveyer supported on alloy firing racks designed to withstand the repeated thermal cycles. Very efficient U-type furnaces, in which the outgoing ware preheats the incoming ware, have been built. Gas-fired furnaces have alloy muffles to separate the combustion gases from the furnace atmosphere. Electrically fired furnaces have special alloy resistance-heating elements on the surface of the refractory lining.

Enamels are fired to mature coatings in a matter of minutes. The firing time in the hot zone of a continuous furnace is about 3–6 minutes at 750–850 °C. Cover-coat firing is generally carried out at similar temperatures, especially when two-coat–one-fire application processes are used. For two-coat enameling, it is preferable to fire the ground coat about 30 °C higher than the subsequent cover-coating, in order to minimize hairlining in the cover coat and pull-through of the ground coat.

Enamel firing temperature is dictated by the coating composition, metal thickness, and the type of metal used. Enamels for aluminum are fired at 510–540 °C, whereas those for high temperature alloys (qv) are fired up to 930 °C.

The industrial porcelain enameling process can be automated to a great degree, from metal pretreatment (pickling) through the firing process. Flow-coating, electrostatic dry powder spraying, or electrophoretic deposition can be machine programmed. Robot sprayers controlled by a computerized sensing mechanism can coat complex shapes, and flow-coaters can be programmed to uniformly coat complicated shapes such as dishwasher cavities and washing machine baskets. Automated coating and firing of cast iron has also been achieved.

The energy needed to heat 0.45 kg of enamel ware and tooling to the firing temperature ranges from 400–1000 kJ/kg (300–450 Btu/lb) and depends on such factors as furnace loading, tool weight, and, in

gas-fired furnaces, flue-gas losses. Advances in furnace design, firing systems, and low thermal mass insulating materials have reduced the total energy needed over the years. Thus overall energy requirements for enameling have dropped as much as 50% since the 1970s. Technologies such as electrostatic frit powder application, various two-coat–one-fire processes (e.g., dry-over-dry, dry-over-wet, and wet-over-wet), as well as reductions in the metal pretreatment requirements have also contributed.

Composition

Porcelain enamels are basically alkali borosilicate glasses. These enamels are complex, however, because of the large number and types of oxides which are needed to develop proper adherence and functional properties. Network-forming ingredients and modifiers are used as in normal glass making practice. See also **Glass**. The principal network formers are SiO_2, B_2O_3, and P_2O_5. Modifiers include the alkali metal oxides (Na_2O, K_2O, and Li_2O) and alkaline-earth metal oxides (CaO, BaO, and SrO). Other common oxides include Al_2O_3, MgO, ZrO_2, ZnO, TiO_2, Sb_2O_3, and the halide F^-. Transition-metal oxides such as Fe_2O_3, CoO, NiO, CuO, and MnO_2 are used for adherence to the sheet-steel substrate and color development in ground coats. Continuous-cleaning (catalytic) oven enamels have high percentages of the transition-metal oxides to achieve cleaning effectiveness. Less frequently used oxides of cerium, cadmium, lead, and tin are used in sheet-steel, cast-iron, and aluminum enamels.

Enamels used on cast iron and aluminum have traditionally been composed of SiO_2, B_2O_3, P_2O_5, and PbO. The lead oxide produces good surface quality, fusibility, and acid resistance when properly formulated with other oxides. More recently some nonlead-bearing compositions have been developed for both cast-iron and aluminum metals. Glasses containing lead oxide are not recommended for food contact surfaces.

Porcelain enamels meet a variety of performance characteristics required for different applications. The common characteristics of all enamels include good adherence to the substrate and good thermal expansion fit to the metal. Specific properties depend on usage; for example, acid and alkali resistance, hot water resistance, abrasion resistance, thermal shock resistance, high gloss, high reflectance, specific color, heat resistance, and cleanability.

The recrystallization of titanium dioxide in a cover-coat glass is very important to the development of thin, highly opaque finish coats. Titania, TiO_2, is the primary opacifying agent for white finish coats. Two polymorphic forms of titania, anatase and rutile, may be present in the enamel. See also **Titanium**. Anatase is preferred because anatase crystals are present in the size range (0.1–0.2 μm) for maximum reflectance, and therefore generate the most desirable bluish white color.

Properties

Thermal expansion measurements are typically carried out on dilatometric equipment consisting of a fused quartz pusher rod inside a tube of the same material.

A porcelain enamel glass becomes less viscous as the temperature is increased during firing. Above the softening point, the enamel is relatively fluid and conforms to the metal surface. As the porcelain enamel is cooled from the firing temperature of 750–800 °C to the softening point, the fluid glass does not retain stress. However, as cooling proceeds below the softening point, the expansion (or contraction) or the coating exceeds that of the steel, and tensile stresses begin to develop in the coating. On further cooling, the stress increases until the temperature at which the expansion of the glass equals that of the metal. With still further cooling, the coefficient of expansion of the glass is less than that of the metal, coating tensile stresses decrease, and compressive stresses develop and are retained at room temperature.

Thermal expansion comparisons of the coating and metal have often been used to determine residual stresses in the coatings.

The modulus of elasticity of the enamel glass–steel composite system has been shown to lie between the modulus of the glass and that of the metal. The composite modulus can be calculated by $E_c = (E_m - E_e)Q^3 + E_e$, where E_c, E_m, and E_e are the modulus of elasticity of the composite, the metal, and the enamel, respectively; and Q = thickness of the metal divided by total thickness of the composite.

Residual compressive stress in commercial ground coat enamels varies with enamel thickness.

Thinner coatings have higher compressive stresses, other factors being equal. Higher residual compressive stress in the coating also can be obtained by using enamel glass having a lower thermal expansion coefficient, or a metal having a higher expansion coefficient or a higher modulus of elasticity.

Strain in enamels that leads to failure is on the order of 0.002–0.003 cm/cm. Thinner enamels having higher residual compressive stresses are more flexible and can be strained to a greater degree.

Some other physical properties of enamel glass are density, from 2.5–3.5 g/mL; Mohs' hardness, 5–6; tensile strength, 34–103 MPa (4,900–15,000 psi); compressive strength, 1380–2760 MPa ($2–4 \times 10^5$ psi); modulus of elasticity, 55–83 GPa ($8–12 \times 10^6$ psi); and dielectric constant, 5–10.

Porcelain enamel allows the designer great variety with regard to color, texture, and aesthetic appeal. The enamels exhibit exceptional color stability whether used in domestic interiors or architectural exteriors. Colors should be grouped according to the type and the usage of enamel. Categories are (1) ground coats, which can generally be used by themselves as a finish coat or a base coat; (2) cover coats that are self-opacified; and (3) clear and semiopaque enamels, used for developing a wide range of colors. Transition-metal oxides used principally to develop a bond between the glass and the substrate metal also produce specific colors. Those range in shades of grays from blue to yellow and red to green. Combinations of each are also possible. Cobalt oxide is the principal colorant for blue, nickel oxide, and iron oxide, Fe_2O_3, for green, manganese dioxide for red, and nickel oxide with other oxides for yellow.

Cover coats such as self-opacified titanium enamels derive their color from titanium dioxide crystals nucleated in the glass during firing of the coating.

Textures in enamels are developed by the use of semicrystalline glasses or by the addition of refractory materials such as quartz, alumina, zirconia and zircon, feldspar, various clays, and titania. More refractory glasses are also added to impart a lower gloss and a texture.

Colored enamels are produced by tinting the titania enamels during the smelting operation through the addition of colorant oxides. Control of enamel color is most popularly done using computer-controlled color measuring systems consisting of spectrophotometric detectors (380–720 nm) and hardware to measure, integrate, evaluate, report, and store the color data. The most common systems in use are the Commission Internationale de l'Eclairage (CIE) $L^*a^*b^*$ and Rd, *a,b* color scales and various illuminates.

The decoration of enamels is primarily done by silk screening. Other methods include indirect printing such as use of decals (decalcomania), and indirect lithographic, thermoplastic, and total transfer printing. Photographic printing is also done as a specialty.

The microstructure of enamels is of importance to understanding and thus being able to control the macroproperties of the enamel. The microstructure is also related to thickness of the enamel and its firing history. Porcelain enamels typically have a bubble structure which is a result of gas evolution during firing.

The thickness of the enamel layer varies with the type of use and metal.

The study of cross sections is extremely valuable as a way of tracking defects and determining sources of contaminant once the enameled article has been produced.

The development of standards for porcelain enamel coatings is shared by several national and international organizations. Enamel is tested for abrasion resistance, adherence, impact resistance, thermal shock resistance, resistance to chemical attack, and enamel defects.

ENANTIOTROPY. The property possessed by a substance of existing in two crystal forms, one stable below, and the other stable above, a certain temperature called the transition point.

ENARGITE. A grayish-black or iron-black orthorhombic mineral Cu_2AsS_4. It is an important copper ore, occurring in veins of small crystals or granular masses. Often contains antimony up to about 6% and sometimes, small amounts of iron and zinc.

ENCEPHALITIS. An infection of brain tissue usually caused by one of several viruses, but which also may be caused less frequently by the ingestion of a drug or toxin, a systemic fungal infection, or by a space-occupying lesion, such as a tumor or subdural hematoma. Postinfectious encephalitis also may occur with mumps, measles, rubella, or chickenpox. The incidence of encephalitis from these infections is no longer common with the exception of rubella, for which no satisfactory vaccine is yet available. The symptoms and course of encephalitis are quite variable, depending upon the causative agent and initial condition of the patient. In encephalitis resulting from some viruses, the symptoms may be a brief illness, so mild that the patient does not seek extra rest; or it may be a grave illness with high fever persisting for several days or weeks. Stupor and weakness of eye muscles are the most notable symptoms in some patients, while less commonly there may be violent delirium, insomnia, and involuntary muscle activity. Muscular rigidity and rhythmical tremor may be seen, as in paralysis. There may be a rapid fatal termination, or the illness may be chronic. Unless the disease occurs during an appropriate viral season for which epidemiological data are available, diagnosis can be difficult. Specific diagnosis usually requires extensive laboratory examination of blood and cerebrospinal fluid. In the case of enteroviruses, throat and stool cultures may be a useful diagnostic tool. In the case of herpes simplex type 1 encephalitis, a CAT scan will reveal involvement of the temporal, frontal, or parietal lobes. In some cases, open brain biopsy may be indicated for the purposeof cerebral decompression and of ruling out lesions, such as brain abscesses, tumors, or fungal infections.

Simple viral encephalitis usually is self-limiting, running a course of about two weeks. Authorities indicate that less than 50% of the roughly 2000 cases of encephalitis reported in the United States each year are properly diagnosed. The incidence in any given year depends primarily on whether arboviral or enteroviral epidemics occur in any givenyear. The togaviruses are responsible for most cases of the disease. Other agents, less frequently encountered, include Colorado tick fever virus, varicella-zoster virus, mumps virus, and herpes simplex type 1 virus. Sometimes aseptic meningitis caused by coxsackievirus B presents essentially an encephalitic picture.

ENCODER (Computer System). A device or subsystem which will accept an input and produce an output in coded form. This definition includes digital-logic configurations, which convert a digital input word in one code into an output word in a different code. Examples would include a decimal-to-binary or a decimal-to-octal decoding circuit. Encoder also refers to a device or subsystem that converts an analog quantity into a digital representation by the use of a quantization technique. See also **Encoder (Electromechanical)**.

ENCODER (Electromechanical). A device that provides position, direction, speed, and displacement information. The rotary encoder, frequently used in automated industrial systems, satisfies the IEEE definition of *encode: "to produce a unique combination of a group of output signals in response to each group of input signals."* Sometimes the comparison of an encoder with the familiar micrometer caliper (Fig. 1) is made. With the caliper, the micrometer screw is turned to accurately measure the dimension of a piece held between the jaws of the device. The micrometer barrel is divided so that measurements to an accuracy of one-thousandth of an inch (0.025 mm) or better can be made. Each revolution of the barrel advances the micrometer spindle 25 thousandths of an inch, thus requiring 40 complete revolutions of the micrometer screw to advance the micrometer spindle one linear inch. Of course, the larger the barrel, the more divisions per turn to read, and consequently the greater the accuracy. Instead of manually reading and interpolating a scale, the encoder translates the simple analog rotation into discrete electrical signals that are directly related to shaft position and hence to the distance traveled. Shaft encoders are of two basic types — *absolute and incremental.*

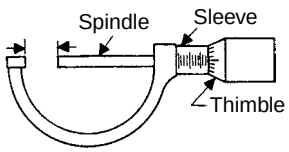

Fig. 1. An encoder, in operation, resembles a micrometer caliper.

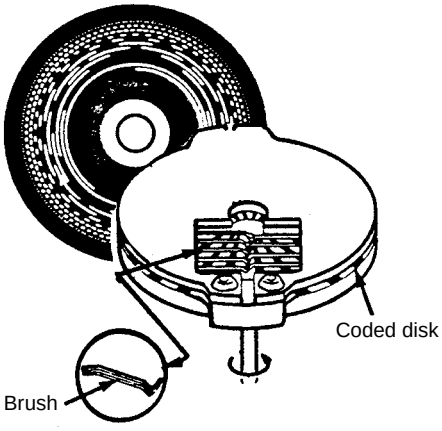
Absolute Encoder. This device provides a unique output signal for each single or multiple revolution of shaft gearing. The device outputs a complete binary code (digital output) for each position. Absolute encoders are generally used in applications where position information rather than change in position is important. These devices have an individual digital address for each incremental move and thus the position within a single revolution can be determined without a starting reference. By gearing two or more absolute encoders together, so that the second advances one increment for each complete revolution of the first (reminiscent of a mechanical counter), the range of absolute position can be extended.

The disk type is manufactured with a coded track pattern to provide a digital signal output (0-1 or on-off). The absolute shaft encoder uses either (a) contact (brush), or (b) non-contact schemes of sensing position. The contact type is shown in Fig. 2(a). The device incorporates a brush assembly to make direct electrical contact with the electrically conductive paths of the coded disk for reading address information. The noncontact type, shown in Fig. 2(b), uses optical means (commonly photoelectric) to sense position from the coded disk. In this case, the disk consists of opaque and transparent (to light) segments. These segments are laid down in the same pattern as the electrically conductive paths used by the brush-type encoder.

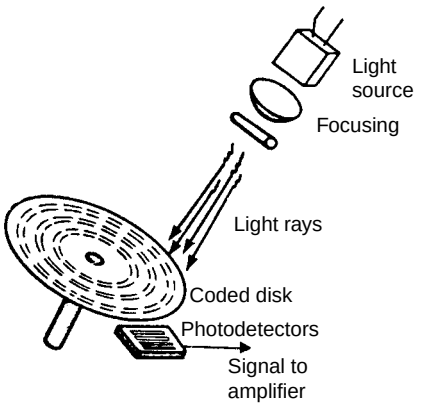
The principle of operation is demonstrated by Fig. 3. The number of tracks may be increased as well as the number of segments around the disk, until the number of graduations equals the desired resolution. Since position information is directly on the coded disk assembly, the disk has a built-in "memory system" and a system power failure will not cause this information to be lost. Thus, it is not necessary to return to a "home" or "start" position after reenergizing power.

Incremental Encoder. This device produces a symmetrical pulse for each incremental change in position. Pulses from the incremental encoder are counted for each incremental movement from a calibrated starting point in an up/down counter to track position. The operating principle of an incremental encoder (also sometimes called *optical encoder* or *digital tachometer*) is shown and described by Fig. 4. Another area that is application-dependent is the disk assembly. Depending upon the resolution and accuracy, the material used may limit the encoder for some applications. The disk can be made by using slits in metal, or by using lines on glass. The metal disk is normally a low-resolution device. Glass provides higher resolution and accuracy, but must be handled with care to avoid breakage.

An incremental encoder can be either *unidirectional* or *bidirectional.* A unidirectional encoder yields information about speed or amount of



(**a**)



(**b**)

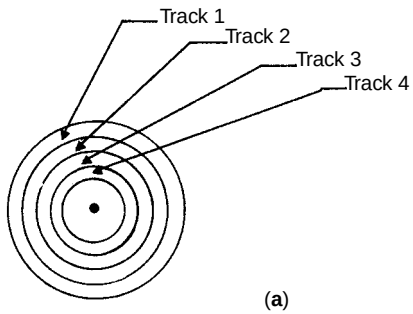
Fig. 2. Absolute encoder: (**a**) coded-disk type with contact or brush; (**b**) non-contact, photoelectric type.

displacement. A bidirectional encoder provides this same information as well as *direction* information, i.e., clockwise or counterclockwise rotation. Direction information is obtained by monitoring two signals electrically separated by 90 degrees. As shown in Fig. 5, phase relationship between these two signals is utilized to determine rotation direction. Incremental encoders may have several tracks. As illustrated, a second track can be used for a "zero" index or "home" reference pulse.

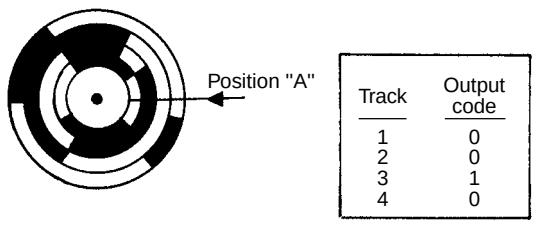
Specifying parameters applicable to incremental encoders include the following. (1) *Line count*, which is the number of pulses per revolution. The number of lines is determined by the positional accuracy needed for a given application. Standard line counts commercially available range from 100 to 1000 pulses/revolution. In some specially designed "self-contained" encoders, higher line counts are obtainable. (2) The *output signal* can be either sine or square-wave. (3) The *number of channels*. Either one or two channel outputs can be provided. The two-channel version provides a signal relationship to obtain motion direction. In addition, a zero index pulse can be provided.

A typical servo application using digital feedback is shown by the block diagram of Fig. 6. The input command signal loads an up/down counter. The number of pulses in the counter represents the position the load must be moved to. As the motor accelerates (Fig. 7), the pulses emitted from the encoder continue at a faster rate until motor run speed is obtained. During run, the pulses are emitted at a constant frequency directly related to motor speed. The counter counts down to "zero" and, at a determined position, the motor is commanded to slow down. This is to prevent overshooting of the desired position. When the counter is within one or two pulses of the desired position, the motor is commanded to decelerate and stop. The load should now be in position.

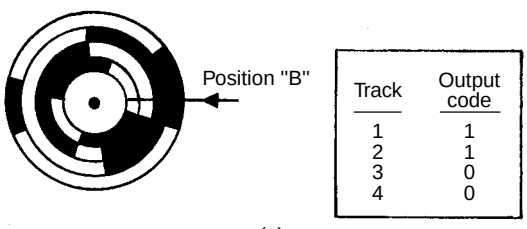
Representative Problem. An incremental encoder is required on a milling machine to provide a digital readout display. The display must read directly in thousands of an inch. The total travel of the milling machine bed is 36 inches. The travel is regulated by a precision lead screw which moves the milling machine bed $\frac{1}{10}$ inch for every revolution (360°) of the lead screw. Since the display must read directly in $\frac{1}{1000}$ inch increments,



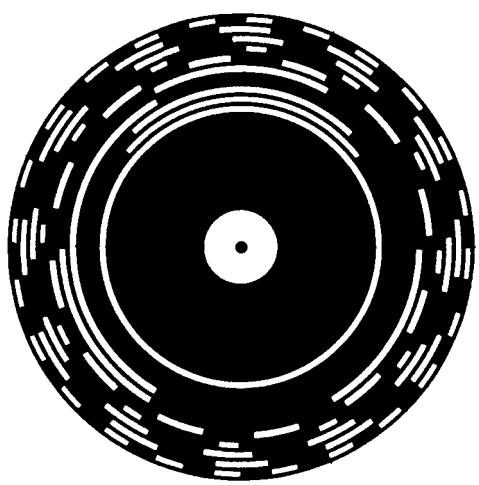
(**a**)



(**b**)



(**c**)



(**d**)

Fig. 3. Operating principle of absolute encoder: (**a**) Several concentric tracks (only four shown in oversimplified diagram) are present on the disk. (**b**) Portions of each track are either opaque or transparent to light emanating from a point source. The pattern of opaque/transparent segments is designed so that for every degree of rotation (360°) of the disk, a unique coded address will be presented. The detail required is not shown in diagrams (**b**) and (**c**). When the disk is in position "A" as shown in (**b**), the segments on tracks 1 and 2 are transparent, thus each yielding an output of 0; the segment on track 3 is transparent, thus yielding an output of 1; the segment on track 4 is opaque, yielding an output of 0. Thus, the complete address is 0010. In (**c**), the disk has rotated so that tracks 1 and 2 are opaque and tracks 3 and 4 are transparent, providing the address of 1100. A reasonable representation of a full disk with 10 tracks is shown in (**d**).

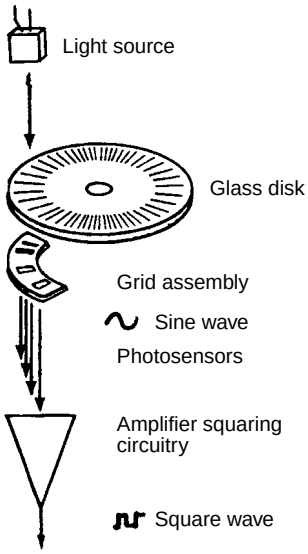


Fig. 4. Incremental encoder. This device provides an output pulse signal as the disk assembly rotates; thus total information is obtained by counting pulses. The disk is manufactured with opaque lines which are aligned with a grid assembly. A light source and photosensors complete the assembly. Light from a light emitting diode (LED) or tungsten filament lamp passes through the transparent segments of the disk and is sensed by photosensors. As the disk assembly rotates, an alternating light/dark pattern is produced. The output from the photosensors is a sinusoidal wave that can be amplified in some situations. Electronic processing transforms this signal into a square-wave pulse for digital circuitry compatibility.

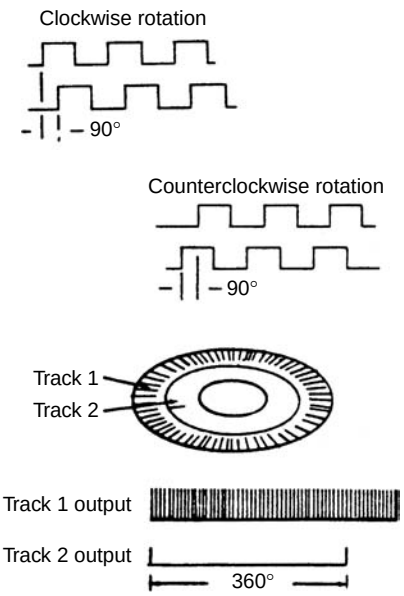

Fig. 5. Top of view shows phase relationship between two signals for determining rotation direction. Incremental encoders may have several tracks. As shown here, a second track can be used for a "zero" index or "home" reference pulse.

the encoder must provide 100 pulses per revolution where each pulse represents 0.001 inch.

Solution. An encoder disk is connected to the shaft of the motor and the shaft is rotated. A pulse train is generated by photoelectric means as previously described. These pulses are fed directly into an appropriate electric counter with digital display. Starting from a known reference position, the operator resets the counter to zero. The operator moves the milling machine bed from the zero position until the number 19.031 is shown on the counter. The operator is now exactly 19.031 inches from the zero position.

In some systems, the number 19.031 is entered on the counter's preset function. When the counter counts 19,031 pulses, it stops the travel automatically. At this position, a hole is bored to a specific depth. An

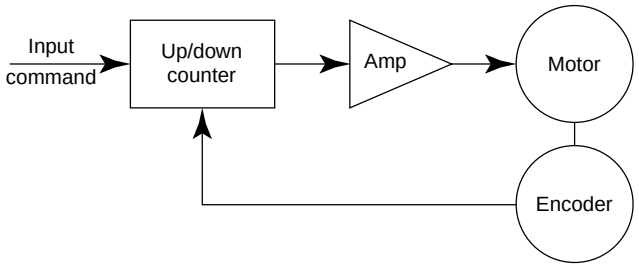

Fig. 6. Block diagram of servosystem using digital feedback to an up/down counter.

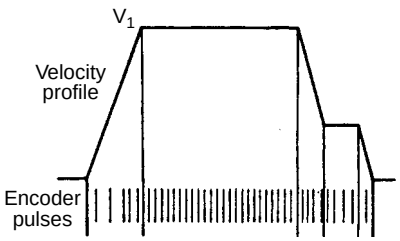

Fig. 7. As the motor accelerates, the pulses emitted from the incremental encoder (digital tachometer) continue at a faster rate until motor run speed is attained. During run, the pulses are emitted at a constant frequency directly related to motor speed. The counter counts down to "zero" and, at a determined position, the motor is commanded to slow down — to prevent overshooting the desired position. When motor is within two pulses of desired position, the motor is commanded to decelerate and stop.

encoder on the z-axis of the machine controls the drilling to a specified depth. Add to this an encoder for bed travel on the other axis, plus tape control for the preset functions and sequences, and automated numerical control is the result.

Encoder Interfacing. The square-wave output is derived, as previously mentioned, from electronic processing, or shaping circuitry within the encoder package. The output signal level is nominally 5 V and zero (logic "1" is 2.4 V minimum and logic "0" is 0.4 V maximum). Signal distortion may be a result of cable capacitance (length) — the longer the cable, the more distortion. Beyond 30 feet (9 meters) in length, the signal must be reshaped if reliability is not to suffer. Good shielding must be used to keep noise to a minimum.

The sine wave output normally will be used where the designer performs the signal shaping somewhere else in the system, i.e., other than in the encoder package. Signal levels are typically 50 to 100 mV peak to peak into a 2 k ohm load at 40 kHz. A disadvantage is susceptibility to electrical noise because the signal is at such a low level. Signal cables must be isolated from other ac lines and noise generators. Twisted, shielded wires should be used. Signal reshaping usually is not required for distortion, since the receiver is a signal shaper. Distortion is not significant where cable lengths do not exceed 30 feet (9 meters).

In addition to radiated noise, the encoder may be affected by transients caused by its power supply voltage. The regulation is typically specified at $\pm 5\%$ variation, without noise spikes. Spikes, of course, may damage the light source and encoder electronics.

Other Encoder Problem Areas. Of prime importance is the tolerance on the hub inner diameter into which the glass disk is mounted, the motor shaft outer diameter, and the motor shaft's total indicated runout (TIR). If the hub is oversized and/or the shaft undersized, the unit will exhibit eccentricities when mounted and thus yield a moving center rather than a fixed center. Eccentric mounting causes a frequency-modulated signal to be superimposed on top of the encoder output signal. If the sensor reading the line count traces a path on the disk, as shown in Fig. 8, the resulting output signal will be frequency modulated. If the motor shaft has a larger TIR, the disk assembly will "wobble" as shown in Fig. 9. This will produce an amplitude-modulated signal due to the varying illumination of the sensor. This can be corrected by (1) mounting the hub onto the motor shaft and machining, or (2) by utilizing dual optical pickoffs.

See also **Automation**; **Numerical Control**; and **Position and Displacement Measurement**.

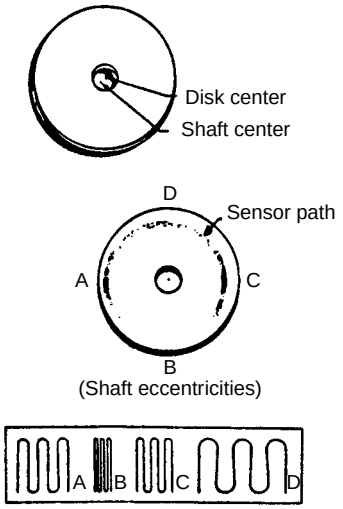

Fig. 8. Shaft eccentricities. If the hub is oversized and/or the shaft is undersized, the encoder will exhibit eccentricities when mounted, thus yielding a moving rather than a fixed center. Eccentric mounting causes a frequency-modulated signal to be superimposed on the encoder output signal. If the sensor reading the line count traces a path on the disk, as indicated here, the resulting output signal will be frequency modulated.

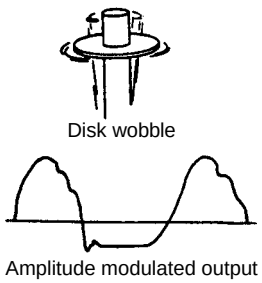

Fig. 9. Disk wobble. If the motor shaft has a large total indicated runout (TIR), the disk assembly will wobble. This will produce an amplitude-modulated signal due to varying illumination received by the sensors. This condition can be corrected either by first mounting the hub onto the motor shaft and machining, or by using dual optical pickoffs.

ENCROACHMENT METHOD. See **Meteorology**.

ENDANGERED SPECIES. For a variety of reasons, several important species of life on Earth have been threatened by extinction during the last several decades. Greater awareness of Earth's environment has progressed much over the past half-century, out of which a serious awareness of the effects of environmental change on the existence of various life forms has developed. Polluted air and water affect the natural habitats of most species in one way or other. Other anthropogenically created alterations, such as overfishing, destroying forests and wetlands, also adversely affect some species. Several examples of threatened species are given throughout this *Encyclopedia*. As of 1994, the species regarded as endangered or seriously threatened are listed in Table 1. This is only a small part of the total list as developed by naturalists, conservationists, and environmentalists.

TABLE 1. ENDANGERED AND THREATENED SPECIES WORLDWIDE

Mammals	Wolf, Gray and Red
	Zebra, Cape Mountain
Bear, Baluchistan	
Bear, Polar	Reptiles
Cat, Pardel Lynx	
Cat, Little Spotted	Crocodile, American
Cheetah	Iguana, Anegada Ground
Chimpanzee, W. African	Python, Indian
Cougar, Florida	Snake, Atlantic Saltmarsh
Deer, Key	
Deer, Marsh	Amphibians
Elephant, Indian	
Gazelle, Clark's	Frog, Israel Painted
Gazelle, Slender-Horned	Toad, Mount Nimba
Gorilla, Mountain	
Ibex, Walla	
Jaguar	Fish
Leopard	
Leopard, Snow	Catfish, Giant
Lion, Asiatic	Trout, Cutthroat
Mandrill	
Monkey, Long-Haired Spider	Birds
Ocelot	
Prairie Dog, Utah	Albatross, Short-Tailed
Pronghorn, Sonoran	Condor, California
Rat, Morro Bay Kangaroo	Crane, Whooping
Rhinoceros, Great Indian	Crow, Hawaiian
Sloth, Maned	Kestrel, Mauritius
Tiger	Parrot, Paradise
Wallaby, Bridled Naitail	Stork, Oriental White
Whale, Humpback	Woodpecker, Ivory-Billed

ENDEMIC. A term applied to a disease caused by agents (especially of an infective nature) that are constantly present in a particular human community, leading to a generally higher incidence of the disease in that community than elsewhere. See also **Foodborne Diseases**.

ENDERS, JOHN FRANKLIN (1897–1985). Enders was an American microbiologist known for his work in cultivating viruses in tissue culture, notably the poliovirus, which led directly to the development of vaccines for poliomyelitis as well other diseases such as mumps, measles and rubella.

Born in West Hartford, Connecticut, to a local banker, Enders followed a meandering path until he settled on biological research as a career. He began his studies at Yale University in 1917 but had to leave early because of World War I. After serving in the American Air Force as a pilot he returned to Yale from where he graduated in 1920 with a degree in English. He dabbled briefly in real estate but quickly decided to go back to academic life and entered Harvard University for graduate studies in English and ancient languages. He got a Masters degree in 1922 and began a doctorate, but influenced by Harvard bacteriology professor Hans Zinsser, decided to switch to biology. He received a PhD in microbiology in 1930 and remained associated with Harvard for the remainder of his career, rising through the ranks from assistant professor to full professor of bacteriology and immunology in 1956, and University Professor in 1962. During this period he established a laboratory of infectious diseases research at the Children's Medical Center, where he conducted most of his research.

Enders' best known work, for which he and his colleagues Thomas Weller and Frederick Robbins won the Nobel Prize in Physiology or Medicine in 1954, was the development in 1949 of techniques for growing animal viruses *in vitro*, i.e. in artificial culture in the laboratories. The inability to grow viruses in this manner was one of the major reasons for the lag in the development of treatments and vaccines against viral diseases in comparison with those available for bacterial diseases. Poised as they are at the threshold of life, viruses had presented many problems to scientists attempting to grow them and study their properties in reproducible experiments. Unlike bacteria, they could not be grown in artificial media, and had a strict requirement for living hosts. The available methods for growing them entailed inoculation into live animals and, after a suitable period of time, the purification of virus from the blood or tissues of these animals. Not only was this more time-consuming and less dependable–the growth conditions cannot be monitored for instance–but it was also more expensive. Furthermore, there was tremendous wastage of resources as the animals were quite capable of succumbing to disease and dying before adequate quantities of viruses had been grown.

The *in vitro* techniques developed by Enders' team built on the methods developed some years earlier, by the physiologist and surgeon Alexis Carrel, for growing cells from animal tissues in test tubes. By inoculating

viruses into such cells (called tissue culture cells) Enders was able to grow larger quantities of virus, at a much faster rate, than through animal inoculations. The first virus to be grown in this manner was the poliovirus, with immediate and dramatic impact. Within just a few years, Jonas Salk utilized these culture methods to produce enough virus to develop the first successful vaccine against poliomyelitis. Enders meanwhile, went on to work on the culturing of other viruses including those causing measles, mumps and rubella (German measles), thereby contributing to the development of vaccines for all these diseases as well. See also **Virology (The History)**.

NEERAJA SANKARAN, Yale University, New Haven, CT

ENDOCARDITIS. Inflammation of the endocardium, a thin layer of tissue lining the inner surfaces of the heart. Bacterial endocarditis is a bacterial infection of the endocardium. It accounts for 2% of all organic heart disease. A patient with bacterial endocarditis has an excellent chance for survival with prompt treatment.

Several types of bacteria can cause bacterial endocarditis. It has been known for a long time that bacteria occasionally gain access to the blood vascular system of the body. Usually these invaders are quickly destroyed by the leucocytes, or white cells, of the blood. However, if the bacteria appear in the blood as the result of an infection elsewhere in the body (*septicemia* or blood poisoning), they may be present in very large numbers. Should invading bacteria become attached to the inside of the heart, to one of the valves of the heart, or to the inner wall of one of the major blood vessels, the result is termed bacterial *endocarditis* (affecting the heart); or *endoarteritis* (affecting an artery).
